Abstract Objectives: Estimates of depression prevalence in pregnancy and postpartum are based on the Edinburgh Postnatal Depression Scale (EPDS) more than on any other method. We aimed to determine if any EPDS cutoff can accurately and consistently estimate depression prevalence in individual studies. Methods: We analyzed datasets that compared EPDS scores to Structured Clinical Interview for DSM (SCID) major depression status. Random-effects meta-analysis was used to compare prevalence with EPDS cutoffs versus the SCID. Results: Seven thousand three hundred and fifteen participants (1017 SCID major depression) from 29 primary studies were

included. For EPDS cutoffs used to estimate prevalence in recent studies (≥ 9 to ≥ 14), pooled prevalence estimates ranged from 27.8% (95% CI: 22.0%–34.5%) for EPDS ≥ 9 to 9.0% (95% CI: 6.8%–11.9%) for EPDS ≥ 14 ; pooled SCID major depression prevalence was 9.0% (95% CI: 6.5%–12.3%). EPDS ≥ 14 provided pooled prevalence closest to SCID-based prevalence but differed from SCID prevalence in individual studies by a mean absolute difference of 5.1% (95% prediction interval: –13.7%, 12.3%). Conclusion: EPDS ≥ 14 approximated SCID-based prevalence overall, but considerable heterogeneity in individual studies is a barrier to using it for prevalence estimation. © 2020 The Authors. Abstract Background Clinical findings indicate heterogeneity of depressive disorders, stressing the importance of subtyping depression for research and clinical care. Subtypes of the common late life depression are however seldom studied. Data-driven methods may help provide a more empirically-based classification of late-life depression. Methods Data were used from the Netherlands Study of Depression in Older People (NESDO)

derived from 359 persons, aged 60 years or older, with a current diagnosis of major depressive disorder. Latent class analysis (LCA) was used to identify subtypes of depression, using ten CIDI-based depression items. Classes were then characterized using various sociodemographic and clinical characteristics. Results The most prevalent class, as identified by LCA, was a moderate-severe class (prevalence 46.5%), followed by a severe melancholic class (prevalence 38.4%), and a severe atypical class (prevalence 15.0%). The strongest distinguishing features between the three classes were appetite and weight and, to a lesser extent, psychomotor symptoms and loss of interest. Compared with the melancholic class, the severe atypical class had the highest prevalence of females, the lowest mean age, the highest BMI, and highest prevalence of both cardiovascular disease, and metabolic syndrome. Limitations The strongest distinguishing symptoms, appetite and weight, could be correlated. Further, only longitudinal studies could demonstrate whether the identified classes are stable on the long term. Discussion In older persons with depressive disorders, three distinct subtypes were identified, similar to subtypes found in younger adults. The strongest distinguishing features were appetite and weight; moreover, classes differed strongly on prevalence of metabolic syndrome and cardiovascular disease. These findings suggest differences in the involvement of metabolic pathways across classes, which should be considered when investigating the pathogenesis and (eventually) treatment of depression in older persons. © 2017

Dermoscopic diagnosis of melanoma in a 4D space constructed by active contour extracted features

Item Type Journal Article

Author M. Mete

Author N.M. Sirakov

Abstract Dermoscopy, also known as epiluminescence microscopy, is a major imaging technique used in the assessment of melanoma and other diseases of skin. In this study we propose a computer aided method and tools for fast and automated diagnosis of malignant skin lesions using non-linear classifiers. The method consists of three main stages: (1) skin lesion features extraction from images; (2) features measurement and digitization; and (3) skin lesion binary diagnosis (classification), using the extracted features. A shrinking active contour (S-ACES) extracts color regions boundaries, the number of colors, and lesion's boundary, which is used to calculate the abrupt boundary. Quantification methods for measurements of asymmetry and abrupt endings in skin lesions are elaborated to approach the second stage of the method. The total dermoscopy score (TDS) formula of the ABCD rule is modeled as linear support vector machines (SVM). Further a polynomial SVM classifier is developed. To validate the proposed framework a dataset of 64 lesion images were selected from a collection with a ground truth. The lesions were classified as benign or malignant by the TDS based model and the SVM polynomial classifier. Comparing the results, we showed that the latter model has a better f-measure then the TDS-based model (linear classifier) in the classification of skin lesions into two groups, malignant and benign. © 2012 Elsevier Ltd.

Design a Prototype of the Application System of Classification and Calculating Motor Vehicles on Highway

Item Type Conference Paper

Author M.T. Tamam

Author W. Dwiono

Author R.J.P. Safian

Editor Haryanto null

Abstract The growth rate of the number of motor vehicles has a tendency that is always increasing. The increase in the number of motorised vehicles which is not followed by the addition of roads is a cause of traffic jams on the highway. This study aims to design an application system that is used to determine the level of traffic density on certain road sections by using the background subtraction method to classify and count the number of vehicles passing on that road section. From the results of software testing, three types of vehicles can be classified, namely motorcycles, cars, and trucks/buses with an accuracy of 96%, 83%, and 87.15%, respectively. © 2020 IOP Publishing Ltd.

Design and implementation of a knowledge-based system to improve maximum likelihood classification accuracy

Item Type Journal Article

Author A.A. Alesheikh

Author F. Sadeghi Naeeni Fard

Abstract Numerous classification algorithms have been developed, many of which are highly specific and only solve a reduced class of problems. Maximum likelihood classification (MLC) is the most widely used classification method. The underlying assumption in performing MLC is that the prior probability of land cover is equal. However, a priori occurrence probability has a crucial effect on classification results. The objective of this paper is to improve the accuracy of MLC using a priori information in a knowledge-based system. The mathematical formulations and the strategy are presented. Estimates of a prior probability through crop areas, crop calendar, and some a priori probability about agricultural practices have been used in augmenting the probability of pixels. An industrial agricultural field, Moghan Plain in northwestern Iran, has been selected for testing. A total of 176 ground truth points were identified and measured in the field, and 323 fields were used for accuracy evaluation. Prior probabilities were estimated based on transition matrices of five successive years. Overall classification accuracy based on conditional prior probabilities increased from 53.2% to 66.7% relative to MLC. Knowledge about harvesting time is formalized using a normalized difference vegetation index (NDVI) map from an advanced spaceborne thermal emission and reflection radiometer (ASTER) image. The overall accuracy was then increased to 72.3%. Object-based classification is used to determine the crop type of agricultural fields for which the geometry is constrained. Overall accuracy is then raised to 88.7%. © 2007, Taylor & Francis Group, LLC. All rights reserved.

Design for a Sustainability Approach to Organic Solar Cell Design: The Use of Machine Learning to Quantify the Trade-off between Performance, Stability, and Environmental Impact

Item Type Journal Article

Author T.W. David

Author J. Kettle

Abstract Organic photovoltaics (OPVs) are considered one of the best-performing photovoltaic (PV) technologies from an environmental point of view. Many of the constituent materials possess low embodied energies, which can generally be processed and disposed of in a less energy-intensive manner than other PV technologies. There has been an enormous range of materials used in OPVs; however, identification of the optimal materials and device architectures that provide the best environmental profile within this large search space has yet to have been conducted. This is a non-trivial task because the selection of these materials not only impacts the environmental profile but also on the solar cell efficiency and its operational stability. Here, we have developed a methodology that enables rapid assessment of the trade-off between efficiency, stability, and embodied energy of an OPV using machine learning. To achieve this, a database of OPV data was used, which has been acquired from the literature between 2011 and 2020 and consists of 1580 device data points. Our results highlight the importance of focusing activity on particular transport layers, substrates, and active layer materials, which are discussed further in the manuscript. We demonstrate that the trained and validated models can predict, with a high degree of confidence, the efficiency, stability, and embodied energy of an OPV. The

methodology set out in this work provides a means of identifying optimum device configurations in a rapid manner such that the net energy production is maximized, whereas the environmental impact of OPVs is minimized. Materials which show promise toward delivering a positive net energy are PET + barrier layers, PET (substrates), NiOx, ZrOx, CrO2, ZnO, LiF, and MoO3 (transport layers). Active layer materials which show promise for delivering a positive net energy are DRCN7T, DR3TSBDT, ZnPc, PDPP4T-2F, PCDTBT (donors), and IT-4F, C61 (acceptors). © 2022 American Chemical Society. Design of a hybrid classifier for natural textures in images from the Bayesian and fuzzy paradigms

Item Type Conference Paper

Author M. Guijarro

Author G. Pajares

Author R. Abreu**Author** L. Garmendia**Author** M. Santos

Abstract One objective for classifying textures in natural images is to achieve the best performance possible. The combination of multiple classifiers has been tested as a suitable technique. This is because the individual behaviors of the different classifiers are exploited by joining performances. Two main problems are to be addressed for combining different classifiers. First, which set of classifiers are to be selected? Second, which is the best combination method? Different strategies have been proposed focusing on both problems. We propose a new automatic approach based on two well tested classifiers, the non-parametric Parzen's windows and the Fuzzy clustering. A probability density function (PDF) is estimated through the Parzen's windows estimator to be embedded in the Bayesian framework. The decision is made by combining a likelihood value provided by the PDF and the a priori probability supplied by the Fuzzy clustering strategy through the membership degree. Experimental results for aerial images demonstrate the performance of the proposed design. ©2007 IEEE.

Design of personalised recommendation algorithm for e-commerce platform based on Naive Bayes model and Spark

Item Type Conference Paper

Author L. Bi

Abstract With the rapid growth of user scale and product categories in e-commerce platforms, traditional recommendation algorithms face challenges such as low efficiency of high-dimensional sparse data processing and insufficient real-time performance. With the goal of improving the computational efficiency of the recommendation system, this study proposes a personalised recommendation algorithm based on a Naive Bayes model and Spark. By integrating user behaviour data (including browsing, purchasing, collecting, etc.) and combining the parallelized data processing capability of Spark MLlib machine learning library, an efficient feature extraction and analysis process is constructed. Aiming at the high-dimensional characteristics of user behavioural features, the dynamic update strategy of a priori probability and conditional probability is designed to adapt to the dynamic changes of user interests. The experimental results show that the parallelisation improvement based on Spark architecture effectively solves the scalability bottleneck of the traditional Naive Bayes model in big data scenarios, and provides the e-commerce platform with a recommendation solution with both real-time and accuracy, which has certain application value. © 2025 Copyright held by the owner/author(s).

Detailed monitoring of agricultural production based on the MODIS radiometer data

Item Type Conference Paper

Author V. Povkh

Author I. Sytnyck

Abstract The opportunity of regular receiving of the MODIS/TERRA radiometer data in the direct broadcast mode makes it possible to use these data as perspective information source for the detailed analysis of agricultural production on a regional scale. The most suitable MODIS/TERRA data subset for this purpose is a pair of red and NIR spectral bands with 250 m spatial resolution. The specified spectral ranges are in accordance with the well known remote sensing algorithms applied to estimate vegetation properties. In the SRIA-Centre, Rostov-on-Don supported by the Rostov region administration, techniques have been tested for several years aimed at prompt checking of winter wheat crops by the MODIS/TERRA radiometer data. The type of crops selected for the related studies is due to the large size of individual fields of winter wheat in the region. Thus, any losses of accuracy resulted from the low spatial resolution of MODIS/TERRA radiometer data are diminished. To achieve the needed accuracy, the quality assessment of land vector layers is of great importance. These vector layers are used both for registration of space images and for field masks creation during image interpretation. The vector layers have been created on the basis of the Russian high resolution space photo of the KFA-1000 starting from 1999. Thematic analysis of MODIS/TERRA radiometer data is made with use of supervised classification techniques which require to define training classes prior to execution. Training classes are determined using the selected test sites (crop fields). The numerous regular inspected test sites are sorted in various agricultural zones of the region. GPS receivers serve to make analyses of the inspected fields and probe points location. The scaling test of winter wheat crops monitoring technology was carried out in 2002. Comparison of its results and farm reports has shown a sufficient reliability of remote sensing estimations on both sizes of the areas of agricultural production and crop condition assessment. All remote sensing processing procedures are conducted by ENVI 3.5 software.

Detecting and Correcting for Label Shift with Black Box Predictors

Item Type Conference Paper

Author Z.C. Lipton

Author Y.-X. Wang

Author A.J. Smola

Editor Dy J.

Editor Krause A.

Abstract Faced with distribution shift between training and test set, we wish to detect and quantify the shift, and to correct our classifiers without test set labels. Motivated by medical diagnosis, where diseases (targets), cause symptoms (observations), we focus on label shift, where the label marginal $p(y)$ changes but the conditional $p(x|y)$ does not. We propose Black Box Shift Estimation (BBSE) to estimate the test distribution $p(y)$. BBSE exploits arbitrary black box predictors to reduce dimensionality prior to shift correction. While better predictors give tighter estimates, BBSE works even when predictors are biased, inaccurate, or uncalibrated, so long as their confusion matrices are invertible. We prove BBSE's consistency, bound its error, and introduce a statistical test that uses BBSE to detect shift. We also leverage BBSE to correct classifiers. Experiments demonstrate accurate estimates and improved prediction, even on high-dimensional datasets of natural images. © 2018 by the author(s).

Abstract The sound-evoked electrical compound potential known as auditory brainstem response (ABR) represents the firing of a heterogenous population of auditory neurons in response to sound stimuli, and is often used for clinical diagnosis based on wave amplitude and latency. However, recent ABR applications to detect human cochlear synaptopathy have led to inconsistent results, mainly due to the high variability of ABR wave-1 amplitude. Here, rather than focusing on the amplitude of ABR wave 1, we evaluated the use of ABR wave curvature to detect cochlear synaptic loss. We first compared four curvature quantification methods using simulated ABR waves, and identified that the cubic spline method using five data points produced the most accurate quantification. We next evaluated this quantification method with ABR data from an established mouse model with cochlear synaptopathy. The data clearly demonstrated that curvature measurement is more sensitive and consistent in identifying cochlear synaptic loss in mice compared to the amplitude and latency measurements. We further tested this curvature method in a different mouse model presenting with otitis media. The change in curvature profile due to middle ear infection in otitis media is different from the profile of mice with cochlear synaptopathy. Thus, our study suggests that curvature quantification can be used to address the current ABR variability issue, and may lead to additional applications in the clinic diagnosis of hearing disorders. Detecting Distributional Shift Responsible for Predictive Model's Failure

Item Type Conference Paper

Author D.S. Mukherjee

Author D. Bhandari

Author N.G. Yeri

Abstract Any predictive software deployed with this hypothesis that test data distribution will not differ from training data distribution. Real time scenario does not follow this rule, which results inconsistent and non-transferable observation in various cases. This makes the dataset shift, a growing concern. In this paper, we've explored the recent concept of Label shift detection and classifier correction with the help of Black Box shift detection(BBSD), Black Box shift estimation(BBSE) and Black Box shift correction(BBSC). Digits dataset from 'sklearn' and 'LogisticRegression' classifier have been used for this investigation. Knock out shift was clearly detected by applying Kolmogorov-Smirnov test for BBSD. Performance of the classifier got improved after applying BBSE and BBSC from 91% to 97% in terms of overall accuracy. © 2022 IEEE.

Abstract In Morocco there is an enormous issue to keep students engaged and focused on a math class because this directly affects the way they learn and perform at schools overall. A 2022 to 26 June Strategic Roadmap for Education Reform clarified that the loss of concentration is a scourge that affects performance and participation. With the help of data from the TIMSS 2023 assessment, which focuses on students in the eighth grade, this study seeks to identify the major factors that affect the ability of students to stay focused in mathematics classes. Prior to analysis, we cleansed and processed the data by eliminating the absence of entries and by aggregating related categories. After that, we used an autoencoder to reduce the size of the data and help to reveal the hidden patterns in behavior and contexts in the classroom. Based on these capabilities, several models, such as random forests, decision trees, XGBoost, and an unstructured neural network, were developed to categorize students based on their attention level as either low or high. SHAP values revealed which variables were the most influential on the students' attention, making it easier to understand the findings. The results highlighted some persistent factors: the environment of the classroom and instructional delivery, technology accessibility, and the quality of interactions between teachers and students are all essential for maintaining focus. The research was able to show that explicable AI can be an extremely asset in research on education, providing explicit information and strategies that can be implemented by teachers and policymakers in the position to facilitate involvement in mathematics education. © 2025 IEEE.

Abstract Accurate detection and prevalence estimation of behavioral health conditions, such as opioid use disorder (OUD), are crucial for identifying at-risk individuals, determining treatment needs, monitoring prevention and intervention efforts, and recruiting

treatment-naïve participants for clinical trials. The availability of extensive health data, combined with advancements in machine learning (ML) frameworks, has enabled researchers to employ various ML techniques to predict or identify OUD within patient health data. Ideally, we could directly estimate the prevalence, or the proportion of a population with a condition over time. However, underdiagnosis and undercoding of conditions in patient health records make it challenging to determine the true prevalence of these conditions and to identify at-risk patients with less severe conditions who are more likely to be missed. Consequently, patients without diagnoses may comprise positive and negative examples for a given condition. Treating all undiagnosed (uncoded) patients as negative when applying ML methods can introduce bias into models, affecting their predictive power. To address this issue, we employed Positive Unlabeled Learning Selected Not At Random (PULSNAR), a Positive and Unlabeled (PU) learning technique, to estimate the probability of a given patient having OUD during a time window and the overall population prevalence of OUD. In a sample of 3,342,044 commercially insured US patients with at least one opioid prescription filled, PULSNAR estimated that 5.08% of patients have a cumulative prevalence of OUD over a 2-5 a observation period, compared to the 1.35% with a recorded OUD diagnosis, with 73.5% of cases not diagnosed/coded. The prevalence estimates provided by PULSNAR are consistent with those reported in other studies. © 2013 IEEE.

Abstract Given a pre-trained in-distribution (ID) model, the inference-time out-of-distribution (OOD) detection aims to recognize OOD data during the inference stage. However, some representative methods share an unproven assumption that the probability that OOD data belong to every ID class should be the same, i.e., these OOD-to-ID probabilities actually form a uniform distribution. In this paper, we show that this assumption makes the above methods incapable when the ID model is trained with class-imbalanced data. Fortunately, by analyzing the causal relations between ID/OOD classes and features, we identify several common scenarios where the OOD-to-ID probabilities should be the ID-class-prior distribution and propose two strategies to modify existing inference-time detection methods: 1) replace the uniform distribution with the ID-class-prior distribution if they explicitly use the uniform distribution; 2) otherwise, reweight their scores according to the similarity between the ID-class-prior distribution and the softmax outputs of the pre-trained model. Extensive experiments show that both strategies can improve the OOD detection performance when the ID model is pre-trained with imbalanced data, reflecting the importance of ID-class prior in OOD detection. The codes are available at https://github.com/tmlr-group/class_prior. © 2023 Proceedings of Machine Learning Research. All rights reserved.

Detecting Signs of Depression Using Social Media Texts Through an Ensemble of Ensemble Classifiers

Item Type Journal Article

Author R. Chiong

Author G.S. Budhi

Author E. Cambria

Abstract Artificial intelligence-based machine learning models have been widely used to explore and address various mental health-related problems in recent years, including depression. In this study, we present an ensemble approach to complement the 90 unique input features that we proposed in a previous study on depression detection using social media texts. Our proposed Ensemble of Ensemble Classifiers (EECs) combines many ensemble models, including Bagging Predictors, Random Forests, Adaptive Boosting and Gradient Boosting, as inner ensembles. These inner ensembles are arranged in a parallel fashion, where each of them is trained using

different subsets of data sampled from the training data via bootstrap sampling. After the models are trained, during the testing phase, the results of all inner ensembles are processed using two methods—majority vote or class priority threshold—to get the final result as an output. From the experiments, we find that EECs are accurate in detecting signs of depression in social media users by analysing their posts in social media platforms such as Twitter. Our approach outperforms other ensemble methods on the public datasets we used. Moreover, if set correctly, the parameters of EECs can further improve the performance of the proposed ensemble in detecting signs of depression. © 2010-2012 IEEE.

Abstract Background: Underdiagnosis and undercoding are common across mental health conditions, particularly suicide and self-harm. This leaves health care datasets lacking reliable negative examples needed for predictive modeling, phenotype prevalence estimation, and identification of individuals at elevated risk. We use positive and unlabeled (PU) learning to address this challenge. Objective: This study aims to identify US Veterans whose self-harm events were not explicitly captured through diagnostic codes in electronic health records (EHRs) and estimate the underlying prevalence using a novel PU learning algorithm. Methods: We performed a retrospective cohort study using Veterans Health Administration EHRs (from October 1, 1999, to August 31, 2019), selecting a random 25% sample of 1,329,120 Veterans out of 5,316,480 (1,193,563 males and 135,557 females) with at least 2 years of observation. The study cohort comprised 24,625 Veterans with coded self-harm and 1,304,495 uncoded, with the mean ages of 38.39 (SD 12.17) and 48.76 (SD 15.04) years, respectively. We applied our PULSNAR (positive unlabeled learning selected not at random) algorithm to estimate the proportion of individuals with uncoded self-harm. Covariates included age, medical conditions, procedures, and clinical observations. Four experts (raters) independently reviewed charts of 97 uncoded Veterans, each selected from 1% intervals of calibrated PULSNAR probabilities from 0.01 to 0.97. Agreement was assessed among raters, PULSNAR classifications, and consensus review decisions. Post hoc calibration was used to refine prevalence estimates. Results: Of the 159,049 covariates in the dataset, PULSNAR's Extreme Gradient Boosting (XGBoost) model identified 1302 (0.82%) as informative for classification. Only 1.85% (24,625/1,329,120) of Veterans had diagnostic codes indicating self-harm events, while PULSNAR estimated an overall prevalence of 10.46% (139,026/1,329,120) by identifying an additional $\alpha=8.77\%$ (114,404/1,304,495) of self-harm cases among the uncoded population. Of the 97 chart-reviewed patients, 39 had documented but uncoded self-harm. PULSNAR probabilities were post hoc calibrated such that their sum over the 97 cases equaled 39, which adjusted the combined coded and imputed prevalence downward from 10.46% to 7.91% (105,133/1,329,120). By applying this calibration to shift the probabilities of all uncoded Veterans, with bootstrapping for confidence intervals, PULSNAR estimates that coded self-harm represents only 23.4% (95% CI 17.76% to 31.51%) of all documented (coded+notes) self-harm. Conclusions: Under the "selected not at random" assumption, PULSNAR provides an innovative and scalable framework for estimating the clinically documented prevalence of mental health conditions and identifying the uncoded individuals with calibrated prediction, without requiring confirmed negative labels. This method offers an alternative to time-consuming chart reviews for detecting likely cases missing structured coding capture. By addressing diagnostic undercoding of mental health conditions in EHRs, this

approach has the potential to enhance the estimation of mental health prevalence and support screening, activation of automated clinical decision support, targeted intervention, better resource allocation, and research to improve outcomes in real-world settings. © Praveen Kumar, Alexandria D Vízolay, Rajesh Upadhyaya, Fariha Moomtaheen, Donald R Greer, Cristian G Bologa, Kristan A Schneider, Sharon E Davis, Michael E Matheny, David van der Goes, Gerardo Villarreal, Yiliang Zhu, Mauricio Tohen, Scott A Malec, Jeremy J Yang, Elliot M Fielstein, Christophe Gerard Lambert.

Abstract The goal of this project is to use acoustic signatures to detect, classify, and count the calls of four acoustic populations of blue whales so that, ultimately, the conservation status of each population can be better assessed. We used manual annotations from 350 h of audio recordings from the underwater hydrophones in the Indian Ocean to build a deep learning model to detect, classify, and count the calls from four acoustic song types. The method we used was Siamese neural networks (SNN), a class of neural network architectures that are used to find the similarity of the inputs by comparing their feature vectors, finding that they outperformed the more widely used convolutional neural networks (CNN). Specifically, the SNN outperform a CNN with 2% accuracy improvement in population classification and 1.7%-6.4% accuracy improvement in call count estimation for each blue whale population. In addition, even though we treat the call count estimation problem as a classification task and encode the number of calls in each spectrogram as a categorical variable, SNN surprisingly learned the ordinal relationship among them. SNN are robust and are shown here to be an effective way to automatically mine large acoustic datasets for blue whale calls. © 2021 Acoustical Society of America.

Detection and classification of neurotoxins using a novel short-term plasticity quantification method

Item Type Journal Article**Author** G. Gholmieh**Author** S. Courellis**Author** S. Fakheri**Author** E. Cheung**Author** V. Marmarelis**Author** M. Baudry**Author** T. Berger

Abstract A tissue-based biosensor is described for screening chemical compounds that rapidly affect the nervous system. The proposed sensor is an extension of a previous work on cultured hippocampal slices [Biosens. Bioelectron. 16 (2001) 491]. The detection of the chemical compounds is based on a novel quantification method of short-term plasticity (STP) of the CA1 system in acute hippocampal slices, using random electrical impulse sequences as inputs and population spike (PS) amplitudes as

outputs. STP is quantified by the first and the second order kernels using a variant of the Volterra modeling approach. This approach is more specific and time-efficient than the conventional paired pulse and fixed frequency train methods [J. Neurosci. Methods 2 (2002) 111]. Describing the functional state of the biosensor, the kernels changed accordingly as chemical compounds were added. The second order kernel was decomposed into nine Laguerre functions. The corresponding Laguerre coefficients along with the first order kernel were used as features for classification purposes. The biosensor was tested using picrotoxin (100 μ M), trimethylpropane phosphate (10 μ M), tetraethylammonium (4 mM), valproate (5 mM), carbachol (5 mM), DAP5 (25 μ M), CNQX (3 μ M), and DNQX (0.15, 1.5, 3, 5 and 10 μ M). Each chemical compound gave a different feature profile corresponding to its pharmacological class. The first order kernel and the Laguerre coefficients formed the input to an artificial neural network (ANN) comprised of a single layer of perceptrons. The ANN was able to classify each tested compound into its respective class. © 2003 Elsevier Science B.V. All rights reserved.

Abstract Objective: Breast arterial calcifications (BAC) are a sex-specific cardiovascular disease biomarker that might improve cardiovascular risk stratification in women. We implemented a deep convolutional neural network for automatic BAC detection and quantification. Methods: In this retrospective study, four readers labelled four-view mammograms as BAC positive (BAC+) or BAC negative (BAC-) at image level. Starting from a pretrained VGG16 model, we trained a convolutional neural network to discriminate BAC+ and BAC- mammograms. Accuracy, F1 score, and area under the receiver operating characteristic curve (AUC-ROC) were used to assess the diagnostic performance. Predictions of calcified areas were generated using the generalized gradient-weighted class activation mapping (Grad-CAM++) method, and their correlation with manual measurement of BAC length in a subset of cases was assessed using Spearman ρ . Results: A total 1493 women (198 BAC+) with a median age of 59 years (interquartile range 52–68) were included and partitioned in a training set of 410 cases (1640 views, 398 BAC+), validation set of 222 cases (888 views, 89 BAC+), and test set of 229 cases (916 views, 94 BAC+). The accuracy, F1 score, and AUC-ROC were 0.94, 0.86, and 0.98 in the training set; 0.96, 0.74, and 0.96 in the validation set; and 0.97, 0.80, and 0.95 in the test set, respectively. In 112 analyzed views, the Grad-CAM++ predictions displayed a strong correlation with BAC measured length ($\rho = 0.88$, $p < 0.001$). Conclusion: Our model showed promising performances in BAC detection and in quantification of BAC burden, showing a strong correlation with manual measurements. Clinical relevance statement: Integrating our model to clinical practice could improve BAC reporting without increasing clinical workload, facilitating large-scale studies on the impact of BAC as a biomarker of cardiovascular risk, raising awareness on women's cardiovascular health, and leveraging mammographic screening. Key Points: • We implemented a deep convolutional neural network (CNN) for BAC detection and quantification. • Our CNN had an area under the receiving operator curve of 0.95 for BAC detection in the test set composed of 916 views, 94 of which were BAC+. • Furthermore, our CNN showed a strong correlation with manual BAC measurements ($\rho = 0.88$) in a set of 112 views. © 2023, The Author(s).

Detection and quantification of temperature sensor drift using probabilistic neural networks

Item Type Journal Article

Author M. Pereira

Author B. Glisic

Abstract Temperature effects are a major driver of strain and deformations in weather-exposed civil infrastructure, such as bridges and buildings. For such structures, long-term temperature data holds the potential for data-driven prediction of expected structural behavior, which in turn enables the detection of anomalous structural behavior. For this reason, structural health monitoring (SHM) strategies typically employ temperature sensors. However, the success of SHM is contingent on the quantity and quality of the available temperature data. Hence, accurate automatic methods for the detection and quantification of anomalies in temperature data are needed. In particular, gradual temperature sensor drifts are difficult to detect and can introduce

errors into the thermal compensation of strain sensors, which can be erroneously confounded with time-dependent structural behavior. Current data-driven methods use air temperature as predictor because it exhibits good correlation with temperatures in the structure. Sensor drift is typically quantified by analysis of the prediction residuals; however, these methods are not robust to outliers and can be affected by seasonal biases. In this work, a probabilistic neural network is used as the nonlinear data-driven temperature prediction model which enables the introduction of a sensible threshold to mitigate seasonal model bias. Furthermore, a novel drift detection method based on the evolution of parameters of a trinomial probability distribution is introduced, together with a robust drift quantification method. The performance of this method is assessed using real temperature data from a pedestrian bridge, spanning over seven years of the structure's life. © 2022 The Author(s)

Detection of Blood Cancer Cells using Microscopic Image

Item Type Journal Article

Author J. Kirubakaran

Author P. Vedhanath

Author P. Lakshman

Author Y. Surya Ashok

Abstract For the automatic diagnosis and classification of leukemia and leukemoid reactions, the IDB2 (acute lymphoblastic leukemia-image database) dataset has been utilized. This paper focuses on an automated method to differentiate between leukemoid and leukemia reactions using images of blood smear. MobileNetV3 is employed to classify and count WBC types from segmented images. The BCCD (Blood Cell Count Detection) dataset, which contains 364 images of blood smear and 349 single WBC type images, has been used in this work. The image segmentation algorithm incorporates Fuzzy C-means clustering, the snake algorithm, and fusion rules. For classification, the VGG19 CNN (Convolutional Neural Network) architecture-based deep learning technique is implemented. Python and Google colab is used for designing and executing the algorithm respectively. © 2024 Inventive Research Organization.

Detection of Phenotypic Alterations Using High-Content Analysis of Whole-Slide Images

Item Type Journal Article

Author A. Shirinifard

Author S. Thiagarajan

Author P. Vogel

Author A. Sablauer

Abstract Tumors exhibit spatial heterogeneity, as manifested in immunohistochemistry (IHC) staining patterns. Current IHC quantification methods lose information by reducing this heterogeneity in each whole-slide image (WSI) or in selective fields of view to a single staining index. The aim of this study was to investigate the sensitivity of an IHC quantification method that uses this heterogeneity to reliably compare IHC staining patterns. We virtually partitioned WSIs by a grid of square tiles, and computed the staining index distributions to quantify heterogeneities. We used samples from these distributions as inputs to non-parametric statistical comparisons. We applied our grid method to fixed tumor samples from 26 tumors obtained from a double-blind preclinical study of a patient-derived orthotopic xenograft model of pediatric neuroblastoma in CD1 nude mice. We compared the results of our grid method to the results based on whole-slide indices, the current practice. We show that our grid method reliably detects phenotypic alterations that other tests based on whole-slide indices fail to detect. Based on robustness and increased sensitivity of statistical inference, we conclude that our method of whole-slide grid quantification is superior to existing whole-slide quantification techniques. © 2016, © The Author(s) 2016.

Detection, Classification and Counting of Moving Vehicles from Videos

Item Type Conference Paper

Author A. Sunny

Author N. Manohar

Editor Guru D.S.

Editor Kumar N.V.

Editor Javed M.

Abstract Detecting and Classifying vehicles into several categories demonstrates a considerable possibility in the field of intelligent transportation systems. In this paper, we aim to propose a Convolutional Neural network integrated with YOLO framework to detect, classify and count vehicles from videos considering different climatic conditions like rainy, foggy, night and sunny weathers. Experimental results show that on applying this proposed network on MIO vision Traffic Camera Dataset for training and testing the model with different traffic videos, the network has a good testing and classification ability taking into consideration of the complex features of the image dataset. Our algorithm achieves an average accuracy of 94.4% in the detection, classification and counting of vehicles depending on the visibility of the image in the frame. © The

Abstract Distinguishing normal white blood cells from leukemia cells plays a role in assisting in the diagnosis of blood diseases. Up to now, many automated methods are applied to provide more time efficiency, timing, and accuracy such as YOLO, SVM, CNN,

and Faster CNN. In this research, we propose to use YOLOv8 to detect, classify, and count normal white blood cells and leukemia cells. The result of the experiment method with accuracy is 95.1% using the first number of blood images is 1500 images from AML public source and Hanoi Medical University collected by ourselves, and after augmentation is 3629 images that are used for training, validation, and testing. At the same time, we compare the accuracy of this method with studies using different versions of YOLO. © MIR Labs

Determination of glycated hemoglobin using near-infrared spectroscopy combined with equidistant combination partial least squares

Item Type Journal Article

Author Y. Han

Author J. Chen

Author T. Pan

Author G. Liu

Abstract A novel near-infrared-spectroscopy-based quantification method for glycated hemoglobin (HbA1c), a major clinical diagnosis indicator of diabetes, was developed on the basis of simultaneous determination of hemoglobin (Hb) and absolute HbA1c content (Hb•HbA1c) in human hemolysate samples. Equidistant combination partial least squares (EC-PLS) method was proposed to perform wavelengths selection.

Competitive adaptive reweighted sampling PLS (CARS-PLS) and Monte Carlo uninformative variable elimination PLS (MC-UVE-PLS) methods were also conducted for comparison. A randomness and stability dependent rigorous process of calibration, prediction, and validation was performed to produce objective and stable models. The search range covered the unsaturated region (780-1880. nm, 2090-2330. nm). For Hb and Hb•HbA1c, only 6 and 14 wavelengths were selected with EC-PLS, 23 and 30 wavelengths were selected with CARS-PLS, and 100 and 120 wavelengths were selected with MC-UVE-PLS, respectively. The predicted values of relative percentage HbA1c were calculated from the predicted Hb and Hb•HbA1c values. The sensitivity and specificity for diabetes were 93.5% and 97.1% with EC-PLS, 91.3% and 94.1% with CARS-PLS, and 89.1% and 76.5% with MC-UVE-PLS, respectively. In three methods, EC-PLS not only employed the least wavelengths but also produced the best quantification accuracy for HbA1c. EC-PLS also achieved the highest classification accuracy for negative and positive samples for diabetes. The results confirm the feasibility of HbA1c quantification based on the simultaneous analysis of Hb and Hb•HbA1c with NIR spectroscopy. This technique is rapid and simple when compared with conventional methods, and is a promising tool for screening diabetes in large populations. © 2015 Elsevier B.V.

Determining a mutual fund's equity class

Item Type Journal Article

Author F.L. Detzel

Abstract Mutual fund investors who use an asset allocation model must be able to readily identify each fund's equity class. Prior studies examine two approaches to classifying equity funds, factor loadings and portfolio characteristics. Their implementation is not feasible for many investors, however. I investigate a practicable alternative, Morningstar's characteristics-based style box. I find that it does not predict mutual fund returns as well as a discrete factor-loadings-based alternative during 1994 to 2004 overall, but predicts better in 2003 to 2004 after Morningstar changed its methodology. I also find that fund classifications drift considerably over the years. Actively-managed-fund investors need to monitor their portfolios regularly. © 2006 Academy of Financial Services. Abstract Mineral texture is a critical factor which controls ore variability and is an important attribute in geometallurgy. In relation to downstream processes, it affects the fracture pattern during breakage, where rock strength is inherently a function of mineral texture. Because of the subjective nature of mineral texture, it has not been easy to quantify, especially in the context of a measurement suitable for use in geometallurgical programmes. The aim of this paper is to present the first steps in developing a 3D mineral texture quantification method for drill core and to assess its sensitivity to differences in rock strength using a case study. The methodology includes classifying the textural information using the 3D grey level co-occurrence matrices (GLCM) and X-ray computed tomography (XCT) coupled method. Rock strength tests were performed using the split Hopkinson pressure bar (SHPB). The case study investigates a heterogeneous polymetallic sulphide deposit and a homogeneous shale subdivided into three 'mineral textural types'. The variability is largely captured by the GLCM matrices, and preliminary trends can be observed where the shale is finer grained and has a higher yield strength in comparison with the coarser grained polymetallic sulphide ore. © 2019 South African Institute of Mining and Metallurgy. Development and Evaluation of a Clinical Prediction Model for Acute Kidney Injury Risk in Elderly Patients with Heart Failure with Reduced Ejection Fraction

Item Type Journal Article

Abstract Background: Acute kidney injury (AKI) is a significant complication among patients with heart failure with reduced ejection fraction (HFrEF). Once AKI occurs, therapeutic options are limited to supportive care, underscoring the clinical importance of early identification of patients at risk. This study sought to identify independent predictors of AKI development in geriatric HFrEF patients and subsequently establish a clinically applicable bedside risk quantification. Method: A total of 1,496 elderly patients (≥60 years) diagnosed with HFrEF at Guangdong Provincial People's Hospital from January 2010 to December 2024 were enrolled according to predefined inclusion/exclusion criteria and stratified into an AKI group (n = 300) and a non-AKI group (n = 1196). Relevant parameters were screened using LASSO (Least Absolute Shrinkage and Selection Operator) regression, and risk factors for AKI in HFrEF patients were identified through univariate and multivariate

logistic regression analyses. A nomogram was developed based on multivariate logistic regression results, accompanied by a corresponding heatmap. The predictive accuracy of the nomogram was evaluated using receiver operating characteristic (ROC) curves and calibration plots, while its clinical utility was demonstrated through decision curve analysis (DCA). Result: This study identified four independent predictors of AKI in patients with HFrEF, including N-terminal pro-B-type natriuretic peptide (NT-proBNP), uric acid (UA), CRP (C-reaction protein) and urea. A nomogram was developed based on these factors. The evaluation results demonstrated that the model exhibited good diagnostic accuracy, with an area under the receiver operating characteristic curve (AUC) of 0.721 (95% CI: 0.658-0.785). The calibration curve and DCA further indicated that the model possesses favorable clinical applicability. Conclusion: This study developed and validated a nomogram model for predicting AKI in patients with HFrEF. Clinicians can utilize this model to optimize clinical decision-making based on individualized patient characteristics, enabling personalized risk stratification for therapeutic interventions and prognostic evaluations. © 2026, Ubiquity Press. Development and evaluation of a culture-independent method for source determination of fecal wastes in surface and storm waters using reverse transcriptase-PCR detection of FRNA coliphage genogroup gene sequences

Item Type	Journal Article
Author	J. Paar

Author	R.A. Haugland
Abstract	A method, incorporating recently improved reverse transcriptase-PCR primer/probe assays and including controls for detecting interferences in RNA recovery and analysis, was developed for the direct, culture-independent detection of genetic

markers from FRNA coliphage genogroups I, II & IV in water samples. Results were obtained from an initial evaluation of the performance of this method in analyses of waste water, ambient surface water and stormwater drain and outfall samples from predominantly urban locations. The evaluation also included a comparison of the occurrence of the FRNA genetic markers with genetic markers from general and human-related bacterial fecal indicators determined by current or pending EPA-validated qPCR methods. Strong associations were observed between the occurrence of the putatively human related FRNA genogroup II marker and the densities of the bacterial markers in the stormwater drain and outfall samples. However fewer samples were positive for FRNA coliphage compared to either the general bacterial fecal indicator or the human-related bacterial fecal indicator markers particularly for ambient water samples. Together, these methods show promise as complementary tools for the identification of contaminated storm water drainage systems as well as the determination of human and non-human sources of contamination. © 2015.

Development and Evaluation of a Volumetric Quantification Method for Fecal Particle Size Classification in Rainbow Trout Fed Different Diets

Item Type Journal Article

Author T.L. Welker

Author K. Overturf

Author F. Barrows

Abstract Alternative plant protein sources, such as soybean meal, can interfere with digestion due to the presence of anti-nutritional factors that cause a diarrhea-like condition in Rainbow Trout *Oncorhynchus mykiss*, resulting in very fine fecal particles that can adversely affect aquaculture systems and the environment. More research is needed to examine the impacts of feed formulation changes on fecal quality. The prevailing method (laser diffraction) used to measure fecal particle size (FPS) requires expensive equipment and is labor intensive. Methods for FPS measurement that are affordable and easy to implement are required. We developed a visual, volumetric method that can separate feces into three particle size-classes. Feces were collected from tanks fitted with radial flow separators, transferred to Imhoff cones, and allowed to settle. Three distinct layers were visually identified, and microscopic analysis was used to categorize them into three particle size-classes: larger than 1.2 mm (bottom layer or large particles), 0.6–1.2 mm (middle layer or mid-sized particles), and 0.5 mm or smaller (top layer or fines). Independent observations confirmed that the method is reproducible and without observer bias. In a second study, the method was validated and further tested during a 4-week trial evaluating the effects of three diets (fish meal, plant based, or plant based + guar gum) and two feeding methods (hand feeding to satiation or automated belt feeding) on FPS production. Diets were isonitrogenous and isoenergetic, containing protein at 40 g/kg and lipid at 20 g/kg. Addition of guar gum significantly reduced the production of fines and increased the production of large fecal particles in Rainbow Trout (150 g/fish) that were fed the plant-based diet, but feeding method had no effect on FPS. Development and use of a quantum dot probe to track multiple yeast strains in mixed culture

Item Type Journal Article**Author** F.S. Gustafsson**Author** M.D. Whiteside**Author** V. Jiranek**Author** D.M. Durall

Abstract *Saccharomyces cerevisiae* strains vary in their ability to develop and enhance sensory attributes of alcoholic beverages and are often found growing in mixed strain fermentations; however, quantifying individual strains is challenging due to quantification inaccuracies, low marker longevity, and compromised kinetics. We developed a fluorescent probe, consisting of glutathione molecules conjugated to a quantum dot (QD). Two *S. cerevisiae* strains were incubated with different coloured probes (QD attached to glutathione molecules, QD-GSH), fermented at multiple ratios, and quantified using confocal microscopy. The QD method was compared with a culture method using microsatellite DNA analysis (MS method). Probes were taken up by an ADP1 encoded transporter, transferred from mother cell to daughter cell, detectable in strains throughout fermentation, and were non-toxic. This resulted in a new quantification method that was more accurate and efficient than the MS method.

Abstract	Context: For regulatory reasons, a biowaiver is characterized as the substitution or exemption of bioavailability and/or bioequivalence research with in vitro dissolution tests, according to the Biopharmaceutical Classification System (BCS). These studies need validated quantification methods to give reliable results. Aims: To develop and validate the UV spectrophotometric method for biowaiver studies in pyrazinamide tablets. Methods: The parameters for validation, such as specificity, linearity, range, accuracy, precision, stability of the analytical solution, filter test, limits of detection, and quantification, were assessed according to the standards set by the guidelines of the International Conference on Harmonization and the United States Pharmacopeia. The dissolution operating conditions were 900 mL of dissolution media at pH 1.2, 4.5, and 6.8, with the paddle method at 75 rpm and sampling times of 5, 10, 15, 20, and 30 minutes. Results: The wavelength of maximum absorbance was 268 nm for the three dissolution media. The method was linear in the range of 1.1112–13.3334 µg/mL (r2>0.998). The limits of detection ranged from 0.0157 to 0.0222 µg/mL, and the limits of quantification were between 0.0415 and 0.0546 µg/mL. The recovered values were between 99.4 and 103.0%. No interference from the placebo was observed. The relative standard deviation values were less than 2% for precision. For robustness, different conditions were evaluated as wavelengths, changes in concentration, and Whatman No. 40, 41, and 42 filters; they did not modify the method response. The samples were kept unchanged for a period of 24 hours at 25°C. Conclusions: The UV spectrophotometric method was linear, accurate, specific, and precise in the concentration range studied and in the dissolution media at pH levels of 1.2, 4.5, and 6.8, being suitable for biowaiver studies in pyrazinamide tablets. © 2024 Academic Association of Pharmaceutical Sciences from Antofagasta (ASOCIFA). Author B. Zhang

Abstract The amount of impervious surface is an important indicator in the monitoring of the intensity of human activity and environmental change. The use of remote sensing techniques is the only means of accurately carrying out global mapping of impervious surfaces covering large areas. Optical imagery can capture surface reflectance characteristics, while synthetic-aperture radar (SAR) images can be used to provide information on the structure and dielectric properties of surface materials. In addition,

nighttime light (NTL) imagery can detect the intensity of human activity and thus provide important a priori probabilities of the occurrence of impervious surfaces. In this study, we aimed to generate an accurate global impervious surface map at a resolution of 30m for 2015 by combining Landsat 8 Operational Land Image (OLI) optical images, Sentinel-1 SAR images and Visible Infrared Imaging Radiometer Suite (VIIRS) NTL images based on the Google Earth Engine (GEE) platform. First, the global impervious and nonimpervious training samples were automatically derived by combining the GlobeLand30 land-cover product with VIIRS NTL and MODIS enhanced vegetation index (EVI) imagery. Then, the local adaptive random forest classifiers, allowing for a regional adjustment of the classification parameters to take into account the regional characteristics, were trained and used to generate regional impervious surface maps for each $5^{\circ} \times 5^{\circ}$ geographical grid using local training samples and multisource and multitemporal imagery. Finally, a global impervious surface map, produced by mosaicking numerous $5^{\circ} \times 5^{\circ}$ regional maps, was validated by interpretation samples and then compared with five existing impervious products (GlobeLand30, FROM-GLC, NUACI, HBASE and GHSL). The results indicated that the global impervious surface map produced using the proposed multisource, multitemporal random forest classification (MSMT_RF) method was the most accurate of the maps, having an overall accuracy of 95.1% and kappa coefficient (one of the most commonly used statistics to test interrater reliability; Olofsson et al., 2014) of 0.898 as against 85.6% and 0.695 for NUACI, 89.6% and 0.780 for FROM-GLC, 90.3% and 0.794 for GHSL, 88.4% and 0.753 for GlobeLand30, and 88.0% and 0.745 for HBASE using all 15 regional validation data. Therefore, it is concluded that a global 30m impervious surface map can accurately and efficiently be generated by the proposed MSMT_RF method based on the GEE platform. The global impervious surface map generated in this paper is available at <https://doi.org/10.5281/zenodo.3505079> (Zhang and Liu, 2019). © Author(s) 2020.

Development of a simultaneous quantification method for ten trichothecenes including deoxynivalenol-3-glucoside in feed

Item Type Journal Article

Author M. Nomura

Author K. Shidara

Author I. Yasuda

Author K. Aoyama

Author A. Takahashi

Author T. Ishibashi

Abstract An analytical method for the simultaneous quantitation of ten trichothecenes of type A (HT-2 toxin, T-2 toxin, diacetoxyscirpenol, and neosolaniol) and type B (3-acetyldeoxynivalenol, 15-acetyldeoxynivalenol, deoxynivalenol, deoxynivalenol-3-glucoside, nivalenol, and fusarenon-X) in feed has been developed using liquid chromatography with tandem mass spectrometry. Mycotoxins extracted twice from samples using aqueous acetonitrile were purified using a multifunctional clean-up column, followed by a phospholipid removal column. Trichothecenes were analysed using liquid chromatography atmospheric pressure chemical ionization tandem mass spectrometry. The extraction efficiency of the mycotoxins and the repeatability of some were improved by repeated extractions. Ionization enhancement (signal enhancement) of some mycotoxins was improved by using the phospholipid removal column at the clean-up step. Spike and recovery tests of trichothecenes were conducted on maize, barley, soybean meal, rapeseed meal, and formula feeds (for starting broiler chicks, suckling pigs, and beef cattle). The mean recovery values were 70.6–119% with relative standard deviations < 17%. The limit of quantification and the limit of detection of our method were 20 and 6 µg/kg, respectively, for 3-acetyldeoxynivalenol and 15-acetyldeoxynivalenol; 10 and 3 µg/kg, respectively, for T-2 toxin, deoxynivalenol, and fusarenon-X; and 5 and 2 µg/kg, respectively, for nivalenol and the remaining mycotoxins. © 2020, Society for Mycotoxin (Research Gesellschaft für Mykotoxinforschung e.V.) and Springer-Verlag GmbH Germany, part of Springer Nature.

Development of an Environment-Aware Locomotion Mode Recognition System for Powered Lower Limb Prostheses

Item Type Journal Article

Author M. Liu

Author D. Wang

Author H. Helen Huang

Abstract This paper aimed to develop and evaluate an environment-aware locomotion mode recognition system for volitional control of powered artificial legs. A portable terrain recognition (TR) module, consisting of an inertia measurement unit and a laser distance meter, was built to identify the type of terrain in front of the wearer while walking. A decision tree was used to classify the terrain types and provide either coarse or refined information about the walking environment. Then, the obtained environmental information was modeled as a priori probability and was integrated with a neuromuscular-mechanical-fusion-based locomotion mode (LM) recognition system. The designed TR module and environment-aware LM recognition system was evaluated separately on able-bodied subjects and a transfemoral amputee online. The results showed that the TR module provided high quality environmental information: TR accuracy is above 98% and terrain transitions are detected over 500 ms before the time required to switch the prosthesis control mode. This enabled smooth locomotion mode transitions for the wearers. The obtained environmental information further improved the performance of LM recognition system, regardless of whether coarse or refined information was used. In addition, the environment-aware LM recognition system produced reliable online performance when the TR

output was relatively noisy, which indicated the potential of this system to operate in unconstructed environment. This paper demonstrated that environmental information should be considered for operating wearable lower limb robotic devices, such as prosthetics and orthotics. © 2001-2011 IEEE.

Abstract In the pursuit of personalized diagnostics and tailored treatments, quantitative protein tests contribute to a more precise definition of health and disease. The development of new quantitative protein tests should be driven by an unmet clinical need and performed in a collaborative effort that involves all stakeholders. With regard to the analytical part, mass spectrometry (MS)-based platforms are an excellent tool for quantification of specific proteins in body fluids, for example focused on cancer. The obtained readouts have great potential in determining tumor aggressiveness to facilitate treatment decisions, and can furthermore be used to monitor patient response. Internationally standardized TNM classifications of malignant tumors are beneficial for diagnosis, however treatment outcome and survival of cancer patients is poorly predicted. To this end, the importance of the tumor microenvironment has endorsed the introduction of the tumor-stroma ratio as a prognostic parameter in solid primary tumor types. Currently, the stromal content of tumor tissues is determined via routine diagnostic pathology slides. With the development of liquid chromatography (LC)-MS methods we aim at quantification of tumor-stroma specific proteins in body fluids. In this mini-review the analytical aspect of this developmental trajectory is further detailed. © 2022 THE AUTHORS

DFSA: A classification capability quantification method for human action recognition

Item Type Conference Paper

Author C. Xu

Author J. He

Author X. Zhang

Abstract Motion related human action recognition using wearable sensors can potentially enable various useful daily applications. So far, most studies view it as a stand-alone mathematical classification problem without considering the physical nature of human motions. Consequently, they suffer from data dependencies and encounter the disaster of dimension problem and the over-fitting issue, and their models are never human-readable. In this study, we start from a deep analysis on natural physical properties of human motions, and then propose a useful feature selection method to quantify each feature's classification contribution capability. On one hand, the 'disaster of dimension' problem can be avoided to some extent, due to the constrained dimension of key features; On the other hand, over-fitting issue can be eased since the knowledge implied in human motions are nearly invariant, which compensates the possible data inadequacy. The experiment results indicate that the proposed method performs superior to those adopted in related works, such as decision tree, k-NN, SVM, neural networks. © 2017 IEEE.

DGCNet: a clinical knowledge-driven model for the segmentation of reflux esophagitis in endoscopic images

Item Type Journal Article**Author** Z. Ge**Author** Y. Fang**Author** J. Chang**Author** Z. Yu**Author** Y. Qiao**Author** Y. Hu**Author** J. Zhang**Author** Z. Duan**Author** X. Yang

Abstract Background: Digestive endoscopy is vital for diagnosing reflux esophagitis (RE) and is crucial for assessing disease severity. Although some existing pixel-level precision segmentation models can achieve fine-grained lesion region recognition, artificial intelligence-assisted diagnosis of RE is still in its infancy. The mutable shape, uneven distribution, and indistinct inflammatory texture boundaries inherent to RE endoscopic features pose formidable challenges for accurate lesion recognition and segmentation. This study proposes a classification and segmentation model to improve the Los Angeles grade (LA-grade) accuracy and enable precise lesion identification and quantification. Methods: In this study, we compiled the largest RE endoscopic image dataset, conducted a detailed classification study on it, and tested current mainstream and classic models. Based on RE endoscopic features, we introduced a clinical knowledge-driven RE segmentation model: the Deep Graph Convolution Network (DGCNet). We devised two novel modules: the Point Preservation Module to enhance model adaptability to lesion edge features and the Edge Graph Extraction Module for multi-scale fusion of edge and internal lesion features. Results: For classification results, we tested four classic models. The Swin Transformer model achieved the best performance for various evaluation indicators, with a classification accuracy of $86.2\% \pm 2.1\%$ and an F1 Score of $82.9\% \pm 2.3\%$. This study proposed a DGCNet framework and compared it with six classic segmentation networks. The results showed that our proposed model is significantly better than the other models, with mean Dice reaching $87.8\% \pm 1.4\%$ and mean IoU of $79.2\% \pm 1.6\%$. Conclusions: DGCNet demonstrates exceptional segmentation performance, showing promise for enhancing the accuracy of endoscopic LA-grade classification and precise recognition and segmentation of lesions. © The Author(s) 2026. Abstract Objectives: To compare the diagnostic accuracy of texture analysis (TA)–derived parameters combined with machine learning (ML) of non-contrast-enhanced T1w and T2w fat-saturated (fs) images with MR elastography (MRE) for liver fibrosis quantification. Methods: In this IRB-approved prospective study, liver MRIs of participants with suspected chronic liver disease who underwent liver biopsy between August 2015 and May 2018 were analyzed. Two readers blinded to clinical and histopathological findings performed TA. The participants were categorized into no or low-stage (0–2) and high-stage (3–4) fibrosis groups. Confusion matrices were calculated using a support vector machine combined with principal component analysis. The diagnostic accuracy of ML-based TA of liver fibrosis and MRE was assessed by area under the receiver operating characteristic curves (AUC). Histopathology served as reference standard. Results: A total of 62 consecutive participants (40 men; mean age $\pm$ standard deviation, 48 ± 13 years) were included. The accuracy of TA and ML on T1w was 85.7% (95% confidence interval [CI] 63.7–97.0) and 61.9% (95% CI 38.4–81.9) on T2w fs for classification of liver fibrosis into low-stage and high-stage fibrosis. The AUC for TA on T1w was similar to MRE (0.82 [95% CI 0.59–0.95] vs. 0.92 [95% CI 0.71–0.99], $p = 0.41$), while the AUC for T2w fs was significantly lower compared to MRE (0.57 [95% CI 0.34–0.78] vs. 0.92

[95% CI 0.71–0.99], $p = 0.008$). Conclusion: Our results suggest that liver fibrosis can be quantified with TA-derived parameters of T1w when combined with a ML algorithm with similar accuracy compared to MRE. Key Points: • Liver fibrosis can be categorized into low-stage fibrosis (0–2) and high-stage fibrosis (3–4) using texture analysis–derived parameters of T1-weighted images with a machine learning approach. • For the differentiation of low-stage fibrosis and high-stage fibrosis, the diagnostic accuracy of texture analysis on T1-weighted images combined with a machine learning algorithm is similar compared to MR elastography. © 2020, European Society of Radiology.

Diagnostic Gain from Surgical Biopsy for Interstitial Lung Disease - When is it Worth the Risk?

Item Type Journal Article

Author C. Biancosino

Abstract Background: History, clinical presentation, lung function testing, radiographs including HRCT and nonsurgical biopsy techniques in most cases provide sufficient information for classification of interstitial lung disease (ILD). However, in a small percentage it is not possible to establish the diagnosis so that lung biopsy may be required. We analyzed under which circumstances a reduction of invasive procedures is reasonable. Methods: Between January 1997 and December 2009 we examined 3399 specimens from 1299 patients with benign inflammatory and granulomatous diseases in whom ILD was clinically hypothesized. We compared the probability of disease according to Bayes before and after surgery which corresponds to the clinical diagnosis (a priori probability) and the final diagnosis (a posteriori probability). Additionally, procedures, operation related complications and the patients smoking habits were documented. Results: In 111 patients (8.5%) surgical evaluation was performed (14 mediastinoscopies, 97 thoracotomies/VATS biopsies). All mediastinoscopies substantiated a epitheloid cell granulomatosis. In 30% of all VATS procedures a prolonged air leak of more than 4 days was observed. One patient died and one had to get a new chest tube after removal. Changes of a priori/a posteriori probabilities was shown for non-smokers in Wegners granulomatosis (0.6 vs. 2.2%) and IPF (16.7 vs. 34.8%), for smokers in Langerhans cell histiocytosis (1.4 vs. 7.8%) and IPF (16.7 vs. 33.3%). In the majority of cases even a reduction of probability was seen. Conclusion: Considering complications and limited diagnostic gain, lung biopsies for diagnosis of ILD should be recommended only in selected patients. © 2016 Georg Thieme Verlag KG Stuttgart New York.

Abstract Background : Electroencephalography (EEG) interpretation for epilepsy diagnosis faces persistent challenges including specialist shortages, variable interpretation accuracy, and limited accessibility. Artificial intelligence (AI)-based automated interpretation systems promise to address these limitations, yet their diagnostic performance compared to clinical experts remains incompletely characterized. Objective: To systematically evaluate and meta -analyze the diagnostic accuracy of AI-enabled EEG interpretation compared with human clinical experts for epilepsy detection. Methods : We conducted a systematic review following PRISMA-DTA and Cochrane MECIR standards, searching PubMed, Scopus, IEEE Xplore, and Google Scholar through June 2025. Studies directly comparing AI algorithms with human expert interpretation using identical EEG datasets were included. Quality assessment employed QUADAS-AI criteria. Bivariate meta -analysis was performed to estimate pooled sensitivity, specificity, diagnostic odds ratios, and likelihood ratios. It is important to note that AI algorithms evaluated in these studies were trained using expert-labeled EEG data through supervised learning approaches; our comparison focuses on diagnostic accuracy outcomes rather than algorithmic independence from expert knowledge. Results : Three studies encompassing 9,775 EEG examinations met inclusion criteria. AI demonstrated superior pooled sensitivity (0.83–0.85 vs. 0.77–0.80) and specificity (0.83–0.85 vs. 0.72–0.75) compared to human experts. The diagnostic odds ratio for AI was approximately double that of humans (12–13 vs. 6–7). AI exhibited consistently narrower confidence intervals, indicating greater interpretive reliability. For normal versus abnormal EEG classification, AI achieved 86–90% sensitivity with enhanced consistency compared to human evaluators. However, substantial heterogeneity (I² ' 75%) and methodological limitations were identified across studies. Conclusions: AI-based EEG interpretation demonstrates diagnostic performance equal or superior to human experts with enhanced consistency, supporting potential implementation as clinical triage tools. However, limited transparency, patient selection bias, and deployment feasibility constraints warrant further investigation before widespread clinical adoption. Multiple sources of uncertainty affect AI-based diagnostic systems in clinical applications. Internal uncertainties include model parameter uncertainty, threshold selection variability, and training data limitations. External uncertainties encompass population heterogeneity, EEG acquisition variability, and clinical context differences. Parametric uncertainties arise from model architecture choices, while non-parametric uncertainties reflect distribution-free variations in real-world data. The amounts and structures of these uncertainties are often unknown in operational settings, necessitating robust uncertainty quantification methods for safe clinical deployment. © 2026 The Author(s).

Author Y. Hara

Abstract Background: Dermal blood vessels beneath the epidermis play critical roles in epidermal homeostasis and are functionally divided into several types, such as capillaries. Optical coherence tomography angiography (OCTA) is a powerful tool for the non-invasive assessment of dermal vasculature. However, the classification of vessel types has been limited. To address this issue, we proposed an algorithm for diameter-dependent classification that preserves three-dimensional (3D) information using OCTA. Methods: OCTA data were acquired by a prototype swept-source-type optical coherence tomography (OCT) system, which was processed through several imaging filters: an optical microangiography (OMAG) imaging filter, a vesselness imaging filter, and a diameter map filter. All vessels were visually classified into

three types based on their diameters, as micro-vessels, intermediate vessels, and thick vessels. Aging-related alterations and their association with the epidermis were investigated for each vessel type. The measurements were conducted on the cheeks of 124 female subjects aged 20–79 years. Results: The 3D vascular structure was visualized by applying our proposed post-processing filters. Based on visual assessment, the thresholds for the diameters of the micro, intermediate and thick vessels were set at 80 and 160 μm . It was found that micro-vessels were predominantly located in the upper layer of the dermis and thick vessels in the deeper layer. Analysis of vessel metrics revealed that the volume density of the micro-vessels decreased significantly with age ($r=-0.36$, $P<0.001$) and was positively correlated with epidermal thickness ($r=0.50$, $P<0.001$). In contrast, the volume density of thick vessels significantly increased with age ($r=0.2$, $P<0.05$) and was not significantly correlated with epidermal thickness ($r=0.13$, $P\geq 0.05$). Conclusions: In this study, we proposed a 3D quantification method using OCTA for dermal blood vessels and various vessel metrics, such as vessel volume density. This proposed classification will be beneficial for determining the function of the dermal vasculature and its diagnostic applications. © Quantitative Imaging in Medicine and Surgery. “Did you read about Berlin?” Terrorist attacks, online media reporting and support for refugees in Germany

Item Type Journal Article

Author A.W. Schmidt-Catran

Author C.S. Czymara

Abstract We analyze whether the Islamist terror attack on the Christmas market in Berlin in 2016 had an impact on public opinion toward immigration in general and, since the attacker has entered Germany to apply for asylum, toward refugees in particular. An analysis of this natural experiment reveals a negative shift regarding the latter, while no differences are observed for the former. To shed more light on the driver of attitude change, we combine these findings with a quantitative content analysis of online media reporting about refugees before and after the attack. Mass media have long been considered to have an impact on exclusionary attitudes toward ethnic minorities. However, empirical evidence on this relationship remains largely anecdotal. We draw upon unsupervised machine learning to quantify the developments in reporting in three popular German online news websites. Results reveal that the attack had significant impact on media reporting on these websites. However, the strong focus on the attack was only short lived, quickly decreasing already in the second week after the attack. Linking media data to the public opinion data reveals no clear connection between reporting and attitudes. In contrast to theoretical expectations, descriptive evidence even shows that both follow almost opposite trends, since people changed their attitudes only weeks after the attack. We discuss potential explanations of these, at first sight, counterintuitive findings. © 2020 Nomos Verlagsgesellschaft mbH und Co. All rights reserved.

Differentiable sampling of molecular geometries with uncertainty-based adversarial attacks

Item Type Journal Article

Author D. Schwalbe-Koda

Author A.R. Tan

Author R. Gómez-Bombarelli

Abstract Neural network (NN) interatomic potentials provide fast prediction of potential energy surfaces, closely matching the accuracy of the electronic structure methods used to produce the training data. However, NN predictions are only reliable within well-learned training domains, and show volatile behavior when extrapolating. Uncertainty quantification methods can flag atomic configurations for which prediction confidence is low, but arriving at such uncertain regions requires expensive sampling of the NN phase space, often using atomistic simulations. Here, we exploit automatic differentiation to drive atomistic systems towards high-likelihood, high-uncertainty configurations without the need for molecular dynamics simulations. By performing adversarial attacks on an uncertainty metric, informative geometries that expand the training domain of NNs are sampled. When combined with an active learning loop, this approach bootstraps and improves NN potentials while decreasing the number of calls to the ground truth method. This efficiency is demonstrated on sampling of kinetic barriers, collective variables in molecules, and supramolecular chemistry in zeolite-molecule interactions, and can be extended to any NN potential architecture and materials system. © 2021, The Author(s).

Abstract Background Rectal cancers show a highly varied response to neoadjuvant radiotherapy/chemoradiation (RT/CRT) and the impact of the tumor immune microenvironment on this response is poorly understood. Current clinical tumor regression grading systems attempt to measure radiotherapy response but are subject to interobserver variation. An unbiased and unique histopathological quantification method (change in tumor cell density (δ TCD)) may improve classification of RT/CRT response. Furthermore, immune gene expression profiling (GEP) may identify differences in expression levels of genes relevant to different radiotherapy responses: (1) at baseline between poor and good responders, and (2) longitudinally from preradiotherapy to postradiotherapy samples. Overall, this may inform novel therapeutic RT/CRT combination strategies in rectal cancer. Methods We generated GEPs for 53 patients from biopsies taken prior to preoperative radiotherapy. TCD was used to assess rectal tumor response to neoadjuvant RT/CRT and δ TCD was subjected to k-means clustering to classify patients into different response categories. Differential gene expression analysis was performed using statistical analysis of microarrays, pathway enrichment analysis and immune cell type analysis using single sample gene set enrichment analysis. Immunohistochemistry was performed to validate specific results. The results were validated using 220 pretreatment samples from publicly available datasets at metalevel of pathway and survival analyses. Results δ TCD scores ranged from 12.4% to -47.7% and stratified patients into three response categories. At baseline, 40 genes were significantly upregulated in poor (n=12) versus good responders (n=21), including myeloid and stromal cell genes. Of several pathways showing significant enrichment at baseline in poor responders, epithelial to mesenchymal transition, coagulation, complement activation and apical junction pathways were validated in external cohorts. Unlike poor responders, good responders showed longitudinal (preradiotherapy vs postradiotherapy samples) upregulation of 198 immune genes, reflecting an increased T-cell-inflamed GEP, type-I interferon and macrophage populations. Longitudinal pathway analysis suggested viral-like pathogen responses occurred in post-treatment resected samples compared with pretreatment biopsies in good responders. Conclusion This study suggests potentially druggable immune targets in poor responders at baseline and indicates that tumors with a good RT/CRT response reprogrammed from immune "cold" towards an immunologically "hot" phenotype on treatment with radiotherapy. ©

Abstract Different neurodegenerative diseases can cause memory disorders and other cognitive impairments. The early detection and the stratification of patients according to the underlying disease are essential for an efficient approach to this healthcare challenge. This emphasizes the importance of differential diagnostics. Most studies compare patients and controls, or Alzheimer's disease with one other type of dementia. Such a bilateral comparison does not resemble clinical practice, where a clinician is faced with a number of different possible types of dementia. Here we studied which features in structural magnetic resonance imaging (MRI) scans could best distinguish four types of dementia, Alzheimer's disease, frontotemporal dementia, vascular dementia, and dementia with Lewy bodies, and control subjects. We extracted an extensive set of features quantifying volumetric and morphometric characteristics from T1 images, and vascular characteristics from FLAIR images. Classification was performed using a multi-class classifier based on Disease State Index methodology. The classifier provided continuous probability indices for each disease to support clinical decision making. A dataset of 504 individuals was used for evaluation. The cross-validated classification accuracy was 70.6% and balanced accuracy was 69.1% for the five disease groups using only automatically determined MRI features. Vascular dementia patients could be detected with high sensitivity (96%) using features from FLAIR images. Controls (sensitivity 82%) and Alzheimer's disease patients (sensitivity 74%) could be accurately classified using T1-based features, whereas the most difficult group was the dementia with Lewy bodies (sensitivity 32%). These results were notable better than the classification accuracies obtained with visual MRI ratings (accuracy 44.6%, balanced accuracy 51.6%). Different quantification methods provided complementary information, and consequently, the best results were obtained by utilizing several quantification methods. The results prove that automatic quantification methods and computerized decision support methods are feasible for clinical practice and provide comprehensive information that may help clinicians in the diagnosis making. © 2016 The Authors.

Differential Privacy for Positive and Unlabeled Learning with Known Class Priors

Item Type Conference Paper

Author A.T. Pham

Author R. Raich

Abstract Despite the increasing attention to big data, there are several domains where labeled data is scarce or too costly to obtain. For example, for data from information retrieval, gene analysis, and social network analysis, only training samples from the positive class are annotated while the remaining unlabeled training samples consist of both unlabeled positive and unlabeled negative samples. The specific positive and unlabeled (PU) data from those domains necessitates a mechanism to learn a two-class classifier from only one-class labeled data. Moreover, because data from those domains is highly sensitive and private, preserving training samples privacy is essential. This paper addresses the challenge of private PU learning by designing a differentially private algorithm for positive and unlabeled data. We first propose a learning framework for the PU setting when the class prior probability is known, with a theoretical guarantee of convergence to the optimal classifier. We then propose a privacy-preserving

mechanism for the designed framework where the privacy and utility are both theoretically and empirically proved. © 2018 IEEE.

Abstract Machine learning algorithms benefit greatly from a large amount of data in the big data regime, however, the labeling cost for all training samples is prohibitively high. Semi-supervised learning is a designed framework to overcome the labeling challenge. In particular, in semi-supervised learning, there are only a small number of labeled samples and unlabeled samples are used as side information to leverage the overall performance. Additionally, preserving the privacy of the data is another challenge in big data analysis. This paper addresses challenges by designing a privacy-preserving method for semi-supervised learning. Assuming that class priors are available, the proposed method can achieve the optimal classifier. Moreover, the privacy and utility of the proposed method are theoretically guaranteed. Experiments on real UCI datasets illustrate the effectiveness of our proposed method. © 2018 IEEE.

Abstract Objectives: Beyond total kidney and cyst volume (TCV), non-cystic tissue plays an important role in autosomal dominant polycystic kidney disease (ADPKD) progression. This study aims at presenting and preliminarily validating a diffusion MRI (DWI)-based TCV quantification method and providing evidence of DWI potential in characterising non-cystic tissue microstructure. Methods: T2-weighted MRI and DWI scans ($b = 0, 15, 50, 100, 200, 350, 500, 700, 1000$; 3 directions) were acquired from 35 ADPKD patients with CKD stage 1 to 3a and 15 healthy volunteers on a 1.5 T scanner. ADPKD classification was performed using the Mayo model. DWI scans were processed by mono- and segmented bi-exponential models. TCV was quantified on T2-weighted MRI by the reference semi-automatic method and automatically computed by thresholding the pure diffusivity (D) histogram. The agreement between reference and DWI-based TCV values and the differences in DWI-based parameters between healthy and ADPKD tissue components were assessed. Results: There was strong correlation between DWI-based and reference TCV ($\rho = 0.994, p < 0.001$). Non-cystic ADPKD tissue had significantly higher D, and lower pseudo-diffusion and flowing fraction than healthy tissue ($p < 0.001$). Moreover, apparent diffusion coefficient and D values significantly differed by Mayo imaging class, both in the whole kidney (Wilcoxon $p = 0.007$ and $p = 0.004$) and non-cystic tissue ($p = 0.024$ and $p = 0.007$). Conclusions: DWI shows potential in ADPKD to quantify TCV and characterise non-cystic kidney tissue microstructure, indicating the presence of microcysts and peritubular interstitial fibrosis. DWI could complement existing biomarkers for non-invasively staging, monitoring, and predicting ADPKD progression and evaluating the impact of novel therapies, possibly targeting damaged non-cystic tissue besides cyst expansion. Clinical relevance statement: This study shows diffusion-weighted MRI (DWI) potential to quantify total cyst volume and characterise non-cystic kidney tissue microstructure in ADPKD. DWI could complement existing biomarkers for non-invasively staging, monitoring, and predicting ADPKD progression and evaluating the impact of novel therapies, possibly targeting damaged non-cystic tissue besides cyst expansion. Key Points: • Diffusion magnetic resonance imaging shows potential to quantify total cyst volume in ADPKD. • Diffusion magnetic resonance imaging might allow to non-invasively characterise non-cystic kidney tissue microstructure. • Diffusion magnetic resonance imaging-based biomarkers significantly differ by Mayo imaging class, suggesting their possible prognostic value. © 2023, The Author(s), under exclusive licence to European Society of Radiology.

Abstract Diffusion tensor imaging (DTI) has been advocated as a promising tool for delineation of the extent of tumor infiltration by primary brain tumors. First reports show conflicting results mainly due to difficulties in reproducible determination of DTI-derived parameters. A novel method based on probabilistic voxel classification for a user-independent analysis of DTI-derived parameters is presented and tested in healthy controls and patients with primary brain tumors. The proposed quantification method proved to be highly reproducible both in healthy controls and patients. Fiber integrity in the corpus callosum (CC) was measured using this quantification method, and the profiles of fractional anisotropy (FA) provided additional information of the possible extent of infiltration of primary brain tumors when compared to conventional imaging. This yielded additional information on the nature of ambiguous contralateral lesions in patients with primary brain tumors. The results show that DTI-derived parameters can be determined reproducibly and may have a strong impact on evaluation of contralateral extent of primary brain tumors. © 2006 Elsevier Inc. Abstract Current understanding of fibrosis remains incomplete despite the increasing burden of related diseases. Preclinical models are used to dissect the pathogenesis and dynamics of fibrosis, and to evaluate anti-fibrotic therapies. These studies require objective and accurate measurements of fibrosis. Existing histological quantification methods are operator-dependent, organ-specific, and/or need advanced equipment. Therefore, we developed a robust, minimally operator-dependent, and tissue-transposable digital method for fibrosis quantification. The proposed method involves a novel algorithm for more specific and more sensitive detection of collagen fibers stained by picrosirius red (PSR), a computer-assisted segmentation of histological structures, and a new automated morphological classification of fibers according to their compactness. The new algorithm proved more accurate than classical filtering using principal color component (red-green-blue; RGB) for PSR detection. We applied this new method on established mouse models of liver, lung, and kidney fibrosis and demonstrated its validity by evidencing topological collagen accumulation in relevant histological compartments. Our data also showed an overall accumulation of compact fibers concomitant with worsening fibrosis and evidenced topological changes in fiber compactness proper to each model. In conclusion, we describe here a robust digital method for fibrosis analysis allowing accurate quantification, pattern recognition, and multi-organ comparisons useful to understand fibrosis dynamics. © 2020 by the authors. Digital imaging applications and informatics in dermatology

Item Type Journal Article**Author** F. Giuste**Author** J.C. Vizcarra**Author** D.A. Gutman

Abstract In this chapter, we present the use of whole slide imaging (WSI) and dermoscopy in the field of dermatology. Image digitization has allowed for increasing computer-assisted clinical decision-making. An introduction to common digital imaging data sources such as WSI and dermoscopy is provided. We also review some commonly used image quantification methods and their potential applications in dermatology. Finally, we review how machine learning approaches utilize novel large dermatology image datasets. © 2019 Frontline Medical Communications

Abstract Although many studies highlight the implication of circular RNAs (circRNAs) in carcinogenesis and tumor progression, their potential as cancer biomarkers has not yet been fully explored in the clinic due to the limitations of current quantification methods. Here, we report the use of the nCounter platform as a valid technology for the analysis of circRNA expression patterns in non-small cell lung cancer (NSCLC) specimens. Under this context, our custom-made circRNA panel was able to detect circRNA expression both in NSCLC cells and formalin-fixed paraffin-embedded (FFPE) tissues. CircFUT8 was overexpressed in NSCLC, contrasting with circEPB41L2, circBNC2, and circSOX13 downregulation even at the early stages of the disease. Machine learning (ML) approaches from different paradigms allowed discrimination of NSCLC from nontumor controls (NTCs) with an 8-circRNA signature. An additional 4-circRNA signature was able to classify early-stage NSCLC samples from NTC, reaching a maximum area under the ROC curve (AUC) of 0.981. Our results not only present two circRNA signatures with diagnosis potential but also introduce nCounter processing following ML as a feasible protocol for the study and development of circRNA signatures for NSCLC. © 2022 The Authors. DIMER: EEG-based DNA-inspired multi-dimension feature emotion quantization recognition method

Item Type Journal Article

Author L. Hou

Author X. Li

Author D. Liu

Author Y. Zhou

Abstract A novel DNA-Inspired Multi-dimensional Emotion Recognition Network (DIMER) is proposed to address critical challenges in affective computing. Firstly, addressing the issue of incomplete emotional state quantification in the field of emotion recognition, a 16-level emotion quantification methodology based on valence, arousal, dominance, and liking is proposed, enabling fine-grained classification of emotional states. Secondly, to overcome the complexity of EEG feature extraction and poor multi-dimensional feature fusion performance, a dynamic complementary fusion approach for multi-dimensional features based on DNA interaction mechanisms is introduced. This approach conceptualizes EEG differential entropy features and their visualized representations as DNA double-strand carriers, quantifying the complementary degree between features by simulating hydrogen bond strength through feature affinity calculations. Finally, main chain-complementary chain feature associations are established based on DNA base-pairing principles, thereby achieving adaptive feature fusion. Experimental results on the DEAP emotion dataset demonstrate that subject-dependent experiments achieve 95.07% accuracy, outperforming MLP and LSTM by 1.82% and 18.16%, respectively, while subject-independent experiments attain 94.82% accuracy, surpassing MLP and LSTM by 15.66% and 33.33%, respectively. The proposed method effectively advances the development of high-precision multi-dimensional emotion recognition. © 2026

Abstract Identification of organic acid is crucial indicator for field of environment, healthcare and industry, which involves the time-consuming and labor-intensive progress. The simultaneous detection for complex mixture becomes a new target when large-scale instruments is the mainstream measurement approach. With the burst development of machine learning in solving complex problem, the progress is being made for quick detection of mixtures. The next challenge is to provide sufficient data to satisfy the need of algorithm. In this work, we proposed the modified spectrometer technology combined with the deep learning to quantify the mixed organic acids. Organic acids interact with light in the various background to map the information in the form of images. Deep learning could establish the relationship between images and concentrations. According to the result, trained convolutional neural network could achieve the goal of simultaneous measurement of organic acids, which speeds up the implementation in the parallel detection and suggests new twists in the field of chemistry. © 2021 Wiley-VCH GmbH

Discrete Box-Constrained Minimax Classifier for Uncertain and Imbalanced Class Proportions

Item Type Journal Article

Author C. Gilet

Author S. Barbosa

Author L. Fillatre

Abstract This paper aims to build a supervised classifier for dealing with imbalanced datasets, uncertain class proportions, dependencies between features, the presence of both numeric and categorical features, and arbitrary loss functions. The Bayes classifier suffers when prior probability shifts occur between the training and testing sets. A solution is to look for an equalizer decision rule whose class-conditional risks are equal. Such a classifier corresponds to a minimax classifier when it maximizes the Bayes risk. We develop a novel box-constrained minimax classifier which takes into account some constraints on the priors to control the risk maximization. We analyze the empirical Bayes risk with respect to the box-constrained priors for discrete inputs. We show that this risk is a concave non-differentiable multivariate piecewise affine function. A projected subgradient algorithm is derived to maximize this empirical Bayes risk over the box-constrained simplex. Its convergence is established and its speed is bounded. The optimization algorithm is scalable when the number of classes is large. The robustness of our classifier is studied on diverse databases. Our classifier, jointly applied with a clustering algorithm to process mixed attributes, tends to equalize the class-conditional risks while being not too pessimistic. © 1979-2012 IEEE.

Discrete Minimax Regret Classifier for Sustainability Development**Item Type** Conference Paper**Author** C. Gilet**Author** L. Fillatre

Abstract While supervised classification is becoming increasingly used in sustainability development, the issue of prior probability shifts often occurs in these contexts and remains important to be addressed. Prior probability shift characterizes an evolution of the prior probabilities between test samples and the class proportions observed in training dataset. A robust approach to address this issue is the minimax regret strategy. The regret corresponds to the loss of performance associated with a classifier compared to the optimal performance reached by the Bayes classifier with respect to given prior probabilities. The minimax-regret strategy minimizes the maximum regret of a classifier that can be reached when prior probabilities shifts occur. This paper is devoted to learn a minimax regret classifier in a context of mixed attributes, that can be coupled with any pre-trained neural networks for sustainable classification tasks, and that can take into account given costs of classification errors provided by the experts of the application domain. We especially show that we can learn a minimax regret classifier by learning a usual minimax classifier when considering a specific loss function. Experiments on real databases for sustainability development illustrate the benefits of our proposed approach. © 2026 IEEE.

Discrete Perineural Invasion Focus Number in Quantification for T1-T2 Oral Squamous Cell Carcinoma

Item Type Journal Article

Author P.-Y. Wei

Author W.-Y. Li

Author S.-K. Tai

Abstract Objective: Perineural invasion (PNI) has been an established poor prognostic feature for T1-T2 oral squamous cell carcinoma (OSCC). Different presentations and amounts of PNI are commonly observed, but PNI is currently recorded as being present or absent. This study asked whether the quantification of PNI provides additional information for early OSCC. Study Design: Retrospective cohort study. Setting: Tertiary referral medical center. Subjects and Methods: Pathologic reevaluations were performed for 314 patients with T1-T2 OSCC who underwent curative surgery from June 2001 to August 2009. A novel parameter, PNI focus number, was defined for PNI quantification. With 5 PNI foci as the cutoff, patients were categorized into 3 groups: no PNI (0 PNI foci), low PNI (PNI foci, 1-5), and high PNI (PNI foci >5). Rate of cervical lymph node metastasis (LN+), 5-year disease-specific survival (DSS), and 5-year overall survival (OS) were analyzed among these groups. Results: PNI focus number independently predicted for LN+, poor DSS, and poor OS in multivariate analysis after controlling for T classification, lymphovascular invasion, differentiation, margin, and tumor thickness. The 5-year DSS demonstrated a dose-dependent decrease among the 3 groups (no PNI, 88.6%; low PNI, 75.2%; high PNI, 33.8%; $P < .001$). Moreover, the 5-year DSS of the high PNI group was significantly worse than that of the low PNI group. Conclusion: PNI focus number can be a novel parameter for PNI quantification in early OSCC. Although optimal quantification methods still require further investigation, this study offers clear clinical support for the nerve-tumor interaction hypothesis and advocates further mechanistic research for the exploration of PNI-related treatment concepts for OSCC. © American Academy of Otolaryngology–Head and Neck Surgery Foundation 2018.

Discriminant Insights: Applying Linear Discriminant Analysis to Tamil Vowel Usage for Social Awareness and Emotional Lyrics in Education

Item Type Conference Paper
Author B. Sharmila
Author S.P. Gnana Prakasam Louis Raja
Author R. Ganesan

Author N. Kalaiyarasi

Author N. Vijayan

Abstract Tamil lyrics occupy a central role in language and literature classrooms, where they are used to explore phonology, stylistic variation, and the interaction between linguistic form and social meaning. This paper presents an exploratory baseline tool rather than a production classifier: it investigates whether a compact and statistically transparent model can support pedagogical analysis by summarizing vowel usage patterns across two lyric categories - Social Awareness and Emotional lyrics - frequently discussed in teaching and cultural discourse. Each of 54 authors is represented by raw counts of the twelve Tamil vowels, Uyir Ezhuthukal. Linear Discriminant Analysis (LDA) is applied with equal class priors to derive a single canonical discriminant function. The model yields an eigenvalue of 0.411 and a canonical correlation of 0.540, indicating moderate separation. Wilks' lambda is 0.709 ($p=0.198$), confirming non-significant class separation and limiting strong inferential claims. Resubstitution accuracy is 74.1% and leave-one-out cross-validation accuracy is 55.6%, corroborating the baseline nature of the approach. Despite modest predictive performance, interpretable LDA coefficients, centroids, and diagnostic statistics constitute structured decision-support artifacts that augment - rather than replace - instructor judgment in classroom discussion, example selection, and hypothesis formation. Raw counts are used in this baseline to preserve stylistic intensity and enable classroom reproducibility; the pedagogical implications of this choice and directions toward normalized features are explicitly discussed. A teacher-oriented analytical workflow, a concrete classroom deployment example, and governance considerations for responsible educational deployment are outlined, drawing on principles from human-centered design and trustworthy AI. © 2026 IEEE.

Discriminatively trained language models using support vector machines for language identification

Item Type Conference Paper**Author** L.-F. Zhai**Author** M.-H. Siu**Author** X. Yang**Author** H. Gish

Abstract In this paper, we explore the use of the Support Vector Machines (SVMs) to learn a discriminatively trained n-gram model for automatic language identification. Our focus is on practical considerations that make SVM technology more effective. We address the performance related issues of class priors, data imbalance, feature weighting, score normalization and combining multiple knowledge sources with SVMs. Using modified n-gram counts as features, we show that the SVM-trained n-grams are effective classifiers but they are sensitive to changes in prior class distributions. Using balanced prior distributions or score normalization procedures, the SVM-trained n-gram out-performed the traditional n-gram in parallel phoneme recognition with language model and GMM-UBM-based language identification systems by more than 30% relative error reduction on the OGI-TS corpus. © 2006 IEEE.

Discussion on “INTACT: a method for integration of longitudinal physical activity data from multiple sources” by Jingru Zhang, Erjia Cui, Hongzhe Li, and Haochang Shou

Item Type Journal Article

Author D. Fuller

Author K. Stanley

Abstract The INTACT (INtegration of Time varying data from weArable sensors for physiCal acTivity) method proposed by Zhang et al. represents a timely and important contribution to the harmonization of accelerometer data across studies. The authors provide a mathematically rigorous presentation and an open source R package. INTACT has clear utility for large scale data integration initiatives. INTACT draws inspiration from techniques used in domains where latent biological mechanisms are poorly defined. We argue that physical activity research is distinct in that the primary latent constructs, time and intensity, are well understood. Accelerometer summary metrics represent proxies for these constructs, raising questions about whether abstraction through an eigenmodel improves interpretation of the physiological meaning. The post harmonization “activity intensity” metric produced by INTACT lacks clear units, scale consistency, and it is unclear how the harmonized metric would be applied to activity classification methods. The method’s reliance on eigenfunctions is both a strength and a limitation. There are challenges for comparability across studies, and it will be important for applied users to conduct sensitivity analyses to evaluate eigenfunction selection. We also highlight the critical assumption of a shared eigenspace across datasets and populations, which may be violated in contexts with different physical activity patterns. Additional methodological development and clear interpretability will play an important role in the adoption of this method by the research community. © The Author(s) 2026. Disentangling conditional redshift effects in Quasar–Galaxy photometric classification

Item Type Journal Article

Author R. Mattera

Abstract Redshift is widely used to improve photometric classification of astronomical sources, yet the origin of its contribution is rarely examined explicitly. In this work, we propose an experimental framework designed to disentangle whether redshift provides genuine conditional information or primarily reflects distance-driven class priors. We introduce a controlled comparison between original and redshift-matched samples, evaluated via a paired, repeated cross-validation scheme to ensure statistical robustness. Using spectroscopically confirmed sources from the Sloan Digital Sky Survey within an intermediate redshift range, we isolate the marginal redshift effects from non-linear feature interactions. Our analysis reveals that, after marginal balancing, redshift does not improve the performance of linear models, acting as a control validation of the design. In contrast, non-linear classifiers retain a residual, magnitude-dependent gain, which increases toward fainter sources. This demonstrates that our experimental design successfully isolates the conditional role of redshift, showing it contributes through non-linear interactions with photometric features rather than serving solely as a marginal proxy for distance. © 2026 The Author

Disentangling Label Distribution for Long-tailed Visual Recognition

Item Type Conference Paper

Author Y. Hong

Author S. Han

Author K. Choi

Author S. Seo

Author B. Kim

Author B. Chang

Abstract The current evaluation protocol of long-tailed visual recognition trains the classification model on the long-tailed source label distribution and evaluates its performance on the uniform target label distribution. Such protocol has questionable practicality since the target may also be long-tailed. Therefore, we formulate long-tailed visual recognition as a label shift problem where the target and source label distributions are different. One of the significant hurdles in dealing with the label shift problem is the entanglement between the source label distribution and the model prediction. In this paper, we focus on disentangling the source label distribution from the model prediction. We first introduce a simple but overlooked baseline method that matches the target label distribution by post-processing the model prediction trained by the cross-entropy loss and the Softmax function. Although this method surpasses state-of-the-art methods on benchmark datasets, it can be further improved by directly disentangling the source label distribution from the model prediction in the training phase. Thus, we propose a

novel method, Label distribution DisEntangling (LADE) loss based on the optimal bound of Donsker-Varadhan representation. LADE achieves state-of-the-art performance on benchmark datasets such as CIFAR-100-LT, Places-LT, ImageNet-LT, and iNaturalist 2018. Moreover, LADE outperforms existing methods on various shifted target label distributions, showing the general adaptability of our proposed method. © 2021 IEEE

Dist-PU: Positive-Unlabeled Learning from a Label Distribution Perspective

Item Type Conference Paper

Author Y. Zhao

Author Q. Xu

Author Y. Jiang

Author P. Wen

Author Q. Huang

Abstract Positive-Unlabeled (PU) learning tries to learn binary classifiers from a few labeled positive examples with many unlabeled ones. Compared with ordinary semi-supervised learning, this task is much more challenging due to the absence of any known negative labels. While existing cost-sensitive-based methods have achieved state-of-the-art performances, they explicitly minimize the risk of classifying unlabeled data as negative samples, which might result in a negative-prediction preference of the classifier. To alleviate this issue, we resort to a label distribution perspective for PU learning in this paper. Noticing that the label distribution of unlabeled data is fixed when the class prior is known, it can be naturally used as learning supervision for the model. Motivated by this, we propose to pursue the label distribution consistency between predicted and ground-truth label distributions, which is formulated by aligning their expectations. Moreover, we further adopt the entropy minimization and Mixup regularization to avoid the trivial solution of the label distribution consistency on unlabeled data and mitigate the consequent confirmation bias. Experiments on three benchmark datasets validate the effectiveness of the proposed method. © 2022 IEEE.

Distance-based image classification: Generalizing to new classes at near-zero cost

Item Type Journal Article

Author T. Mensink

Author J. Verbeek

Author F. Perronnin

Author G. Csurka

Abstract We study large-scale image classification methods that can incorporate new classes and training images continuously over time at negligible cost. To this end, we consider two distance-based classifiers, the k-nearest neighbor (k-NN) and nearest class mean (NCM) classifiers, and introduce a new metric learning approach for the latter. We also introduce an extension of the NCM classifier to allow for richer class representations. Experiments on the ImageNet 2010 challenge dataset, which contains over \$(106)\$ training images of 1,000 classes, show that, surprisingly, the NCM classifier compares favorably to the more flexible k-NN classifier. Moreover, the NCM performance is comparable to that of linear SVMs which obtain current state-of-the-art performance. Experimentally, we study the generalization performance to classes that were not used to learn the metrics. Using a metric learned on 1,000 classes, we show results for the ImageNet-10K dataset which contains 10,000 classes, and obtain performance that is competitive with the current state-of-the-art while being orders of magnitude faster. Furthermore, we show how a zero-shot class prior based on the ImageNet hierarchy can improve performance when few training images are available. © 1979-2012 IEEE.

Distinguish normal white blood cells from leukemia cells by detection, classification, and counting blood cells using YOLOv5

Item Type Conference Paper**Author** D.T. Luong**Author** D.D. Anh**Author** T.X. Thang**Author** H.T.L. Huong**Author** T.T. Hanh**Author** D.M. Khanh

Abstract Leukemia is a group of blood cancers that usually begin in the bone marrow and result in high numbers of abnormal blood cells. Distinguishing normal white blood cells from leukemia cells plays a role in the diagnosis of blood diseases. Over the years, manual methods can detect, classify, and count blood cells that are labor-intensive slow, time-consuming, subject to error, and costly. An automatic system is applied in the processing detection through microscopic images that will be fast, cheap, and high accuracy without special needs of equipment for lab testing. In this paper, we propose a method of detection, classification, and counting to distinguish five types of normal white blood cells (WBCs) from abnormal white blood cells (leukemia) using the You Only Look Once version 5 (YOLOv5) to aid the diagnosis of blood diseases. After using the YOLOv5 algorithm, we manually labeled the blood cells, and the leukemia cells labeled are the largest with 619 cells, while the number of normal WBCs labeled is a basophil, 115 neutrophils, 23 eosinophils, 80 lymphocytes, and 73

monocytes, respectively. The tested result with the average accuracy of detection and classification of the blood cells is 93.0%. © 2022 IEEE.

Abstract We present the current status of a scalable computing framework to address the need of the multidisciplinary effort to study chemical dynamics. Specifically, we are enabling scientists to process and store experimental data, run large-scale computationally expensive high-fidelity physical simulations, and analyze these results using state-of-the-art data analytics, machine learning, and uncertainty quantification methods using heterogeneous computing resources. We present the results of this framework on a single metadata-driven workflow to accelerate an additive manufacturing use-case. Copyright © Materials Research Society 2020.

Distributed optimization of classifier committee hyperparameters

Item Type Conference Paper

Author S. Aubakirov

Author P. Trigo

Author D. Ahmed-Zaki

Editor Bernardino J.

Editor Quix C.

Abstract In this paper, we propose an optimization workflow to predict classifiers accuracy based on the exploration of the space composed of different data features and the configurations of the classification algorithms. The overall process is described

considering the text classification problem. We take three main features that affect text classification and therefore the accuracy of classifiers. The first feature considers the words that comprise the inputtext; here we use the N-gram concept with different N values. The second feature considers the adoption of textual pre-processing steps such as the stop-word filtering and stemming techniques. The third feature considers the classification algorithms hyperparameters. In this paper, we take the well-known classifiers K-Nearest Neighbors (KNN) and Naive Bayes (NB) where K (from KNN) and a-priori probabilities (from NB) are hyperparameters that influence accuracy. As a result, we explore the feature space (correlation among textual and classifier aspects) and we present an approximation model that is able to predict classifiers accuracy. Distribution Alignment: A Unified Framework for Long-tail Visual Recognition

Item Type Conference Paper

Author S. Zhang

Author Z. Li

Author S. Yan

Author X. He

Author J. Sun

Abstract Despite the recent success of deep neural networks, it remains challenging to effectively model the long-tail class distribution in visual recognition tasks. To address this problem, we first investigate the performance bottleneck of the two-stage learning framework via ablative study. Motivated by our discovery, we propose a unified distribution alignment strategy for long-tail visual recognition. Specifically, we develop an adaptive calibration function that enables us to adjust the classification scores for each data point. We then introduce a generalized re-weight method in the two-stage learning to balance the class prior, which provides a flexible and unified solution to diverse scenarios in visual recognition tasks. We validate our method by extensive experiments on four tasks, including image classification, semantic segmentation, object detection, and instance segmentation. Our approach achieves the state-of-the-art results across all four recognition tasks with a simple and unified framework. © 2021 IEEE

Abstract Graphs are commonly used in machine learning to model relationships between instances. Consider the task of predicting the political preferences of users in a social network; to solve this task one should consider, both, the features of each individual user and the relationships between them. However, oftentimes one is not interested in the label of a single instance but rather in the distribution of labels over a set of instances; e.g., when predicting the political preferences of users, the overall prevalence of a given opinion might be of higher interest than the opinion of a specific person. This label prevalence estimation task is commonly referred to as quantification learning (QL). Current QL methods for tabular data are typically based on the so-called prior probability shift (PPS) assumption which states that the label-conditional instance distributions should remain equal across the training and test data. In the graph setting, PPS generally does not hold if the shift between training and test data is structural, i.e., if the training data comes from a different region of the graph than the test data. To address such structural shifts, an importance sampling variant of the popular adjusted count quantification approach has previously been proposed. In this work, we extend the idea of structural importance sampling to the state-of-the-art KDEy quantification approach. We show that our proposed method adapts to structural shifts and outperforms standard quantification approaches. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2026.

Distribution-Free Uncertainty Quantification for Classification under Label Shift

Item Type Conference Paper
Author A. Podkopaev
Author A. Ramdas
Editor de Campos C.
Editor Maathuis M.H.
Abstract Trustworthy deployment of ML models requires a proper measure of uncertainty, especially in safety-critical applications. We focus on uncertainty quantification (UQ) for classification problems via two avenues - prediction sets using conformal prediction and calibration of probabilistic predictors by post-hoc binning - since these possess distribution-free guarantees for i.i.d. data. Two common ways of generalizing beyond the i.i.d. setting include handling covariate and label shift. Within the context of distribution-free UQ, the former has already received attention, but not the latter. It is known that label shift hurts prediction, and we first argue that it also hurts UQ, by showing degradation in coverage and calibration. Piggybacking on recent progress in addressing label shift (for better

prediction), we examine the right way to achieve UQ by reweighting the aforementioned conformal and calibration procedures whenever some unlabeled data from the target distribution is available. We examine these techniques theoretically in a distribution-free framework and demonstrate their excellent practical performance. © 2021 37th Conference on Uncertainty in Artificial Intelligence, UAI 2021. DISTRIBUTIONALLY ROBUST POST-HOC CLASSIFIERS UNDER PRIOR SHIFTS

Item Type Conference Paper

Author J. Wei

Author H. Narasimhan

Author E. Amid

Author W.-S. Chu

Author Y. Liu

Author A. Kumar

Abstract The generalization ability of machine learning models degrades significantly when the test distribution shifts away from the training distribution. We investigate the problem of training models that are robust to shifts caused by changes in the distribution of class-priors or group-priors. The presence of skewed training priors can often lead to the models overfitting to spurious features. Unlike existing methods, which optimize for either the worst or the average performance over classes or groups, our work is motivated by the need for finer control over the robustness properties of the model. We present an extremely lightweight post-hoc approach that performs scaling adjustments to predictions from a pre-trained model, with the goal of minimizing a distributionally robust loss around a chosen target distribution. These adjustments are computed by solving a constrained optimization problem on a validation set and applied to the model during test time. Our constrained optimization objective is inspired from a natural notion of robustness to controlled distribution shifts. Our method comes with provable guarantees and empirically makes a strong case for distributional robust post-hoc classifiers. An empirical implementation is available at <https://github.com/weijiaheng/Drops>. © 2023 11th International Conference on Learning Representations, ICLR 2023. All rights reserved.

DLQMA: A Deep Learning Framework for Qualitative and Quantitative NMR Analysis of Complex Hydrocarbon Mixtures

Item Type Journal Article

Author W. Dong

Author X. Liu

Author D. Xun

Author Y. Wang

Author Y. Qiao

Abstract Nuclear magnetic resonance (NMR) is a key technique for structural and quantitative analysis of organic compounds, yet its application to complex mixtures is hindered by severe spectral overlap and the absence of efficient, standard-free quantification methods. DLQMA (Deep Learning for Qualitative and Quantitative Mixture Analysis) is introduced as a deep learning framework that simultaneously performs compound identification and concentration estimation directly from ¹H NMR spectra. Built on a pseudo-Siamese architecture with an added regression head, DLQMA enables end-to-end analysis without the need for manual spectral reconstruction or external standards. Performance was assessed using C8 hydrocarbon mixtures, a system characterized by severe spectral overlap and composed of multiple industrially relevant isomers with overlapping NMR signals. On this data set, DLQMA achieved 99.39% classification accuracy and a Pearson correlation of 0.98 for concentration predictions across 5,000 pairs of augmented validation spectra. The framework is further compatible with advanced NMR techniques such as 1D CSSF TOCSY, allowing automated interpretation of virtually separated subspectra. A standalone software implementation with an intuitive interface enables automated, high-throughput analysis of complex chemical mixtures. These advances have the potential to transform NMR spectroscopy into a fully automated tool for high-throughput analysis in chemical, petrochemical, and environmental applications. © 2025 American Chemical Society

Abstract A problematic feature of many human cancers is a lack of understanding of mechanisms controlling organ-specific patterns of metastasis, despite recent progress in identifying many mutations and transcriptional programs shown to confer this potential. To address this gap, we developed a methodology that enables different aspects of the metastatic process to be comprehensively characterized at a clonal resolution. Our approach exploits the application of a computational pipeline to analyze and visualize clonal data obtained from transplant experiments in which a cellular DNA barcoding strategy is used to distinguish the separate clonal contributions of two or more competing cell populations. To illustrate the power of this methodology, we demonstrate its ability to discriminate the metastatic behavior in immunodeficient mice of a well-established human metastatic cancer cell line and

its co-transplanted LRRC15 knockdown derivative. We also show how the use of machine learning to quantify clone-initiating cell (CIC) numbers and their subsequent metastatic progeny generated in different sites can reveal previously unknown relationships between different cellular genotypes and their initial sites of implantation with their subsequent respective dissemination patterns. These findings underscore the potential of such combined genomic and computational methodologies to identify new clonally-relevant drivers of site-specific patterns of metastasis. © 2022 The Author(s).

DNA variant classification—reconsidering “allele rarity” and “phenotype” criteria in ACMG/AMP guidelines

Item Type Journal Article

Author C.D. Davieson

Author K.E. Joyce

Author L. Sharma

Author C.L. Shovlin

Abstract Recent guidance suggested modified DNA variant pathogenicity assignments based on genome-wide allele rarity. Different a priori probabilities of pathogenicity operate where patients already have clinical diagnoses, and are found to have a very rare variant in a gene known to cause their disease, compared to predictive testing of a clinically unaffected individual. We tested new recommendations from the ClinGen Sequence Variant Interpretation Working Group for ClinVar-listed, loss-of-function variants meeting the very strong evidence of pathogenicity criterion [PVS1] in genes for 3 specific diseases where causal gene identification can modify clinical care of an individual- Von Willebrand disease, cystic fibrosis and hereditary haemorrhagic telangiectasia. Across these diseases, current rules leave 20/1,278 (1.6%) of loss-of-function variants as variants of uncertain significance (VUS that may not be reported to clinicians), and 207/1,278 (17.2%) as likely pathogenic. Applying the new ClinGen rule enabling PVS1 and the allele rarity criterion PM2 to delineate likely pathogenicity still left 8/1,278 (0.9%) as VUS (reflecting non-PVS1 calls by the submitters), and the majority of null alleles meeting PVS1 as merely likely pathogenic. We favour an approach whereby, for PVS1 variants in patients who personally meet the phenotypic PP4 criterion for a disease where casual variants are commonly family-specific, that PM2 is upgraded to permit a pathogenic call. Of 1,278 ClinVar-listed frameshift, nonsense and canonical splice site variants that met PVS1 in the 3 conditions, 16.0% (204/1,278) would be newly designated as pathogenic, avoiding misinterpretation outside of clinical genetics communities. We suggest further discussion around variant assessment across different clinical applications, potentially guided by PP4 alerts to distinguish personal versus family phenotypic history. © 2021 The Authors

Abstract Evaluating attribute control success in controllable text generation and related generation tasks typically relies on pretrained classifiers. We show that this widely used classify-and-count approach yields biased and inconsistent results, with estimates varying significantly across classifiers. We frame control success estimation as a quantification task and apply a hybrid Bayesian method that combines classifier predictions with a small number of human labels for calibration. To test our approach, we collected a two-modality test dataset consisting of 600 human-rated samples and 60,000 automatically rated samples. Our experiments show that our approach produces robust estimates of control success across both text and text-to-image generation tasks, offering a principled alternative to current evaluation practices. © 2026 Association for Computational Linguistics.

Abstract Unsupervised domain adaptation (UDA) enables the transfer of models trained on source domains to unlabeled target domains. However, transferring complex time series models presents challenges due to the dynamic temporal structure variations across domains. This leads to feature shifts in the time and frequency representations. Additionally, the label distributions of tasks in the source and target domains can differ significantly, posing difficulties in addressing label shifts and recognizing labels unique to the target domain. Effectively transferring complex time series models remains a formidable problem. We present RAINCOAT, the first model for both closed-set and universal domain adaptation on complex time series. RAINCOAT addresses feature and label shifts by considering both temporal and frequency features, aligning them across domains, and correcting for misalignments to facilitate the detection of private labels. Additionally, RAINCOAT improves transferability by identifying label shifts in target domains. Our experiments with 5 datasets and 13 state-of-the-art UDA methods demonstrate that RAINCOAT can improve transfer learning performance by up to 16.33% and can handle both closed-set and universal domain adaptation. © 2023 Proceedings of Machine Learning Research. Abstract Mobile health research on illicit drug use detection typically involves a two-stage study design where data to learn detectors is first collected in lab-based trials, followed by a deployment to subjects in a free-living environment to assess detector performance. While recent work has demonstrated the feasibility of wearable sensors for illicit drug use detection in the lab setting, several key problems can limit labtofield generalization performance. For example, lab-based data collection often has low ecological validity, the groundtruth event labels collected in the lab may not be available at the same level of temporal granularity in the field, and there can be significant variability between subjects. In this paper, we present domain adaptation methods for assessing and mitigating potential sources of performance loss in lab-to-field generalization and apply them to the problem of cocaine use detection from wearable electrocardiogram sensor data. © 2016 ACM.

Abstract We introduce the problem of domain adaptation under Open Set Label Shift (OSLS) where the label distribution can change arbitrarily and a new class may arrive during deployment, but the class-conditional distributions $p(x|y)$ are domain-invariant. OSLS subsumes domain adaptation under label shift and Positive-Unlabeled (PU) learning. The learner's goals here are two-fold: (a) estimate the target label distribution, including the novel class; and (b) learn a target classifier. First, we establish necessary and sufficient conditions for identifying these quantities. Second, motivated by advances in label shift and PU learning, we propose practical methods for both tasks that leverage black-box predictors. Unlike typical open set domain adaptation problems, which tend to be

ill-posed and amenable only to heuristics, OSLs offers a well-posed problem amenable to more principled machinery. Experiments across numerous semi-synthetic benchmarks on vision, language, and medical datasets demonstrate that our methods consistently outperform open set domain adaptation baselines, achieving 10-25% improvements in target domain accuracy. Finally, we analyze the proposed methods, establishing finite-sample convergence to the true label marginal and convergence to optimal classifier for linear models in a Gaussian setup. © 2022 Neural information processing systems foundation. Domain adaptation under structural causal models

Item Type Journal Article

Author Y. Chen

Author P. Bühlmann

Abstract Domain adaptation (DA) arises as an important problem in statistical machine learning when the source data used to train a model is different from the target data used to test the model. Recent advances in DA have mainly been application-driven

and have largely relied on the idea of a common subspace for source and target data. To understand the empirical successes and failures of DA methods, we propose a theoretical framework via structural causal models that enables analysis and comparison of the prediction performance of DA methods. This framework also allows us to itemize the assumptions needed for the DA methods to have a low target error. Additionally, with insights from our theory, we propose a new DA method called CIRM that outperforms existing DA methods when both the covariates and label distributions are perturbed in the target data. We complement the theoretical analysis with extensive simulations to show the necessity of the devised assumptions. Reproducible synthetic and real data experiments are also provided to illustrate the strengths and weaknesses of DA methods when parts of the assumptions in our theory are violated. ©2021 Yuansi Chen and Peter Bühlmann.

Domain adaptation with asymmetrically-relaxed distribution alignment

Item Type Conference Paper

Author Y. Wu

Author E. Winston

Author D. Kaushik

Author Z.C. Lipton

Abstract Domain adaptation addresses the common situation in which the target distribution generating our test data differs from the source distribution generating our training data. While absent assumptions, domain adaptation is impossible, strict conditions, e.g. covariate or label shift, enable principled algorithms. Recently-proposed domain-adversarial approaches consist of aligning source and target encodings, an approach often motivated as minimizing two (of three) terms in a theoretical bound on target error. Unfortunately, this minimization can cause arbitrary increases in the third term, a problem guaranteed to arise under shifting label distributions. We propose asymmetrically-relaxed distribution alignment, a new approach that overcomes some limitations of standard domain-adversarial algorithms. Moreover, we characterize precise assumptions under which our algorithm is theoretically principled and demonstrate empirical benefits on both synthetic and real datasets. Copyright © 2019 ASME

Domain adaptation with conditional distribution matching and generalized label shift

Item Type Conference Paper

Author R.T. Des Combes

Author H. Zhao

Author Y.-X. Wang

Author G. Gordon

Abstract Adversarial learning has demonstrated good performance in the unsupervised domain adaptation setting, by learning domain-invariant representations. However, recent work has shown limitations of this approach when label distributions differ between the source and target domains. In this paper, we propose a new assumption, generalized label shift (GLS), to improve robustness against mismatched label distributions. GLS states that, conditioned on the label, there exists a representation of the input that is invariant between the source and target domains. Under GLS, we provide theoretical guarantees on the transfer performance of any classifier. We also devise necessary and sufficient conditions for GLS to hold, by using an estimation of the relative class weights between domains and an appropriate reweighting of samples. Our weight estimation method could be straightforwardly and generically applied in existing domain adaptation (DA) algorithms that learn domain-invariant representations, with small computational overhead. In particular, we modify three DA algorithms, JAN, DANN and CDAN, and evaluate their performance on standard and artificial DA tasks. Our algorithms outperform the base versions, with vast improvements for large label distribution mismatches. Domain compensatory adversarial networks for partial domain adaptation

Item Type Journal Article

Author J. Huang

Author P. Zhang

Author Z. Zhou

Author K. Fan

Abstract Recently, domain adaptation has stimulated interest in the community of machine learning since it can improve the performance of the model in a new domain (target domain) by borrowing knowledge from a labeled source domain. At the same time, the presence of large-scale labeled datasets also raised significant attention in this scenario: the class labels in the new domain are only a subset of those in the source domain. We propose an adversarial-net-based method in this paper, called domain compensatory adversarial network (DCAN). The critical difficulty of this problem is to reduce the negative impact of source instances with weak discriminability and filter out outlier source classes by exploiting the prior probability of classes. DCAN can identify source instances with weak discriminability and reverse its domain label to compensate for the target label space, which alleviates the negative effect of mismatching label space. Besides, DCAN reweights outlier source classes with the class prior distributions of source data for both category classifier and domain classifier to promote positive transfer. Experiments have revealed the superiority of DCAN compared to the existing methods. © 2021, Springer Science+Business Media, LLC, part of Springer Nature.

Domain Expansion and Boundary Growth for Open-Set Single-Source Domain Generalization

Item Type Journal Article

Author P. Jiao

Author N. Zhao

Author J. Chen

Author Y.-G. Jiang

Abstract Open-set single-source domain generalization aims to use a single-source domain to learn a robust model that can be generalized to unknown target domains with both domain shifts and label shifts. The scarcity of the source domain and the unknown data distribution of the target domain pose a great challenge for domain-invariant feature learning and unknown class recognition. In this article, we propose a novel learning approach based on domain expansion and boundary growth to expand the scarce source samples and enlarge the boundaries across the known classes that indirectly broaden the boundary between the known and unknown classes. Specifically, we achieve domain expansion by employing both background suppression and style augmentation on the source data to synthesize new samples. Then we force the model to distill consistent knowledge from the synthesized samples so that the model can learn domain-invariant information. Furthermore, we realize boundary growth across classes by using edge maps as an additional modality of samples when training multi-binary classifiers. In this way, it enlarges the boundary between the inliers and outliers, and consequently improves the unknown class recognition during open-set generalization. Extensive experiments show that our approach can achieve significant improvements and reach state-of-the-art performance on several cross-domain image classification datasets. © 1999-2012 IEEE.

Domain-invariant adversarial learning with conditional distribution alignment for unsupervised domain adaptation

Item Type Journal Article**Author** X. Wang**Author** B. Sun**Author** H. Dong

Abstract Unsupervised domain adaption aims to reduce the divergence between the source domain and the target domain. The final objective is to learn domain-invariant features from both domains that get the minimised expected error on the target domain. The divergence between domains which is also called domain shift is mainly between the distributions of domains' samples. Additionally, the label shift is also a

tricky challenge in domain adaptation. In this study, domain-invariant adversarial learning with conditional distribution alignment is proposed to alleviate the effect of domain shift with label shift. To obtain the domain-invariant features, the proposed method modifies adversarial auto-encoder architecture and performs semi-supervised learning to enlarge the inter-class discrepancy. The marginal distribution is aligned in the adversarial learning process of extracting domain-invariant features. Meanwhile, the label information is incorporated in this way to align the conditional distribution. The proposed work also theoretically analyses the generalisation bound of the proposed model. Finally, the proposed method is evaluated based on several domain adaptation tasks, including digit classification and object recognition, and achieves state-of-the-art performance. © 2020 Institution of Engineering and Technology. Abstract The LeQua 2022 competition was conducted with the purpose of evaluating different quantification methods on text data. In the following, we present the solution of our team “DortmundAI”, which ranked first in the multi-class quantification task T1B. This solution is based on a modification of the well-known Saerens-Latinne-Decaestecker (SLD) method. Here, the SLD method, which is based on expectation maximization, is extended by a regularization technique. Additional experiments with the test data, which we took out after the competition closed, reveal that our excellent ranking stems primarily from an extensive hyperparameter tuning of the classifier. © 2022 Copyright for this paper by its authors.

Downscaling multilayer soil moisture using parameterized depth profiles associated with environmental factors

Item Type Journal Article

Author M. Zhang

Author Y. Ge

Author Y. Ma

Author Y. Jin

Author Y. Chen

Author S. Liu

Abstract High-resolution multilayer soil moisture is valuable for water resources management, drought monitoring, and crop optimization. However, integrating process-based models into statistical downscaling methods to estimate multilayer soil moisture can increase both prediction uncertainty and computational complexity of parameterization. Here, three parameterized equations (Peak, Trough, and Balance) were proposed to quantify soil moisture profiles associated with environmental factors, and downscale multilayer soil moisture. Global (0–40 cm) and local (0–10, 10–20, and 20–40 cm) fitting strategies represented the vertical extent of environmental influences. Three machine learning models were employed to downscale satellite soil moisture and predict depth parameters, which were then used to generate sub-surface soil moisture. The results indicated that the local fitting strategy consistently outperformed the global strategy across all depths, reducing the mean absolute error (MAE) and root mean square error (RMSE) by 81.8 % and 80.4 %, and increasing the coefficient of determination (R^2) by 22.5 %. Furthermore, local fitting revealed distinct nonlinear and linear patterns within the 0–20 cm and 20–40 cm intervals, respectively. The prediction accuracy of sub-surface soil moisture was improved compared to surface results, with MAE and RMSE reduced by 30.2 %–60.7 % and 34.9 %–56.7 %, respectively. The modified local fitting strategy further enhanced prediction performance, with the Peak–Trough–Balance combination recommended as the optimal configuration. Future studies should account for variations in soil and vegetation cover, refine interval division by incorporating soil-forming processes, and adopt advanced uncertainty quantification methods to enhance its adaptability and robustness. This study provides a reference for multilayer soil moisture downscaling in large-scale regions with depth variability and environmental heterogeneity. © 2025 Elsevier B.V.

DP-EVA: data-efficient fine-tuning framework via maximizing pretrained knowledge of large atomistic models for developing domain-specific machine-learning interatomic potentials

Item Type Journal Article

Author Z. Liu

Author Z. Deng

Author H. Zhao

Author H. Wang

Author M. Chen

Author H. Jiang

Abstract Machine-learning interatomic potentials (MLIPs) have greatly extended the temporal and spatial scales of atomistic simulations, enabling the theoretical study of complex processes at affordable computational cost compared with conventional density functional theory. Recently, large atomistic models (LAMs) have drawn intense interest, as their unified encoders embed extensive chemical knowledge and support fine-tuning methodologies for efficiently adapting models to domain-specific downstream tasks. While many active learning frameworks exist for building MLIP datasets from scratch, dedicated data-generation pipelines for fine-tuning pretrained

LAMs remain scarce. Here, we introduce the Deep Potential EVolution Accelerator (DP-EVA)—a data-efficient fine-tuning framework that maximizes the utilization of the pretrained knowledge of LAMs during data generation, accelerating the evolution of domain-specific fine-tuned models with minimal datasets. DP-EVA collects highly representative data through a dual-dimensional shallow-ensemble-based uncertainty quantification method based on parallel fine-tuning on the LAM decoder and a Dimensionality-Reduced Encoded Clusters with sTratified (DIRECT) sampling strategy based on the LAM encoder. Tests show that DP-EVA delivers optimal chemical space coverage in the task of drastically reducing the size of an existing MLIP dataset for iron-based Fischer–Tropsch synthesis. DP-EVA fills the gap of active learning frameworks suitable for fine-tuning LAMs toward domain-specific MLIPs and it is also open-source, Slurm-native, and agent-ready for the coming era of agentic scientific research. © The Author(s) 2026. Drift mining in data: A framework for addressing drift in classification

Item Type Journal Article

Author V. Hofer

Author G. Krempel

Abstract A novel statistical methodology for analysing population drift in classification is introduced. Drift denotes changes in the joint distribution of explanatory variables and class labels over time. It entails the deterioration of a classifier's performance and requires the optimal decision boundary to be adapted after some time. However, in the presence of verification latency a re-estimation of the classification model is impossible, since in such a situation only recent unlabelled data are available, and the true corresponding labels only become known after some lapse in time. For this reason a novel drift mining methodology is presented which aims at detecting changes over time. It allows us either to understand evolution in the data from an ex-post perspective or, ex-ante, to anticipate changes in the joint distribution. The proposed drift mining technique assumes that the class priors change by a certain factor from one time point to the next, and that the conditional distributions do not change within this time period. Thus, the conditional distributions can be estimated at a time where recent labelled data are available. In subsequent periods the unconditional distribution can be expressed as a mixture of the conditional distributions, where the mixing proportions are equal to the class priors. However, as the unconditional distributions can also be estimated from new unlabelled data, they can then be compared to the mixture representation by means of least-squares criteria. This allows for easy and fast estimation of the changes in class prior values in the presence of verification latency. The usefulness of this drift mining approach is demonstrated using a real-world dataset from the area of credit scoring. © 2012 Elsevier B.V. All rights reserved.

Driving mechanisms of water yield in the Yellow River Basin: Insights from an explainable machine learning approach

Item Type Journal Article

Author J. Hu

Author L. Wang

Author Y. Wang

Author Y. Liu

Author X. Su

Author L. Li

Author J. Li

Abstract Study region: Yellow River Basin, a semi-arid and semi-humid basin in China. Study focus: Water yield (WY) is a critical indicator for water resources assessment. However, existing studies face limitations in WY validation and the exploration of nonlinear driving mechanisms. This study innovatively combines InVEST-modeled WY (validated using surface water and GLEAM_AET data) with explainable machine learning to quantify the nonlinear effects of climatic, anthropogenic, topographic, and soil factors on WY. New hydrological insights for the region: This work obtained more accurate WY and analyzed the nonlinear action mode of driving factors: (1) the new method obtained WY with equal total volume and similar spatial distribution; (2) precipitation (PRE) is the main factor affecting the spatial distribution of WY, with a contribution rate of 37.11 %, and its effect shows obvious geographical differentiation: the effect size gradually increases from north to south. In humid areas (PRE > 400 mm), WY and PRE increase linearly, while in arid areas, the response is not significant; the synergistic effect of altitude and root-restricting layer depth dominates the terrain-soil interaction process; (3) In terms of temporal evolution, the contribution rate of PRE change reached 74.22 %, and its increment was linearly correlated with WY gain. Land use change affects WY by changing evapotranspiration and root depth. © 2025 The Authors

Abstract This study presents sheep detection and quantification methods for video frames captured by UAVs and examine their advantages over traditional UAV video recording. The implementation of two digital image processing approaches for pattern recognition is based on color-shape analysis and the YOLOv5 classifier to detect sheep in a field from a video source. Both methods are implemented in Python 3 using OpenCV tools, where morphological operations and feature classification algorithms are applied. These methods perform multiple operations on the video source and have proven to be effective for detecting sheep images under different lighting conditions, as well as at varying distances between the UAV and the sheep. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2025.

Dual-center RAPID-LSSVM: Radius-adaptive, probability and imbalance driven weighting for Alzheimer's diagnosis

Item Type Journal Article

Author M. Akhtar
Author A. Quadir
Author M. Tanveer
Author M. Arshad

Abstract Alzheimer's disease (AD) is a leading neurodegenerative disorder and the primary cause of dementia, where early, reliable diagnosis remains challenging. Although many machine learning methods have been developed for early AD detection, their performance often degrades under label noise, outliers, and class imbalance. To counter these issues, we propose RAPID, a Radius-Adaptive, Probability and Imbalance Driven flexible weighting mechanism, and integrate it into least-squares SVM to obtain two models: RAPID-LSSVM-I (mean-center) and RAPID-LSSVM-II (median-center). RAPID combines three complementary components. First, a radius-adaptive proximity weight that plateaus for samples near the class center and decays smoothly beyond a threshold, preserving the influence of boundary samples while improving robustness to central noise. Second, a local class-probability term that down-weights potentially mislabeled or ambiguous instances, and third, an imbalance-ratio term that compensates for class prior skew. The dual-center design enables either conventional mean centering or a median-based center that is resilient to outliers and asymmetric distributions. To validate the effectiveness of the proposed RAPID-LSSVM models, experiments are conducted on benchmark KEEL and UCI datasets under both clean and label-noise settings. Additionally, we tested the models on the Alzheimer's Disease Neuroimaging Initiative (ADNI) dataset for AD diagnosis. Empirical findings demonstrate the superiority of the RAPID-LSSVM models over baseline models, highlighting their potential in improving AD diagnosis and handling noisy data. © 2026 Elsevier Ltd. Dual-Contrastive Multiview Graph Attention Network for Industrial Fault Diagnosis under Domain and Label Shift

Item Type Journal Article

Author J. Zhu

Author S. Wu

Author Y. Xiao

Author B. Wang

Author R. Cai

Abstract Recently, domain generalization (DG) methods have been actively researched for the complex industrial fault diagnosis, which aims to learn generalized representations from historical working conditions to build a diagnosis model that can perform well on unseen working conditions. However, these methods ignore the interactions between monitoring variables, which may fail to learn the feature representation with topological structure in non-Euclidean space. In addition, these methods assume the same label distribution across historical and unseen working conditions, which is generally challenging in practice, as the probability of faults varies across different working conditions. This label shift problem can negatively impact the generalization performance. To address these issues, a novel dual-contrastive multiview graph attention network (DMGAT) is proposed in this article. Specifically, a multiview graph attention network (GAT) is designed to explore the intrinsic topological structure of the data, which learns an optimal graph structure that best serves DG by integrating both graph learning and graph convolution in a unified network architecture. In addition, a novel dual-weighted contrastive learning strategy is developed. The intradomain contrastive learning facilitates the extraction of expressive node features, while interdomain contrastive learning simultaneously considers the alignment and separation of semantic probability distributions to extract

shared feature representations for multiple source domains under both domain and label shifts. Furthermore, a label sampling probability is used to weight the interdomain contrastive loss and the source domain classification loss, to encourage the model to learn from minor classes in fault diagnosis. Experiments on two cases demonstrate the superiority of the proposed method. © 1963-2012 IEEE.

Abstract INTRODUCTION: Identifying individuals with dementia is crucial for prevalence estimation and service planning, but reliable, scalable methods are lacking. We developed novel set algorithms using both structured and unstructured electronic health record (EHR) data, applying Diagnostic and Statistical Manual of Mental Disorders criteria for dementia case identification. METHODS: Our cohort (n = 1082) included individuals aged ≥ 60 with dementia identified through specialist clinics and a comparison group without dementia. Clinicians from Australia and the United States informed predictor selection. We developed algorithms through a biostatistics stream for structured data and a natural language processing (NLP) stream for text, synthesizing results via logistic regression. RESULTS: The final structured model retained 16 variables (area under the receiver operating characteristic curve [AUC] 0.853, specificity 72.2%, sensitivity 80.6%). NLP classifiers (logistic regression, support vector machine, and random forest models) performed comparably. The final, combined model outperformed all others (AUC = 0.951, $P < 0.001$ for comparison to structured model). DISCUSSION: Embedding text-derived insights within algorithms trained on structured medical data significantly enhances dementia identification capacity. Highlights: Algorithmic tools for detection of individuals with dementia are available; however, previous work has used heterogeneous case definitions which are not clinically meaningful, and has relied on proxies such as diagnostic codes or medications for case ascertainment. We used a novel, dual-stream algorithmic development approach, simultaneously and separately modeling a clinically meaningful outcome (diagnosis of dementia according to specialized clinical impression) using structured and unstructured electronic health record datasets. Our clinically grounded case definition supported the inclusion of key structured variables (such as dementia International Classification of Disease codes and medications) as modeling predictors rather than outcomes. Our algorithms, published in detail to support validation and replication, represent a major step forward in the use of routinely collected data for detection of diagnosed dementia. © 2025 The Author(s). Dual-stream collaborative network (DSCN): Multimodal sentiment analysis via modality-invariant and modality-specific representation learning

Item Type Journal Article
Author S. Chen
Author D. Zhou
Author C. Wei
Author X. Li
Author H. Yao

Author H. Luo

Abstract Multimodal Sentiment Analysis (MSA) is a critical technology for human-machine interaction. It performs sentiment analysis by integrating complementary information from multiple modalities such as text, audio, and vision. However, most existing multimodal fusion methods regard the text as the primary modality and treat speech and visual modalities as auxiliary. This approach limits the potential for synergistic interaction among the three modalities. To address this limitation, this paper proposes a Dual-Channel Collaborative Transformer (DCCT), which enables collaborative interaction among the three modalities. DCCT incorporates a Self-modal Binding Channel (SBC) to enhance intra-modal consistency, and a Cross-modal Binding Channel (CBC) to complement the idiosyncratic features of other modalities. Then, a Feed-Forward Network (FFN) integrates the outputs of both channels for effective trimodal feature fusion. Furthermore, to mitigate the label shift problem in multi-task joint learning, we propose a framework that distinguishes between intensity and polarity tasks based on modality decomposition. By separating common and idiosyncratic features, we design dedicated tasks for intensity and polarity, and use a shared-private linear layer in the Trimodal Label Generator (TMLG) to capture the interrelation between the two aspects and facilitate task adaptation. Experiments conducted on the CMU-MOSI and CMU-MOSEI datasets show that the proposed Dual-Stream Collaborative Network (DSCN), which integrates DCCT and TMLG, achieves ACC-2 accuracy of 86.75 % and 86.69 %, respectively. These results outperform the best existing baseline by 0.65 % and 0.83 %. © 2025 Elsevier B.V.

DWLR: Domain Adaptation under Label Shift for Wearable Sensor

Item Type Conference Paper

Author J. Li

Author Y. Yang

Author J. Zhang

Author Z. Lai

Author L. Pan

Editor Larson K.

Abstract Wearable sensors play a crucial role in real-world scenarios, such as human activity recognition, sleep monitoring and electrocardiogram monitoring. However, deploying classifiers on them is challenged by distribution shifts across users and devices. Unsupervised domain adaptation (UDA) is proposed to address this, yet existing methods mostly focus on feature distribution shift, neglecting the potential misclassification due to label shift. In this paper, we propose Domain adaptation under label shift for Wearable sensor with Learnable Reweighting (DWLR) to handle both feature and label shifts. Specifically, DWLR employs learnable reweighting to align label distributions between source and target domains. It incorporates elements of information gain during the reweighting process to counter potential distribution shift that could emerge from over-reliance on data with high-confidence pseudo labels. Importantly, since wearable sensor data is time-series data, and can be subjected to distribution shifts originating from either the time domain, the frequency domain, or both, DWLR performs reweighting and alignment separately in these two domains to more robustly handle potential feature distribution shifts. Extensive experiments on three distinct wearable sensor datasets demonstrate the effectiveness of DWLR, yielding a remarkable average performance improvement of 5.85%. © 2024 International Joint Conferences on Artificial Intelligence. Dynamic Evolution of Financial Technology and Artificial Intelligence for Economy Based on Bayesian Algorithm in Cyber-Physical System

Item Type Journal Article

Author X. Wang

Abstract With the rapid development of information technology and the popularity of big data, the demand for data analysis has become increasingly large. In recent years, data mining technology has received extensive attention. It is a technology that converts a large amount of data into useful information and finds the relationship between data and information. The classification algorithm is one of the important research contents in data mining. It mainly divides the data items in the dataset into a fixed category according to various classifiers. From the perspective of the development trend of the world economy, technological progress, consumption upgrading and institutional change are mutually reinforcing and integrating. In financial technology, the evolution of technology is reshaping the financial industry. Data intelligence technology based on machine learning and other algorithms is changing rapidly. Data is the largest means of production, the most important factor of production of artificial intelligence (AI), and the core factor of production. Big data, cloud computing, AI and other emerging technologies build different data structures for processing through deep learning and other learning algorithms to achieve accurate analysis, rapid decision-making and other characteristics. At the same time, it also provides financial institutions with more accurate and comprehensive data services. It has established long-term cooperation with financial institutions, promoting the accelerated integration of finance and technology and jointly creating a more intelligent financial system. Bayesian algorithm is a classical algorithm in classification algorithms. It is a possibility reasoning method based on probability statistics. Bayesian algorithm calculates a posteriori probability through a priori probability. Because of its small error rate, it has been widely used in various fields. This paper will analyze banking financial technology and AI economy based on cyber-physical systems and Bayesian algorithms. The research results showed that

Bank A added 1,275 small customers in the first quarter of 2020, accounting for 69.52% in 2019; in the first quarter of 2020, inclusive microfinance increased by 4.7 billion yuan, with a year-on-year growth of 35.34%, indicating that Bank A played an irreplaceable role in using financial technology in times of crisis. It points out a new development direction for the application of cyber-physical systems. © This is an Open Access article distributed under the terms of the Creative Commons Attribution Non-Commercial License (<http://creativecommons.org/licenses/by-nc/3.0/>) which permits unrestricted non-commercial use, distribution, and reproduction in any medium, provided the original work is properly cited.

Dynamic Quantification With Constrained Error Under Unknown General Dataset Shift

Item Type Journal Article

Author B. Denham

Author E.M.-K. Lai

Author R. Sinha

Author M.A. Naeem

Abstract Quantification research has sought to accurately estimate class distributions under dataset shift. While existing methods perform well under assumed conditions of shift, it is not always clear whether such assumptions will hold in a given application. This work extends the analysis and experimental evaluation of our Gain-Some-Lose-Some (GSLs) model for quantification under general dataset shift and incorporates it into a method for dynamically selecting the most appropriate quantification method. Selection by a Kolmogorov-Smirnov test for any shift followed by a newly proposed 'Adjusted Kolmogorov-Smirnov' test for non-prior shift is found to best balance quantification and runtime performance. We also present a framework for constraining quantification prediction intervals to user-specified limits by requesting a smaller set of instance class labels from the user than required with confidence-based rejection. © 1989-2012 IEEE.

DyS: A framework for mixture models in quantification

Item Type Conference Paper

Author A. Maletzke

Author D. dos Reis

Author E. Cherman

Author G. Batista

Abstract Quantification is an expanding research topic in Machine Learning literature. While in classification we are interested in obtaining the class of individual observations, in quantification we want to estimate the total number of instances that belong to each class. This subtle difference allows the development of several algorithms that incur smaller and more consistent errors than counting the classes issued by a classifier. Among such new quantification methods, one particular family stands out due to its accuracy, simplicity, and ability to operate with imbalanced training samples: Mixture Models (MM). Despite these desirable traits, MM, as a class of algorithms, lacks a more in-depth understanding concerning the influence of internal parameters on its performance. In this paper, we generalize MM with a base framework called DyS: Distribution y-Similarity. With this framework, we perform a thorough evaluation of the most critical design decisions of MM models. For instance, we assess 15 dissimilarity functions to compare histograms with varying numbers of bins from 2 to 110 and, for the first time, make a connection between quantification accuracy and test sample size, with experiments covering 24 public benchmark datasets. We conclude that, when tuned, Topsøe is the histogram distance function that consistently leads to smaller quantification errors and, therefore, is recommended to general use, notwithstanding Hellinger Distance's popularity. To rid MM models of the dependency on a choice for the number of histogram bins, we introduce two dissimilarity functions that can operate directly on observations. We show that SORD, one of such measures, presents performance that is slightly inferior to the tuned Topsøe, while not requiring the sensible parameterization of the number of bins. © 2019, Association for the Advancement of Artificial Intelligence (www.aaai.org).

Early Detection of Crack Vulnerability in Foldable Displays Through Critical-Angle Curvature Analysis

Item Type Conference Paper

Author K. Park

Author J. Kim

Author D. Kim

Abstract Foldable displays have become increasingly popular due to their portability and the provision of larger screens when unfolded. However, the use of flexible materials makes them more susceptible to mechanical failures, particularly crack formation in the hinge area where stress concentration is highest during folding operations. This study presents a novel approach to predict crack formation in foldable displays by measuring the curvature of the hinge area at a specific critical angle—where the mechanical stress peaks—and analyzing this data using Principal Component Analysis (PCA). The curvature measurements were initially reduced using PCA, retaining two principal components that captured around 60% of the dataset's variance. While this facilitated visualization, it was insufficient for clear classification between defective and non-defective samples due to overlapping data points and information loss. To enhance predictive accuracy, we introduced an uncertainty quantification method based on a -nearest neighbors approach with distance-weighted contributions. This method calculates an uncertainty score for each sample, reflecting the confidence in classifying it as susceptible or resistant to cracking. By integrating the uncertainty analysis into an artificial intelligence (AI) model, we assigned a numerical score ranging from +1 (clearly non-defective) to -1 (high risk of cracking) to each sample. Applying this model to a larger dataset of 200 samples, we successfully quantified the risk of crack occurrence—a task previously unfeasible with conventional methods. The model demonstrated strong discriminative power, effectively distinguishing between at-risk and safe samples. This integrated

methodology combining precise curvature measurement, uncertainty analysis, and AI modelling provides a robust framework for early detection and prediction of crack formation in foldable displays. The approach enhances product reliability and contributes valuable insights into material behavior under stress, supporting improved quality control measures in manufacturing. Future work will focus on expanding the dataset and incorporating additional features to further refine the model's predictive capabilities. © 2025, John Wiley and Sons Inc. All rights reserved.

Author G. Iannello
Author P. Soda

Abstract Prostate cancer is the most common form of cancer in Western countries and there is the need to develop clinical decision support systems able to support physicians in the diagnosis of clinical relevant prostate cancer and avoid useless invasive prostate biopsies. In this respect, this paper introduces a radiomic approach that classifies the prostate cancer aggressiveness by combining Three Orthogonal Planes-Local Binary Pattern (TOP - LBP) with other texture measures. Furthermore, to combat the skewed nature of class priors, our proposal employs a data augmentation technique. The results achieved on 99 samples are up-and-coming, they favorably compare against conventional PI-RADS-based approach, and they show also the benefit given by the introduction of TOP-LBP in the radiomic signature. © 2019 IEEE.

Easy Interpretation of Image Classification Results with Feature-Level Visualization

Item Type Conference Paper

Author D. Bhati

Author Y. Zhao

Author T.-H. Wu

Author M. Amiruzzaman

Author J. Yang

Abstract Given a picture classified as a Persian cat by an AI model, users may ask questions such as, “What are the contributions of the eyes and ears to the classification result?” or “Which features contribute the most?” While existing post-hoc XAI methods effectively explain model predictions at the pixel or patch level, they are limited in directly quantifying the contributions of human-interpretable semantic features. In this paper, we propose a visual analytics approach for feature-level interpretation of image classification results. Our contributions are twofold. First, we introduce a semantic contribution quantification method that builds upon existing pixel-level attribution techniques (e.g., Layer-wise Relevance Propagation, Grad-CAM). Specifically, we aggregate and normalize pixel-level relevance scores over predefined semantic regions (such as eyes, ears, and body) to compute comparable contribution scores for each semantic feature within an image. Second, we present an interactive visual interface that leverages these quantified semantic feature contributions to support exploration, comparison, and analysis of AI outputs across image collections. Through illustrative scenarios and expert feedback, we demonstrate that our approach provides an intuitive, scalable, and semantically meaningful means to interpret image classification explanations. ©2026 Society for Imaging Science and Technology.

ECG based human identification using Second Order Difference Plots

Item Type Journal Article

Author G. Altan

Author Y. Kutlu

Author M. Yeniad

Abstract Background and objective: ECG is one of the biometric signals that has been studied in peer-reviewed over past years. The developments on the signal analysis methods show that the studies on the ECG would continue unabatedly. It has a common use on cardiac diseases with high rates of classification performances by integrating it with signal analysis methods. The aim of the study is to utilize the ECG for human identification. Methods: Second Order Difference Plot (SODP) is a non-linear time-series analysis method that allows determining the features using the statistical analysis of the wave distributions. The SODP features were extracted using different quantification methods for ECG-based human identification. A new quantification approach has been proposed on the SODP for ECG-based human identification. The proposed method, Logarithmic Grid Analysis, was compared with the existing quantification methods on the SODP. The region of the SODP was divided into sub-regions with logarithmically increasing distances and the numbers of data points in each logarithmic sub regions were calculated in the proposed method. Three different databases were used to test the validity of the method. These records have been tested with the conventional feature extraction methods on the SODP. The long-term ECG signals were divided into 5-s short-term ECG signals. Results: The Logarithmic Grid Analysis features that were counted from short-time ECG signals were classified with k-Nearest Neighbor algorithm using 10-fold cross validation, and the identification performance of the proposed model was evaluated. Consequently, high accuracy rates of 91.96%, 99.86% and 95.12% were achieved on ECG-based human identification using the Logarithmic Grid Analysis method on the SODP. Conclusions: The density score of data points at the center of the SODP is too high. This case increases the importance of the regions close the center in order to find the detailed and significant features from the SODP. The number of data points at the center has been extracted in more detail and the vertex areas of the major axes of the SODP can be interpreted in the aggregate sub-regions by using logarithmically increasing distances with a small number of feature size. © 2019 Elsevier B.V.

Abstract Semantic segmentation of remote sensing images in urban scenes suffers from blurred multi-scale target boundaries, insufficient use of global context, and classification errors caused by high inter-class variance and low intra-class variance. Therefore, we propose a semantic segmentation network with edge and class guidance (ECGNet). First, ECGNet introduces multi-scale edge prior knowledge to address the problem of blurred target boundaries. Second, ECGNet applies synergistic class augmented attention to introduce class prior knowledge while retaining rich spatial dimensional localization information to alleviate the problem of classification errors caused by low intra-class variance and high inter-class variance. Finally, the multi-scale large receptive field attention in ECGNet simulates a large convolutional kernel to capture multi-scale global context information. Experiments conducted on the ISPRS Vaihingen and ISPRS Potsdam datasets show that the proposed method is competitive. © 2024 Society of Photo-Optical Instrumentation Engineers (SPIE).

Edge-Prioritize IDS: Zero-Retraining Class Prioritization for Real-Time Edge Intrusion Detection

Item Type Journal Article

Author P. Pawar

Author G. Epiphaniou

Abstract Deploying deep neural networks-based intrusion detection systems on resource-constrained edge devices demands inference strategies that balance latency, energy, and accuracy under shifting threat landscapes. This paper presents Edge-Prioritize IDS, a class-prioritized early-exit framework that accelerates inference for high-risk attack classes without post-deployment retraining. A lightweight K-dimensional control vector encodes per-class runtime priorities and steers samples toward earlier exits via adaptive normalization and cost-sensitive training. Evaluation across five benchmarks NSL-KDD, CIC-IDS2017, UNSW-NB15, WISDM, and CIFAR-10 on an NVIDIA Jetson TX2 shows that Edge-Prioritize IDS preserves baseline accuracy (up to 99.6%) while reducing latency by up to 55% and energy by up to 50% for prioritized classes. Ablation studies isolate each component's contribution, and a controlled distribution-shift experiment demonstrates the sliding-window heuristic's ability to recover near-baseline latency within 500 samples under synthetic class-frequency drift. Once trained under the proposed framework, the model requires no additional retraining, firmware updates, or additional memory beyond the priority vector itself when runtime priorities change. © 2026 by the authors.

EEG feature extraction and machine learning for consumer preference analysis of whisky

Item Type Journal Article

Author Z. Zeng

Author X. Liu

Author Y. Xu

Author K. Tang

Abstract Understanding consumer preference for food and beverages is central to product development, yet subjective self-reports alone often lack objectivity. Electroencephalography (EEG) can reveal implicit neural signals of preference. However, existing flavor studies utilizing EEG are mostly confined to group difference analysis, cannot identify stable preference-related EEG markers or achieve objective preference prediction. To address this gap, this study integrated sensory evaluation, systematic EEG feature extraction and machine learning to quantify and predict consumer whisky preference. Twenty-four panelists were tested with 12 whisky samples via 9-point hedonic and 5-point JAR scales. Time-domain and frequency-domain features were extracted from EEG recordings, and four classification models were trained to predict preference. Compared with the accuracy of models built on raw EEG data ($\approx 51\%$), feature extraction significantly boosted performance, with the Random Forest model achieving the highest test accuracy of 82.6%. Feature weight analysis further identified potentially predictive EEG indicators, including frontal α asymmetry and α band power. This work verifies the predictive capacity of EEG features for machine learning modeling, thereby establishing a neurophysiologically based method for the objective evaluation. This scheme complements traditional subjective sensory assessment and delivers actionable technical guidance for industrial flavor tuning and product development. However, the high homogeneity of participants in age and background limits the generalizability of our experimental results. © 2026 The Authors. Published by Elsevier B.V. EEG may serve as a biomarker in Huntington's disease using machine learning automatic classification

Item Type Journal Article**Author** O.F.F. Odish**Author** K. Johnsen**Author** P. van Someren**Author** R.A.C. Roos**Author** J.G. van Dijk

Abstract Reliable markers measuring disease progression in Huntington's disease (HD), before and after disease manifestation, may guide a therapy aimed at slowing or halting disease progression. Quantitative electroencephalography (qEEG) may provide a quantification method for possible (sub)cortical dysfunction occurring prior to or concomitant with motor or cognitive disturbances observed in HD. In this pilot study we construct an automatic classifier distinguishing healthy controls from HD gene carriers using qEEG and derive qEEG features that correlate with clinical markers

known to change with disease progression in HD, with the aim of exploring biomarker potential. We included twenty-six HD gene carriers (49.7 ± 8.5 years) and 25 healthy controls (52.7 ± 8.7 years). EEG was recorded for three minutes with subjects at rest. An EEG index was created by applying statistical pattern recognition to a large set of EEG features, which was subsequently tested using 10-fold cross-validation. The index resulted in a continuous variable ranging from 0 to 1: a low value indicating a state close to normal and a high value pointing to HD. qEEG features that correlate specifically with commonly used clinical markers in HD research were derived. The classification index had a specificity of 83%, a sensitivity of 83% and an accuracy of 83%. The area under the curve of the receiver operator characteristic curve was 0.9. qEEG analysis on subsets of electrophysiological features resulted in two highly significant correlations with clinical scores. The results of this pilot study suggest that qEEG may serve as a biomarker in HD. The indices correlating with modalities changing with the progression of the disease may lead to tools based on qEEG that help monitor efficacy in intervention studies. © 2018, The Author(s).

Abstract This paper proposes a method for classifying ElectroEncephaloGraphic (EEG) signals for Brain-Computer Interface (BCI). BCI is a system that allows people with disabilities to interact directly or indirectly with their environment only by using brain activity. In this study, we present a model for classifying EEG signals from five different mental activities (converse, read, watch video, rest and work). The method of signal acquisition is non-invasive, resulting in significant data loss and artifacts that must be reduced. In order to do this, a quantification method using Fast Fourier Transform (FFT) and Root Mean Square (RMS) for feature extraction are applied to improve the quality of the signal reception. We propose an approach to the neural network Self-Organizing Map (SOM) to classify these filtered signals. © 2018 IEEE.

EEG-based personalized digital experience**Item Type** Conference Paper**Author** O. Sourina**Author** Y. Liu**Author** Q. Wang**Author** M.K. Nguyen

Abstract To make human computer interfaces more immersive and intuitive, a new dimension could be added. Real-time brain state recognition from EEG including emotion recognition and level of concentration recognition would make an access to information more adaptive and personalized. Modern EEG techniques give us an easy and portable way to monitor brain activities by using suitable signal processing and classification methods and algorithms. We proposed a new subject-dependent fractal-based approach to brain state recognition and innovative applications based on EEG-enable user's interaction. The algorithms of the "inner" brain state quantification including emotion recognition would advance research on human computer interaction bringing the proposed novel objective quantification methods and algorithms as new tools in medical, entertainment, and even digital art methodology applications, and allowing us an integration of the brain state quantification algorithms in the human computer interfaces. In this paper, we describe our fractal-based approach to the brain state recognition and its EEG-enable applications such as serious games, emotional avatar, music therapy, music player, and storytelling. © 2011 Springer-Verlag.

EEG-based seizure prediction via hybrid vision transformer and data uncertainty learning

Item Type Journal Article

Author Z. Deng

Author C. Li

Author R. Song

Author X. Liu

Author R. Qian

Author X. Chen

Abstract Feature embeddings derived from continuous mapping using the deep neural network are critical for accurate classification in seizure prediction tasks. However, the embeddings of individual electroencephalogram (EEG) samples learned through modern decoding algorithms may contain ambiguous and noisy representations, owing to the susceptibility of weak EEG signals to interference from other signals unrelated to EEG activity. To address this issue, we consider data uncertainty learning (DUL), which models each representation of the EEG sample as a Gaussian or Laplacian distribution to mitigate potential noise interference and enhance model robustness. Moreover, data uncertainty learning for transformer architectures is seldom explored due to the limitation of multi-headed self-attention mechanisms in processing local features and the vanishing of potential top-level gradients. In this study, we introduce a novel hybrid visual transformer (HViT) architecture, which enhances the processing capability of localized features in the transformer through the convolutional neural network (CNN). Concretely, we learn the mean of the distribution using the HViT, and an additional branch is designed to capture the variance of the Gaussian distribution or the scale of the Laplacian distribution during training. We also propose a learnable manner to learn constraint coefficients in the loss functions for different patients, resulting in better optimization across patients. In addition, we introduce a simple uncertainty quantification method for each alarm of the k-of-n continuous prediction strategy by utilizing the continuity of the EEG signals. Empirical evaluations on two publicly available epilepsy datasets

demonstrate the superiority of our DUL method and the effectiveness of the proposed HViT architecture. © 2023 Elsevier Ltd

Abstract This study examines the effect of feature extraction methods prior to automated pattern recognition based on magnetic resonance spectroscopy (MRS) for brain tumor diagnosis. Since individual inspection of spectra is time-consuming and requires specific spectroscopic expertise, the introduction of clinical decision support systems (DSSs) is expected to strongly promote the clinical use of MRS. This study focuses on the feature extraction step in the preprocessing protocol of MRS when using a DSS. On two independent data sets, encompassing single-voxel and multi-voxel data, it is observed that the use of the full spectra together with a kernel-based technique, handling high dimensional data, or using an automated pattern recognition method based on independent component analysis or Relief-F achieves accurate performances. In addition, these approaches have low cost and are easy to automate. When sophisticated quantification methods are used in a DSS, user interaction should be minimized. The computationally intensive quantification techniques do not tend to increase the performance in these circumstances. The results suggest to simplify the feature reduction step in the pre-processing protocol when using a DSS purely for classification purposes. This can greatly speed up the execution of classifiers and DSSs and may accelerate their introduction into clinical practice. © 2008 Wiley-Liss, Inc.

Effect of separate sampling on classification accuracy

Item Type Journal Article

Author M. Shahrokh Esfahani

Author E.R. Dougherty

Abstract Motivation: Measurements are commonly taken from two phenotypes to build a classifier, where the number of data points from each class is predetermined, not random. In this 'separate sampling' scenario, the data cannot be used to estimate the class prior probabilities. Moreover, predetermined class sizes can severely degrade classifier performance, even for large samples. Results: We employ simulations using both synthetic and real data to show the detrimental effect of separate sampling on a variety of classification rules. We establish propositions related to the effect on the expected classifier error owing to a sampling ratio different from the population class ratio. From these we derive a sample-based minimax sampling ratio and provide an algorithm for approximating it from the data. We also extend to arbitrary distributions the classical population-based Anderson linear discriminant analysis minimax sampling ratio derived from the discriminant form of the Bayes classifier. © 2013 The Author.

Effect of separate sampling on classification and the minimax criterion

Item Type Conference Paper
Author M. Shahrokh Esfahani
Author E.R. Dougherty
Abstract It is commonplace in bioinformatics (and elsewhere) to build a classifier from sample data in which the sample sizes of the classes are not random; that is, they are selected prior to sampling. The result is that there is no estimate of the prior class probabilities available from the data. In this paper, we find an analytic result for the minimax solution for the class prior probabilities for a general Neyman-Pearson induced classifier. From that we derive Anderson's classical minimax prior probability 'estimate.' Using synthetic and real data, we demonstrate the degradation in classifier performance from using inaccurate values for the prior probabilities. © 2013 IEEE.

Effective Anomaly Detection Model Training with only Unlabeled Data by Weakly Supervised Learning Techniques

Item Type Conference Paper

Author W. Yang

Author K.-Y. Lam

Editor Gao D.

Editor Li Q.

Editor Guan X.

Editor Liao X.

Abstract Intrusion detection systems (IDS) play an important role in security monitoring to identify anomalous or suspicious activities. Traditional IDS could be signature-based (or rule-based) or anomaly-based (or analytics-based). With the objectives of detecting zero-day attacks, analytics-based IDS have attracted great interest of the cybersecurity community. Furthermore, machine learning (ML) techniques have been extensively explored for advancing analytics-based IDS. Many ML techniques have been studied to improve the efficiency of intrusion detection and some have shown good performance. However, traditional supervised learning algorithms need strong supervision information, fully correctly labeled (FCL) data, to train an accurate model. Whereas, with the rapid development of network and communication technologies, the volume of network traffic and system logs has increased drastically in recent years, especially with the introduction of Next Generation Broadband Network (NGBN) and 5G networks. This caused huge pressure on analytics-based IDS because, for ML to train predictive models, security-relevant data need to be labeled manually, hence leading to practical barriers to achieving effective IDS. In order to avoid being overly dependent on strong supervision information, weakly supervised learning techniques, which utilize incomplete, inexact, or possibly inaccurate labels, have been studied by cybersecurity researchers in that such weak supervision information are easier and cheaper to obtain than FCL data. This research aims to explore the feasibility of weakly supervised learning techniques in IDS tasks so as to reduce the reliance on a massive amount of strong supervision information, which will only continue to grow tremendously in the big data society. We also investigated the detection stability of the proposed scheme when inaccurate weak supervision information is provided. In this article, we propose an IDS model training scheme that is based on a weakly supervised learning algorithm, which requires only unlabeled data. Experiments have been performed on three publicly available IDS evaluation datasets. The results showed that the proposed scheme performs well and is even better than some supervised learning-based IDS (SL-IDS) models. Experimental results also indicated that the weakly supervised learning based IDS model is robust and can be applied in real world situations. Besides, we examined detection performance of the proposed method when it faces class-imbalanced training data and the experiment results show that it performs better than the

compared methods. © 2021, Springer Nature Switzerland AG.

Effective classification of the prevalence of *Schistosoma mansoni*

Item Type Journal Article

Author S.A. Mitchell

Author M. Pagano

Abstract Objective To present an effective classification method based on the prevalence of *Schistosoma mansoni* in the community. Methods We created decision rules (defined by cut-offs for number of positive slides), which account for imperfect sensitivity, both with a simple adjustment of fixed sensitivity and with a more complex adjustment of changing sensitivity with prevalence. To reduce screening costs while maintaining accuracy, we propose a pooled classification method. To estimate sensitivity, we use the De Vlas model for worm and egg distributions. We compare

the proposed method with the standard method to investigate differences in efficiency, measured by number of slides read, and accuracy, measured by probability of correct classification. Results Modelling varying sensitivity lowers the lower cut-off more significantly than the upper cut-off, correctly classifying regions as moderate rather than lower, thus receiving life-saving treatment. The classification method goes directly to classification on the basis of positive pools, avoiding having to know sensitivity to estimate prevalence. For model parameter values describing worm and egg distributions among children, the pooled method with 25 slides achieves an expected 89.9% probability of correct classification, whereas the standard method with 50 slides achieves 88.7%. Conclusions Among children, it is more efficient and more accurate to use the pooled method for classification of *S. mansoni* prevalence than the current standard method. © 2012 Blackwell Publishing Ltd.

Abstract Background: E-learning is a tool for enhancing knowledge which can potentially increase medical students' ability to learn and understand complex subjects. Objective: To assess the effectiveness of e-learning in increasing understanding of metabolic bone diseases by medical students during their orthopaedic rotation. Materials and Methods: A retrospective cohort study was conducted at the Department of Orthopaedics, Faculty of Medicine, Ramathibodi Hospital. Fifth-year medical students doing their rotation in the Orthopedics Department between August 2012 and July 2013 were enrolled in the study. All participants were instructed to study metabolic bone diseases using a lesson plan, handouts, and a textbook. They were also given the opportunity to volunteer to participate in an e-learning class prior to attending a one-hour case-based lecture. Students who missed the class were excluded from the present study. Baseline characteristics, in-class scores, multiple choice question [MCQ] grades, and orthopaedic grades of the participants were collected. Associations between study factors and outcomes were analyzed using multiple regression analysis. Results: A total of 154 medical students were included in the study. Their average age was 23 years, and 57% were female. Only 12 (8%) participated in the voluntary e-learning class. The e-learning group had higher in-class scores (9.00 ± 0.95) compared to the non e-learning group (7.70 ± 1.30) with p -value = 0.001. Cumulative GPA and participation in the voluntary e-learning class were factors included in the multiple regression analysis. After adjusting for cumulative GPA, attendance at the e-learning class was significantly associated with in-class scores (coefficient 1.20, 95% confidence interval 0.43, 1.96, p -value = 0.002). Participation in the e-learning class was not significantly correlated with either MCQ grades or orthopaedic grades. Conclusion: E-learning as an adjunct to traditional teaching methods can increase knowledge about metabolic bone disorders among medical students, but it does not affect either MCQ grades or orthopaedic grades. © 2018, Medical Association of Thailand. Efficiency of two-phase designs for prevalence estimation

Item Type Journal Article

Author R. McNamee

Abstract Background. Unbiased estimation of the prevalence of diseases and other conditions is important but can be expensive, especially for conditions which do not necessarily lead to contact with health services. A two-phase population survey may seem an attractive option when there is a relatively cheap, although fallible, test for disease status available: the test is used in the first phase of the survey but in the second, only a subsample are classified by the relatively expensive, gold standard. Previously the cost efficiency of such studies compared with simple, one-phase random sample designs was investigated empirically and some questions remain unclear. Methods. A simple formula for the maximum reduction in cost or standard error that can be achieved by two-phase sampling compared with simple random sampling is derived mathematically. A formula for the minimum reduction is also given and the influence of prevalence on efficiency explained. Results. The main result shows that the sensitivity and specificity of the first stage test set an absolute limit on the efficiency of two-phase designs; in particular, two-phase sampling can never be justified on efficiency grounds alone if the test is not accurate enough.

Efficient data integration under prior probability shift

Item Type Journal Article

Author M.-Y. Huang

Author J. Qin

Author C.-Y. Huang

Abstract Conventional supervised learning usually operates under the premise that data are collected from the same underlying population. However, challenges may arise when integrating new data from different populations, resulting in a phenomenon known as dataset shift. This paper focuses on prior probability shift, where the distribution of the outcome varies across datasets but the conditional distribution of features given

the outcome remains the same. To tackle the challenges posed by such shift, we propose an estimation algorithm that can efficiently combine information from multiple sources. Unlike existing methods that are restricted to discrete outcomes, the proposed approach accommodates both discrete and continuous outcomes. It also handles high-dimensional covariate vectors through variable selection using an adaptive least absolute shrinkage and selection operator penalty, producing efficient estimates that possess the oracle property. Moreover, a novel semiparametric likelihood ratio test is proposed to check the validity of prior probability shift assumptions by embedding the null conditional density function into Neyman's smooth alternatives (Neyman, 1937) and testing study-specific parameters. We demonstrate the effectiveness of our proposed method through extensive simulations and a real data example. The proposed methods serve as a useful addition to the repertoire of tools for dealing dataset shifts. © The Author(s) 2024. Efficient integration of generative topic models into discriminative classifiers using robust probabilistic kernels

Item Type Journal Article

Author K.E. Ihou

Author N. Bouguila

Author W. Bouachir

Abstract We propose an alternative to the generative classifier that usually models both the class conditionals and class priors separately, and then uses the Bayes theorem to compute the posterior distribution of classes given the training set as a decision boundary. Because SVM (support vector machine) is not a probabilistic framework, it is really difficult to implement a direct posterior distribution-based discriminative classifier. As SVM lacks in full Bayesian analysis, we propose a hybrid (generative–discriminative) technique where the generative topic features from a Bayesian learning are fed to the SVM. The standard latent Dirichlet allocation topic model with its Dirichlet (Dir) prior could be defined as Dir–Dir topic model to characterize the Dirichlet placed on the document and corpus parameters. With very flexible conjugate priors to the multinomials such as generalized Dirichlet (GD) and Beta-Liouville (BL) in our proposed approach, we define two new topic models: the BL–GD and GD–BL. We take advantage of the geometric interpretation of our generative topic (latent) models that associate a K-dimensional manifold (K is the size of the topics) embedded into a V-dimensional feature space (word simplex) where V is the vocabulary size. Under this structure, the low-dimensional topic simplex (the subspace) defines a document as a single point on its manifold and associates each document with a single probability. The SVM, with its kernel trick, performs on these document probabilities in classification where it utilizes the maximum margin learning approach as a decision boundary. The key note is that points or documents that are close to each other on the manifold must belong to the same class. Experimental results with text documents and images show the merits of the proposed framework. © 2020, Springer-Verlag London Ltd., part of Springer Nature.

Efficient Multimedia Frame-Skipping Architecture Using Deep Learning in Vehicular Networks

Item Type Journal Article

Author U. Ahmed

Author J.C.-W. Lin

Author G. Srivastava

Abstract With the development of 5G networks, vehicle-to-vehicle communication is helping to make travel safe. However, vehicle type detection in the multimedia feed remains a problem. This helps reduce processing time and enable more dynamic connectivity between different vehicles. The development of object classes requires more robust computer vision models and algorithms. However, the main difficulty still lies in image quality, which depends on the lighting conditions, viewing angle, and physical structure of the vehicles. This research mainly focuses on the development and deployment of a deep learning-based system for traffic congestion analysis. The model uses multiple video feeds and vehicle information to detect, classify, and count vehicles in the live traffic feed. The model is trained with a deep learning approach to align the video image and detect the object in top down multimedia. The dynamic skipping method helps to process a long video feed and accurately compares the video image with the viewer. The standard query for the vehicle can help in recognizing and creating the models in real-time traffic situations. The proposed model is suitable for many applications that require a specific area for monitoring real-time data analysis and multimedia routine tasks. © 2022 IEEE.

Efficient Non-stationary Online Learning by Wavelets with Applications to Online Distribution Shift Adaptation

Item Type Conference Paper**Author** Y.-Y. Qian**Author** P. Zhao**Author** Y.-J. Zhang**Author** M. Sugiyama**Author** Z.-H. Zhou**Editor** Salakhutdinov R.**Editor** Kolter Z.**Editor** Heller K.**Editor** Weller A.**Editor** Oliver N.**Editor** Scarlett J.**Editor** Berkenkamp F.

Abstract Dynamic regret minimization offers a principled way for non-stationary online learning, where the algorithm's performance is evaluated against changing comparators. Prevailing methods often employ a two-layer online ensemble, consisting of a group of base learners with different configurations and a meta learner that combines their outputs. Given the evident computational overhead associated with two-layer algorithms, this paper investigates how to attain optimal dynamic regret without deploying a model ensemble. To this end, we introduce the notion of underlying dynamic regret, a specific form of the general dynamic regret that can encompass many applications of interest. We show that almost optimal dynamic regret can be obtained using a single-layer model alone. This is achieved by an adaptive restart equipped with wavelet detection, wherein a novel streaming wavelet operator is introduced to online update the wavelet coefficients via a carefully designed binary indexed tree. We apply our method to

the online label shift adaptation problem, leading to new algorithms with optimal dynamic regret and significantly improved computation/storage efficiency compared to prior arts. Extensive experiments validate our proposal. Copyright 2024 by the author(s)

Abstract Recently, prototype learning has emerged in semi-supervised medical image segmentation and achieved remarkable performance. However, the scarcity of labeled data limits the expressiveness of prototypes in previous methods, potentially hindering the complete representation of prototypes for class embedding. To overcome this issue, we propose an efficient prototype consistency learning via joint uncertainty quantification and data augmentation (EPCL-JUDA) to enhance the semantic expression of prototypes based on the framework of Mean-Teacher. The concatenation of original and augmented labeled data is fed into student network to generate expressive prototypes. Then, a joint uncertainty quantification method is devised to optimize pseudo-labels and generate reliable prototypes for original and augmented unlabeled data separately. High-quality global prototypes for each class are formed by fusing labeled and unlabeled prototypes, which are utilized to generate prototype-to-features to conduct consistency learning. Notably, a prototype network is proposed to reduce high memory requirements brought by the introduction of augmented data. Extensive experiments on Left Atrium, Pancreas-NIH, Type B Aortic Dissection datasets demonstrate EPCL-JUDA's superiority over previous state-of-the-art approaches, confirming the effectiveness of our framework. The code will be released soon. © 2024 IEEE.

Author D. Tortorella

Abstract Network quantification (NQ) is the problem of estimating the proportions of nodes belonging to each class in subsets of unlabelled graph nodes. When prior probability shift is at play, this task cannot be effectively addressed by first classifying the nodes and then counting the class predictions. In addition, unlike non-relational quantification, NQ demands enhanced flexibility in order to capture a broad range of connectivity patterns, resilience to the challenge of heterophily, and scalability to large networks. In order to meet these stringent requirements, we introduce XNQ, a novel method that synergizes the flexibility and efficiency of the unsupervised node embeddings computed by randomized recursive Graph Neural Networks, with an Expectation-Maximization algorithm that provides a robust quantification-aware adjustment to the output probabilities of a calibrated node classifier. In an extensive evaluation, in which we also validate the design choices underpinning XNQ through comprehensive ablation experiments, we find that XNQ consistently and significantly improves on the best network quantification methods to date, thereby setting the new state of the art for this challenging task. XNQ also provides a training speed-up of up to 10x–100x over other methods based on graph learning. © The Author(s) 2025.

Efficient quantifying track structure cracks using deep learning

Item Type Journal Article

Author H. Sun

Author L. Song

Author Z. Yu

Abstract High-speed railway ballastless track structure crack detection usually has a high demand for the efficiency of crack detection technology. To overcome the limitation that current crack quantification methods usually require multiple steps, this paper proposes an efficient quantification method for track structure cracks using deep learning. This method applies the deep neural network (DNN) to the direct prediction of crack severity index values by modifying DNNs used for image classification. This method adopts a deep learning-based multi-step crack quantification method to calculate crack severity index values, establishes a dataset for predicting track structure interlayer crack severity index values using crack width mean values as labels, establishes a dataset for predicting track structure complex crack severity

index values using crack width mean values and crack area values as labels, and utilizes the established datasets to train the modified DNNs. This method crops the track structure panorama in spatial order to obtain images, which not only facilitates DNN prediction but also enables the acquisition of more information such as crack distribution. Under the condition of using the data enhancement method, the mean absolute errors (MAEs) of the prediction results of the trained DNNs under the corresponding testing sets are 0.0191 and 0.0183, and the prediction results are in good agreement with the reference values. The image processing rates of the trained DNNs under the corresponding testing sets are all close to 75 images per second (resolution 512×512), which are 8.57 and 13.93 times as computationally efficient as the adopted deep learning-based multi-step crack quantification method. © 2025 The Author(s). Abstract Despite rapid advances of modern artificial intelligence (AI), there is a growing concern regarding its capacity to be explainable, transparent, and accountable. One crucial step towards such AI systems involves reliable and efficient uncertainty quantification methods. Existing approaches to uncertainty quantification in natural language processing (NLP) take a Bayesian Deep Learning approach. However, the latter is known to not be computationally efficient in testing time, thus hindering its applicability in real-life scenarios. This paper proposes a new focus on the efficiency of uncertainty quantification methods, evaluating them on four multi-label text classification tasks. Our novel methods of representing epistemic and aleatoric uncertainties enable efficient uncertainty quantification (around 13 to 45 times faster than existing approaches, depending on architecture) with posterior analysis in the (approximated) latent- and data space. We conduct extensive experiments and studies on diverse neural network architectures (LSTM, CNN and Transformer) to analyse their power. Our results prove the benefits of explicitly modelling uncertainty in neural networks. © 2022 IEEE.

Abstract Video object classification is a fundamental task with broad applications such as anomaly detection in video streams and wildlife monitoring via camera traps. In practice, video classification is often decomposed into per-frame image classification. However, a major challenge arises from non-stationarity: class priors often vary over time, and a mismatch between training and test priors leads to performance degradation. Previous works have addressed this issue through runtime adaptation, where they exploit the temporal locality of the class occurrence and detect change points. One applies Bayesian filtering for adaptation against class prior change, while another pre-trains lightweight models under different priors and switches among them dynamically. Inspired by these approaches, we focus on class-balance changes over time. At a short timescale, class priors exhibit non-stationarity (e.g., different animals appear at different times of the day), while at a longer timescale, priors can show strong periodicity (e.g., seasonal animal activities). Unlike previous works based on change point detection, our approach leverages training data to predict priors in advance and dynamically adjusts the output of the original classifier at test time through a lightweight prior adaptation framework. Experiments on the wildlife ecological

dataset show that our prior adaptation effectively improves classification accuracy under time-dependent class-balance change. This lightweight and effective adaptation scheme is particularly suited to edge computing environments with constrained resources. © 2026 Copyright held by the owner/author(s).

Egocentric Online Action Segmentation via Evidential Temporal Contextualization

Item Type Journal Article

Author X. Jiang

Author X. Xu

Author Z. Han

Author Z. Wang

Author J. Song

Author H.T. Shen

Abstract The Egocentric Online Action Segmentation (EOAS) task aims to temporally segment a streaming egocentric video into a set of actions. Due to the first-person perspective views and online constraints, the EOAS task raised two intrinsic difficulties: (1) The shot movements could impact the egocentric vision and make it difficult to observe overall activities. (2) The visual signals are processed in real-time, requiring models to understand the observed visual frame without any post-contextual cues after the observed frame. To address these two problems, we proposed a novel EOAS approach named Evidential Temporal Contextualization (ETC), which consists of two key modules: (1) Context-Aggregated TRansformer that predicts and aggregates potential post context to enhance representation of frame-level features, effectively addressing the insufficient temporal contextualization in streaming videos. (2) Evidential Action Contextualization that leverages evidential deep learning to quantify the uncertainty in frame-level classification and dynamically adjust the model training and inference process accordingly. Extensive experiments on three public EOAS benchmark datasets, i.e., GTEA, EgoProceL, and EgoPER, demonstrate our proposed ETC approach outperforms recent state-of-the-art methods. Additionally, we also conduct more ablation studies and generalize our proposed ETC method to exocentric videos, furtherly prove its superiority. © 1999-2012 IEEE.

Author C.L.P. Chen

Abstract The broad learning system (BLS) is a shallow network architecture commonly adopted for classification and regression tasks. However, BLS and its variants struggle with imbalanced classification due to architectural redundancy from random feature projection and the lack of mechanisms for differentiating sample importance across classes, typically resulting in predictions biased toward majority classes. To overcome these challenges, we propose an elastic net-based cost-sensitive BLS with F-measure maximization and density harmonization (FDECBLs). This framework comprises two core innovations: (1) an elastic net regularization applied to singular values to mitigate redundancy and improve discriminative ability; (2) a dual-cost learning mechanism that combines a density-based cost scheme, which dynamically adjusts sample importance based on local neighborhood structures and global class imbalance information, with a penalty mechanism derived from F-measure maximization to impose class-specific costs for minority-class prioritization. The associated optimization problem is solved efficiently via the alternating direction method of multipliers, with theoretical convergence guarantees and empirically verified computational efficiency. Extensive experiments on 35 binary-class and 9 multi-class imbalanced datasets demonstrate the effectiveness and efficiency of FDECBLs. It attains leading average scores of 90.69% in F-measure, 92.77% in G-mean, and 93.24% in AUC on binary tasks, while consistently surpassing state-of-the-art baselines in multi-class settings. The code is available at <https://github.com/AdamMing/FDECBLs>. © 2026 Elsevier Ltd

Electrostatic and Capillary Force-Enhanced Dynamic SERS Combined with Machine Learning for Rapid Quantification of Structurally Similar Triazole Pesticides in Tobacco

Item Type Journal Article**Author** X. He**Author** S. Chao**Author** S. Zhou**Author** R. Zhao**Author** C. Valsecchi**Author** Y. Lin**Author** H. Yang**Author** M. Fan

Abstract Rapid and accurate detection of pesticide residues is crucial for safeguarding both environmental and human health. Nonetheless, the quantitative detection of structurally similar pesticides, which are frequently employed concurrently in agricultural practices to manage a range of pests and diseases, presents significant challenges. In this study, we introduced a methodology that integrates dynamic surface-enhanced Raman spectroscopy (D-SERS) with machine learning to quantify the binary mixtures of triadimenol and triadimefon. Initially, halogen-modified nanoparticles (Ag-Cl NPs) were synthesized to serve as SERS substrates, and the D-SERS method identified an optimal hot spot duration of approximately 60 s through the combined effects of electrostatic and capillary forces. The SERS spectra acquired

at this hot spot exhibited high stability (relative deviation < 9.67%), enabling sensitive detection, with limits of detection (LODs) of 74 ppb for triadimenol and 68 ppb for triadimefon. Using these spectra, a PCA-SVM model was developed and trained to accurately quantify both pesticides, individually and in mixtures, in tobacco samples. This integrated D-SERS and machine learning platform provides a rapid, sensitive, and reliable analytical method for the simultaneous quantification of structurally similar multicomponent pesticides, offering a promising solution for addressing pesticide residue issues in agricultural products. © 2025 American Chemical Society.

Abstract We study the domain adaptation problem with label shift in this work. Under the label shift context, the marginal distribution of the label varies across the training and testing datasets, while the conditional distribution of features given the label is the same. Traditional label shift adaptation methods either suffer from large estimation errors or require cumbersome post-prediction calibrations. To address these issues, we first propose a moment-matching framework for adapting the label shift based on the geometry of the influence function. Under such a framework, we propose a novel method named Efficient Label Shift Adaptation (ELSA), in which the adaptation weights can be estimated by solving linear systems. Theoretically, the ELSA estimator is $\sqrt{n}$ -consistent (n is the sample size of the source data) and asymptotically normal. Empirically, we show that ELSA can achieve state-of-the-art estimation performances without post-prediction calibrations, thus, gaining computational efficiency. © 2023 Proceedings of Machine Learning Research. Emissions Optimization Platform to Quantify and Reduce Rig-Based Emissions

Item Type Conference Paper

Author N. Minhas

Author S. Al Dakhil

Author S. Alsemail

Author J. Razzak

Author M. Jenkins

Abstract Reducing emissions at each step of the Oil & Gas Value chain is needed to help meet the global goal of keeping the temperature increase below 1.5C° of preindustrial level. This paper presents a method to calculate emissions and optimize operations to reduce emissions at the well planning stage. Three specific rigs were chosen and the data from their operations and the diesel consumption over the last 18 months (about 1 and a half years) was used to build a model that links specific operation on the rig with its associated emissions. Part of the data was used for model building while the rest was used for model verification. The energy consumption of each piece of equipment on the rig was also used in the calculations to document their wattage. An optimization tool is developed to help optimize rig operations for emissions reduction by choosing the proper rig and the rest of the equipment. The diesel usage data was lower resolution (one data points per day) compared to the operations (hourly). So, the model development was particularly challenging. It was found that there is considerable room for energy optimization especially with regards to the use of diesel generators. A considerable amount of excess energy is produced which gets wasted. Also, the cementing and casing has the greatest impact on the emissions as both materials emit a huge amount of carbon. Optimization of the emissions on the well planning stage is much more effective than emission reduction strategies post planning as the room for optimization is significantly less. Our approach is based on state-of-the-art deep reinforcement learning (DRL) and data science techniques that have been proven to work on complex systems that have different inputs. DRL trains an algorithm with a reward system that supplies positive and negative feedback (degree of emissions) to an Artificial Intelligence (AI) agent for performing actions. These actions are the various strategies in rig operations the agent takes to reduce emissions, the lower the emissions the higher the rewards for the agent. In iterative process the agent narrows down the best policy (plan) for each rig that lowers the emission. The use of data science and machine learning in well planning for emissions reduction is a novel approach with expert feedback being constant in our methods. Using DRL (deep reinforcement learning) to quantify emissions in well planning is a revolutionary technique. It is the first time in the industry that DRL is being used to assist in emissions

reductions from upstream activities. We bring technology that has redefined the capabilities of AI in a variety of applications, including reservoir optimization and complex decision-making systems. © 2023, Society of Petroleum Engineers.

Author X. Lin

Abstract The steady overexploitation of the Ogallala Aquifer underlying the U.S. High Plains Region has put irrigated crop production at risk, particularly in the Southern and Central High Plains. To manage this issue properly, a data-driven modeling framework is developed and tested that is fast to employ and yet provides reliable

long-term groundwater level (GWL) forecasts as a function of climatological and anthropogenic factors. The modeling framework uses the random forests (RF) technique in combination with ordinary kriging, and is tested in Finney County in southwest Kansas. The introduction of groundwater withdrawal potential as a new surrogate for pumping intensity enables the RF model to capture decline in groundwater depletion rate as the system progresses towards aquifer depletion and/or as a result of well retirement policies. The RF model is executed from 2017 to 2099 for 20 different downscaled global climate models (GCMs) for the two representative concentration pathways (RCP) scenarios of 4.5 and 8.5. The results show the aquifer will cease to support irrigated agriculture in most of the county by 2060 under status quo management and average climate conditions. Moreover, climate will likely shift the aquifer's depletion time frame by 15 years or less in most of the study area. The long-term combined impact of well retirement plans and climate conditions on groundwater depletion trends imply well retirement policies do not lead to sustained groundwater savings. This study demonstrates the capacity of machine learning models to serve as a rapid assessment tool, informing policymakers about future groundwater availability in intensively irrigated regions and under different climate and management conditions. © 2022 Elsevier B.V.

End-To-End Uncertainty Quantification with Analytical Derivatives for Design Under Uncertainty

Item Type Conference Paper

Author B.D. Phillips

Author J. Schmidt

Author R.D. Falck

Author D. Aretskin-Hariton

Abstract Uncertainty quantification (UQ) is a rapidly growing and evolving discipline, especially within the aerospace community. Performing analysis with UQ can provide decision makers with a wealth of information about a candidate design. However, the value of UQ is fully realized when the information gained during UQ analysis is leveraged in a feedback loop of a design optimization process, often referred to as design under uncertainty. Although design under uncertainty can be a powerful risk mitigation technique, there are a number of roadblocks that prevent its implementation. Two primary factors are computational costs and added complexity of the analysis. High fidelity simulations having on the order of tens of uncertain variables quickly become computationally infeasible. Also, implementing UQ into an existing multidisciplinary design and optimization (MDO) process often requires extensive knowledge of the UQ methods and careful treatment of the problem formulation. The objective of this work is to address these two primary roadblocks and enable practitioners to efficiently perform design under uncertainty with limited knowledge of the UQ discipline. Methods outlined in this paper demonstrate MDO incorporating UQ into the design process, leveraging an analytical derivative tool chain through the entire optimization. The proposed approach leverages machine learning techniques to generate a differentiable confidence interval output from polynomial chaos models. This technique, coupled with the incorporation of analytical derivatives through the Polynomial Chaos Expansion (PCE) process, eliminates the need to estimate derivatives, which are usually obtained from finite difference, complex step, or similar methods. Developing a differentiable confidence interval allows mixed uncertainty problems (both epistemic and aleatory) to be modeled. Without such modeling, these problems cannot accurately predict objective functions containing statistical quantities such as mean and variance. The addition of analytical derivatives to a UQ method based on polynomial chaos can decrease the computational costs of performing design under uncertainty by orders of magnitude in comparison with methods such as complex step. The method and codes developed are modular in nature and are a drop-in solution for design under uncertainty within existing MDO problems. Low-fidelity analytical multidisciplinary optimizations under uncertainty for a wing design in OpenMDAO are detailed in this paper. These demonstration cases includes both objective functions and constraints which are influenced by uncertain parameters. Results show an 87.7% reduction in computational costs compared to current methods. Comparison of deterministic and uncertain designs shows significant improvement for the quantity of interest when the optimizer is given information about the uncertain space. © 2024, American Institute of Aeronautics and Astronautics Inc, AIAA. Enhanced classification based on probabilistic extreme learning machine in wastewater treatment process

Item Type Conference Paper

Author L.J. Zhao

Author X.K. Diao

Author D.C. Yuan

Author W. Tang

Abstract A binary classification method, Probabilistic Extreme Learning Machine (called P-ELM), is proposed to enhance the reliability of the classification of an unknown object. P-ELM method integrates ELM, density methods and Bayesian decision theory in order to take into account a priori probability of the process and the uncertainty of the ELM predictions. The P-ELM algorithm may inhibit uncertainty of the extreme learning machine prediction in the different trials of simulation due to the initialization of input weights and bias, which would damage the reliability of the classification for the new objects. Simulations results from a municipal wastewater treatment plant show that the proposed P-ELM binary classification method can provide the reliability of the classification for those samples near the boundaries of the classes and the reliability and accuracy outperform the ELM model. © 2011 Published by Elsevier Ltd.

Abstract Predicting the performance degradation of composite materials is of paramount importance for ensuring the safe operation of composite engineering structures. Traditional experimental methods involve protracted, costly accelerated ageing tests, while theoretical methods also subject to their own inherent limitations. Physics-based methods face parameter-tuning difficulties and incomplete degradation descriptions, while data-driven approaches are data-dependent and may have low accuracy. To overcome these challenges, this paper presents an innovative methodology that integrates interval degradation progress models with Bi-LSTM (Bidirectional Long Short-Term Memory) neural networks to enhance prediction performance. Specifically, the Grey System Theory (GST) is employed to quantify the interval process. By combining GST with physical information, a novel quantification method for the interval degradation process model is proposed. This model serves as a reference framework, enabling the mapping of experimental degradation data. The Bi-LSTM network then harnesses this nonlinear mapping to forecast the degradation trajectory of composite materials, leveraging its powerful sequential learning capabilities. The accuracy of the proposed method is verified using two different experimental datasets: stiffness degradation under hygrothermal conditions and fatigue damage under cyclic stress. The results clearly demonstrate that this fusion approach outperforms existing methods in terms of predictive accuracy, indicating its great potential for practical applications in the field of composite material performance degradation prediction. © 2026 Elsevier Ltd.

Enhanced fuzzy Gaussian networks for sputum image based Mycobacterium detection

Item Type Journal Article

Author K.S. Mithra

Abstract The primary step involved in the diagnosis of Mycobacterium tuberculosis is the Sputum Smear Microscopy. The limitations of manual detection can be avoided with an automated technique which is carried out in this study. This paper uses the Enhanced Fuzzy Gaussian Networks (EFGN) for the detection of TB, by integrating the Gaussian model with the fuzzy and the neural network. In EFGN, the classified output obtained from the enhanced fuzzy and neural network is combined together depending on the Gaussian mixture model. The sputum smear microscopic image acts as the input, to which the process of thresholding is imposed to get the segmented result. Local Gradient Pattern (LGP), length, density, area, and histogram features are utilized to classify and count the bacilli objects using EFGN classifier. The performance is estimated based on the factors, such as Segmentation Accuracy (SA), and Mean Squared Error (MSE). © 2023 The Royal Photographic Society.

Enhanced probabilistic classify and count methods for multi-label text quantification

Item Type Conference Paper

Author R. Levin

Author H. Roitman

Abstract In this work we address the problem of Multi-Label Text Quantification. To this end, for a given collection of documents, each was pre-classified with one or more labels by some multi-label classifier, our goal is to find an estimate of the cardinality of each actual label set, as accurate as possible. We present two enhanced Probabilistic Classify and Count (PCC) methods that focus on improving the quantification accuracy by employing another supervised learning phase. Using a real-world multi-label documents dataset, we report on an experimental evaluation that compares the estimated label counts produced by our solution (and several alternatives) to the actual label counts derived from labels assigned by human experts. Our results confirm that, using our solution, the quantification accuracy can be significantly improved. © 2017 Copyright held by the owner/author(s).

Enhancement Technique Based on the Breast Density Level for Mammogram for Computer-Aided Diagnosis

Item Type Journal Article**Author** N.F. Razali**Author** I.S. Isa**Author** S.N. Sulaiman**Author** N.K. Abdul Karim**Author** M.K. Osman**Author** Z.H. Che Soh

Abstract Mass detection in mammograms has a limited approach to the presence of a mass in overlapping denser fibroglandular breast regions. In addition, various breast density levels could decrease the learning system's ability to extract sufficient feature descriptors and may result in lower accuracy performance. Therefore, this study is proposing a textural-based image enhancement technique named Spatial-based Breast Density Enhancement for Mass Detection (SbBDEM) to boost textural features of the overlapped mass region based on the breast density level. This approach determines the optimal exposure threshold of the images' lower contrast limit and optimizes the parameters by selecting the best intensity factor guided by the best Blind/Reference-less Image Spatial Quality Evaluator (BRISQUE) scores separately for both dense and non-dense breast classes prior to training. Meanwhile, a modified You Only Look Once v3 (YOLOv3) architecture is employed for mass detection by specifically assigning an extra number of higher-valued anchor boxes to the shallower detection head using the enhanced image. The experimental results show that the use of SbBDEM prior to training mass detection promotes superior performance with an increase in mean Average Precision (mAP) of 17.24% improvement over the non-enhanced trained image for mass detection, mass segmentation of 94.41% accuracy, and 96% accuracy for benign and malignant mass classification. Enhancing the mammogram images based on breast density is proven to increase the overall system's performance and can aid in an improved clinical diagnosis process. © 2023 by the authors.

Enhancements of Pass Play Quantification Method with Geometric Features of Formations

Item Type Conference Paper**Author** T. Mimura**Author** Y. Nakada

Abstract In the last two decades, the practical use of player position data has attracted a great deal of attention for analyzing and visualizing plays and tactics in many team sports including soccer, American football, basketball, and rugby. With this background, we proposed a machine learning-based method to quantify pass plays via multiple geometric feature values of formations computed from player position data. This method was successfully applied against a real soccer dataset, but there has still been room for enhancement. In this study, we propose two enhancements of the pass play quantification method to overcome its limitations. The first enhancement is an improvement in modeling by adding pass play feature values as inputs. The improved models are also validated by using a larger real soccer dataset than in our previous work. The second enhancement is related to the visualization for quantification results of the effectiveness and risk for potential pass plays from the detected ball possessor. This visualization is also applied to a real soccer dataset using our visualization tool. © 2022 IEEE.

Enhancing amide proton transfer imaging in ischemic stroke using a machine learning approach with partially synthetic data

Item Type Journal Article**Author** M. Viswanathan**Author** L. Yin**Author** Y. Kurmi**Author** A. Afzal**Author** Z. Zu

Abstract Amide proton transfer (APT) imaging, a technique sensitive to tissue pH, holds promise in the diagnosis of ischemic stroke. Achieving accurate and rapid APT imaging is crucial for this application. However, conventional APT quantification methods either lack accuracy or are time-consuming. Machine learning (ML) has recently been recognized as a potential solution to improve APT quantification. In this paper, we applied an ML model trained on a new type of partially synthetic data,

along with an optimization approach utilizing recursive feature elimination, to predict APT imaging in an animal stroke model. This partially synthetic datum is not a simple blend of measured and simulated chemical exchange saturation transfer (CEST) signals. Rather, it integrates the underlying components including all CEST, direct water saturation, and magnetization transfer effects partly derived from measurements and simulations to reconstruct the CEST signals using an inverse summation relationship. Training with partially synthetic data requires less in vivo data compared to training entirely with fully synthetic or in vivo data, making it a more practical approach. Since this type of data closely resembles real tissue, it leads to more accurate predictions than ML models trained on fully synthetic data. Results indicate that an ML model trained on this partially synthetic data can successfully predict the APT effect with enhanced accuracy, providing significant contrast between stroke lesions and normal tissues, thus clearly delineating lesions. In contrast, conventional quantification methods such as the asymmetric analysis method, three-point method, and multiple-pool model Lorentzian fit showed inadequate accuracy in quantifying the APT effect. Moreover, ML methods trained using in vivo data and fully synthetic data exhibited poor predictive performance due to insufficient training data and inaccurate simulation pool settings or parameter ranges, respectively. Following optimization, only 13 frequency offsets were selected from the initial 69, resulting in significantly reduced scan time. © 2024 The Author(s). Enhancing Anomaly Alert Prioritization Through Calibrated Standard Deviation Uncertainty Estimation With an Ensemble of Auto-Encoders

Item Type Journal Article

Author J.F. Masakuna

Author F. Kabanza

Abstract Deep auto-encoders (AEs) are widely employed deep learning methods in the field of anomaly detection across diverse domains (e.g., cybersecurity analysts managing large volumes of alerts, or medical practitioners monitoring irregular patient signals). In such contexts, practitioners often face challenges of scale and limited processing resources. To cope, strategies such as false positive reduction, human-in-the-loop review, and alert prioritization are commonly adopted. This paper explores the integration of uncertainty quantification (UQ) methods into alert prioritization for anomaly detection using ensembles of AEs. UQ models highlight doubtful classification decisions, enabling analysts to address the most certain alerts first, since higher certainty typically correlates with greater accuracy. Our study reveals a nuanced issue where applying UQ to ensembles of AEs can produce skewed distributions of large reconstruction errors (errors exceeding a pre-defined threshold), which may falsely suggest high uncertainty when standard deviation is used as the

metric. Conventionally, a high standard deviation indicates high uncertainty. However, contrary to intuition, large reconstruction errors often reflect AE is strongly confident that an input is anomalous—not uncertainty about it. Moreover, ensembles of AEs generate reconstruction errors with varying ranges, complicating interpretation. To address this, we propose an extension that calibrates the standard deviation distribution of uncertainties, mitigating erroneous prioritization. Evaluation on 10 benchmark datasets demonstrates that our calibration approach improves the effectiveness of UQ methods in prioritizing alerts, while maintaining favorable trade-offs across other key performance metrics. © 2004-2012 IEEE.

Enhancing decision support in crop production: Analyzing conformal prediction for uncertainty quantification

Item Type Journal Article

Author M. Farag

Author A. Emam

Author J. Leonhardt

Author R. Roscher

Abstract Assessing the confidence of machine learning models is increasingly important for enhancing decision support in digital agriculture. Addressing this challenge involves identifying and classifying sources of uncertainty and applying a suitable quantification method. To fully realize the potential of uncertainty quantification in digital agriculture, it is necessary to explore and evaluate different techniques, demonstrating their effectiveness in diverse scenarios. In this paper, we focus on the conformal prediction (CP) framework, specifically inductive conformal prediction (ICP), as a non-parametric tool for uncertainty quantification. Conformal prediction has gained a foothold for its multiple advantages, including being model-agnostic – requiring no retraining or changes to model architecture – and computationally efficient. Moreover, CP operates under a distribution-free framework, making no assumptions about the data, and provides calibrated uncertainty estimates where empirical errors match pre-defined theoretical levels. These properties make it particularly well-suited for agricultural tasks, where datasets often exhibit variability across regions and lack reliable ground truth labels. Through ablation studies, we comprehensively analyze ICP's performance as a post-hoc approach for ResNet-18 and ViT-B/16, demonstrating that both achieve the required pre-defined error levels. We compare ICP performance against other methods in diverse agricultural tasks, including out-of-distribution detection and covariate shift. Our experiments highlight CP's unique benefits, such as validity, efficiency, and low computational overhead, making it a promising approach for developing more reliable agricultural machine learning systems. © 2025 The Authors

Enhancing Email Security Through Accurate Phishing Detection Using Deep Transformer Models

Item Type Conference Paper

Author S. Irfan

Editor Kumar R.

Editor Kumar R.

Editor Gupta M.

Editor Gupta M.

Abstract Phishing is also a significant issue in cybersecurity, and it needs innovative solutions to make it detected and prevented instantly. The development of email protection infrastructure with the help of ML and DL algorithms has taken the lead in combating phishing. This paper proposes an effective phishing email detecting system based on the DistilBERT-base-uncased model, which is a more computationally efficient version of BERT, yet highly accurate. The Kaggle phishing email data set has undergone several operations including cleaning, one-hot encoding and TF-IDF vectorization and feature scaling. The data was balanced to address the imbalance of classes prior to the model training. The proposed model has already shown important results with a testing accuracy of 98.45, precision of 97.67, recall of 100 and F1score of 98.61, which are superior to already available traditional ML (DT, NB, LR, RF, AdaBoost, NB+KNN) and DL (CNN, LSTM, NN, MLP, RoBERTA) models. These findings indicate that the model is highly contextual, generalizable, and resistant to phishing detection errors. The research reveals that a lightweight transformer is able to offer optimum performance in regards to accuracy and also is power efficient thereby making possibility of scalable and real-time e-mail security solutions. © 2026 IEEE.

Author F. Herrera

Abstract Classification problems with multiple classes suppose a challenge in Data Mining tasks. There is a difficulty inherent to the learning process when trying to find the most adequate discrimination functions among the different concepts within the dataset. Using Fuzzy Rule Based Classification Systems in general, and Evolutionary Fuzzy Systems in particular, provide the advantage of describing smoother borderline areas, thanks to the linguistic label-based representation. In multi-classification, the pairwise learning approach (One-vs-One) has gained a notorious attention. However, there is certain dependence between the goodness of the confidence degrees or scores of binary classifiers, and the final performance shown by the global model. Regarding this fact, the problem of non-competent classifiers is of special relevance. It occurs when a binary classifier outputs a positive score for a couple of classes unrelated with the input example, which may degrade the final accuracy. Precisely, the previously exposed properties of fuzzy classifiers make them more prone to the former condition. In this paper, we propose an extension of the distance-based combination strategy to overcome this non-competence problem. It is based on the truncation of

the confidence degrees of the classes prior to the distance-based tuning. This allows taking advantage of the good classification abilities of Evolutionary Fuzzy Systems, while diminishing the adverse effect of the aforementioned non-competence. Experimental results, using FARC-HD with overlap functions as the fuzzy learning algorithm, show that this new adaptation of the Distance-based Relative Competence Weighting model outperforms both the OVO and standard distance-based approaches, and it is competitive with robust classifiers such as Support Vector Machines. © 2016 Elsevier Inc. Abstract Accurate quantification and detailed classification of construction waste are paramount to improving their management. Over the last decades, various quantification models have been developed to measure, manage, and report construction waste generation. A detailed understanding of those models is essential to explore their applications across the life-cycle stages of a built asset. Existing reviews primarily focused on analysing the functions of quantification methodologies, but the digital and information standards to automate the quantification process are under-explored in the existing literature. A review is adopted to analyse papers published from 2012 to 2022. Out of 279 articles retrieved, 71 papers meeting the eligibility criteria were included. A critical analysis of the models indicates that unified data structure, standard information, life-cycle approach and interoperability between the BIM and waste knowledge bases are vital to automate and reinforce the quantification efficiency. Based on the review findings, a conceptual framework is developed to demonstrate the quantification workflow for building projects. The outcomes from the review will facilitate researchers to identify the prevailing gaps and enhance the waste quantification system to meet digital construction demands. © 2023

Editor Kolter Z.

Abstract Instruction tuning has emerged as an effective approach that notably improves large language models (LLMs) performance, showing particular promise in natural language generation tasks by producing more diverse, coherent, and task-relevant outputs. However, extending instruction tuning to natural language understanding (NLU) tasks presents significant challenges, primarily due to the difficulty in achieving high-precision responses and the scarcity of large-scale, high-quality instruction data necessary for effective tuning. In this work, we introduce Adversarial Noisy Instruction Tuning (ANIT) to improve NLU performance on LLMs. First, we leverage low-resource techniques to construct noisy instruction datasets. Second, we employ semantic distortion-aware techniques to quantify the intensity of noise within these instructions. Last, we devise an adversarial training method that incorporates a noise response strategy to achieve noisy instruction tuning. ANIT enhances LLMs capability to detect and accommodate semantic distortions in noisy instructions, thereby augmenting their comprehension of task objectives and ability to generate more accurate responses. We evaluate our approach across diverse noisy instructions and semantic distortion quantification methods on multiple NLU tasks. Comprehensive empirical results demonstrate that our method consistently outperforms existing approaches across various experimental settings. Abstract Reliable classification of heartbeat sounds is crucial for computer-aided diagnosis in cardiology. This paper presents a deep learning-based framework enhanced with Monte Carlo Dropout (MCD) to estimate predictive uncertainty - an oftenoverlooked aspect in medical AI systems. We evaluate three Convolutional Neural Network (CNN) architectures: a custom Swish-activated CNN, a Two-Stream CNN combining MFCC and Mel-spectrogram features, and a Two-Stream FractalNet. While the Swish CNN attained the highest classification accuracy 85.00%, the Two-Stream CNN demonstrated the most favorable uncertainty profile, with lower predictive entropy and better calibration. These results highlight the importance of not only achieving high accuracy but also understanding model confidence, especially in clinical decision-making scenarios. The use of Monte Carlo Dropout provides deeper insight into model behavior, making it a valuable tool for enhancing the safety and reliability of diagnostic systems. Future work will focus on expanding the dataset, integrating advanced uncertainty quantification methods, and enabling real-time deployment in medical settings. © 2025 IEEE.

Enhancing the Discriminative Ability for Multi-Label Classification by Handling Data Imbalance

Item Type Conference Paper

Author J.-H. Lim

Author M.-S. Oh

Author S.-W. Lee

Abstract In computer vision, long-tailed multi-label visual recognition is a challenging problem due to the imbalance between classes and the recognition of rare classes. Previous methods for resolving data imbalance mostly originate from single-label classification, which can be obstructed by the label co-occurrence issue, and they attempt to minimize or compensate for it. In this paper, we propose a novel tail class priority sampling method for long-tailed multi-label classification that untangles both issues. Our method samples tail class more often and earlier in order to make the model learn tail classes before it has bias toward common classes. Due to label co-occurrence, other classes will be spontaneously learned in same iteration, ensuring a balanced representation of the head and medium classes. To further enhance the recognition performance, we modify to a bilateral structure that samples both original and proposed sampling distribution to better

represent the tail classes. We evaluate our proposed method on two widely used datasets in long-tailed version, COCO-LT and VOC-LT, and compare it with previous methods. The experimental results show that our method achieves a new state-of-the-art performance for tail classes on both datasets. Our method is applicable in various real-world scenarios, making rare class recognition achievable, and can be easily incorporated into conventional recognition frameworks. © 2023 IEEE.

Abstract Retinal vessel segmentation, skeletonization, and the generation of vessel segments are considered significant steps in any automated system for measuring the vessel biomarkers of several disease diagnoses. Most of the current tortuosity quantification methods rely on precise vascular segmentation and skeletonization of the retinal vessels. Additionally, the existence of a reference dataset for accurate vessel segment images is an essential need for implementing deep learning solutions and an automated system for measuring the vessel biomarkers of several disease diagnoses, especially for optimized quantification of vessel tortuosity or accurate measurement of AV-nicking. This study aimed to present an improved method for skeletonizing and extracting the retinal vessel segments from the 504 images in the AV classification dataset. The study utilized the Six Sigma process capability index, sigma level, and yield to measure the vessels' tortuosity calculation improvement before and after optimizing the extracted vessels. As a result, the study showed that the sigma level for the vessel segment optimization improved from 2.7 to 4.39, the confirming yield improved from 88 percent to 99.77 percent, and the optimized vessel segments of the AV classification dataset retinal images are available in monochrome and colored formats. © 2023 by the authors.

Ensemble learning head-neck motion predictor with validation and application in cybersickness evaluation

Item Type Journal Article

Author F. Mo

Abstract Despite growing concerns over cybersickness (CS) in virtual reality (VR) systems, effective methods for quantifying CS and evaluating VR scene comfort remain lacking. This study provided and validated a bio-inspired ensemble learning head-neck motion predictor (HMP) that simulated the human neurosensory-motor control loop through coordinating machine learning models. Building upon the HMP outputs, we developed and evaluated a cybersickness index (CSI) quantification method for VR scenes comfort assessment based on head-neck motion. Using motion data collected from thirty participants exposed to five representative VR scenes, the HMP was trained and evaluated with a subject-independent validation strategy to prevent participant data leakage, achieving a mean absolute error of 1.43 ± 0.59 (dimensionless average of angular and linear errors). CSI quantification effectively stratified scene discomfort levels, with VR scene 1 ($CSI = 3.47 \pm 0.82$) inducing severe symptoms, in stark contrast to the optimal comfort offered by VR scene 5 ($CSI = 0.36 \pm 0.15$). Crucially, spectral analysis identified 0.35 Hz as a biomechanical threshold, where sustained body sway frequencies above this value exponentially increased CS severity. Furthermore, the derived CS risk curve established quantitative design guidelines, proposing $CSI < 2.49$ as a safety benchmark for nausea prevention. While these thresholds were empirically obtained from the tested participant group and VR content set, they serve as foundational references that can inform future validation and generalization efforts. Overall, the proposed framework provides a practical and scalable pathway for mitigating CS and enhancing human-machine interaction performance in VR systems. © 2026 Elsevier Ltd.

Ensemble Multi-Quantiles: Adaptively Flexible Distribution Prediction for Uncertainty Quantification

Item Type Journal Article

Author X. Yan

Author Y. Su

Author W. Ma

Abstract We propose a novel, succinct, and effective approach for distribution prediction to quantify uncertainty in machine learning. It incorporates adaptively flexible distribution prediction of $P(y|X=x)P(y|X=x)$ in regression tasks. This conditional distribution's quantiles of probability levels spreading the interval $(0,1)$ are boosted by additive models which are designed by us with intuitions and interpretability. We seek an adaptive balance between the structural integrity and the flexibility for $P(y|X=x)P(y|X=x)$, while Gaussian assumption results in a lack of flexibility for real data and highly flexible approaches (e.g., estimating the quantiles separately without a distribution structure) inevitably have drawbacks and may not lead to good generalization. This ensemble multi-quantiles approach called EMQ proposed by us is totally data-driven, and can gradually depart from Gaussian and discover the optimal conditional distribution in the boosting. On extensive regression tasks from UCI datasets, we show that EMQ achieves state-of-the-art performance comparing to many recent uncertainty quantification methods. Visualization results further illustrate the necessity and the merits of such an ensemble model. © 1979-2012 IEEE.

Abstract Quantification is a supervised Machine Learning task that estimates the class distribution in an unlabeled test set. Quantification has practical applications in various fields, including medical research, environmental monitoring, and quality control. For instance, medical research often estimates the prevalence of a particular disease in a population. Despite being a thriving research area, most existing quantification methods are limited to binary-class problems. Moreover, recent experimental evidence suggests that modern state-of-the-art quantifiers do not perform well for multi-class problems, which are prevalent in quantification. This paper proposes two novel multi-class ensemble quantifiers, FMC-SQ and FMC-MQ, that use data fusion methods at the classifier and quantifier levels. We conducted experiments with 12 state-of-the-art (single and ensemble) quantifiers

to evaluate our models on 31 multi-class datasets. Our experimental results indicate that FMC-MQ is the best-performing quantifier outperforming other single and ensemble methods. Also, aggregating quantifier outputs seem to be a more promising research direction than aggregating classification scores for quantification. © 2023, The Author(s), under exclusive license to Springer Nature Switzerland AG.

Ensembles of α -trees for imbalanced classification problems

Item Type Journal Article

Author Y. Park

Author J. Ghosh

Abstract This paper introduces two kinds of decision tree ensembles for imbalanced classification problems, extensively utilizing properties of α -divergence. First, a novel splitting criterion based on α -divergence is shown to generalize several well-known splitting criteria such as those used in C4.5 and CART. When the α -divergence splitting criterion is applied to imbalanced data, one can obtain decision trees that tend to be less correlated (α -diversification) by varying the value of α . This increased diversity in an ensemble of such trees improves AUROC values across a range of minority class priors. The second ensemble uses the same alpha trees as base classifiers, but uses a lift-aware stopping criterion during tree growth. The resultant ensemble produces a set of interpretable rules that provide higher lift values for a given coverage, a property that is much desirable in applications such as direct marketing. Experimental results across many class-imbalanced data sets, including BRFS, and MIMIC data sets from the medical community and several sets from UCI and KEEL are provided to highlight the effectiveness of the proposed ensembles over a wide range of data distributions and of class imbalance. © 1989-2012 IEEE.

Ensuring Fairness under Prior Probability Shifts

Item Type Conference Paper

Author A. Biswas

Author S. Mukherjee

Abstract Prior probability shift is a phenomenon where the training and test datasets differ structurally within population subgroups. This phenomenon can be observed in the yearly records of several real-world datasets, for example, recidivism records and medical expenditure surveys. If unaccounted for, such shifts can cause the predictions of a classifier to become unfair towards specific population subgroups. While the fairness notion called Proportional Equality (PE) accounts for such shifts, a procedure to ensure PE-fairness was unknown. In this work, we design an algorithm, called CAPE, that ensures fair classification under such shifts. We introduce a metric, called prevalence difference, which CAPE attempts to minimize in order to achieve fairness under prior probability shifts. We theoretically establish that this metric exhibits several properties that are desirable for a fair classifier. We evaluate the efficacy of CAPE via a thorough empirical evaluation on synthetic datasets. We also compare the performance of CAPE with several state-of-the-art fair classifiers on real-world datasets like COMPAS (criminal risk assessment) and MEPS (medical expenditure panel survey). The results indicate that CAPE ensures a high degree of PE-fairness in its predictions, while performing well on other important metrics. © 2021 ACM.

Epidemiology of multiple childhood traumatic events: Child abuse, parental psychopathology, and other family-level stressors

Item Type Journal Article

Author C. Menard

Author K.J. Bandeen-Roche

Author H.D. Chilcoat

Abstract Background: Multiple family-level childhood stressors are common and are correlated. It is unknown if clusters of commonly co-occurring stressors are identifiable. The study was designed to explore family-level stressor clustering in the general population, to estimate the prevalence of exposure classes, and to examine the correlation of sociodemographic characteristics with class prevalence. Method: Data were collected from an epidemiological sample and analyzed using latent class regression. Results: A six-class solution was identified. Classes were characterized by low risk (prevalence = 23%), universal high risk (7 %), family conflict (11 %), household substance problems (22 %), non-nuclear family structure (24 %), parent's mental illness (13 %). Conclusions: Class prevalence varied with race and welfare status, not gender. Interventions for childhood stressors are person-focused; the analytic approach may uniquely inform resource allocation. © Steinkopff Verlag 2004.

Epidemiology of urticaria including physical urticaria and angioedema in Korea

Item Type Journal Article

Author J.-H. Seo

Author J.-W. Kwon

Abstract Background/Aims: Despite the high burden and frequency of urticaria, its epidemiology is not well known. We investigated the epidemiology of various type of urticaria in Korea and changes in its annual prevalence over 5 years. Methods: We used data from the 2010 to 2014 Health Insurance Review and Assessment database, which covers the claims of 97.0% of the South Korean population. Patients aged > 10 years old were included in this study. The presence of urticaria was identified on physician-certified diagnoses using the International Classification of Diseases 10th Revision (ICD-10) codes that include various type of urticaria (L500–L509) and angioedema (T783). Epidemiology of all type of urticaria, physical urticaria and angioedema were investigated. Results: The prevalence of all-type urticaria over the 5 years was 4.5% with a peak in individuals, especially females, aged 30 to 59 years. The age-specific prevalence of all-type urticaria increased with age from the 10-to 19-year age group to the 70-to 79-year age group. The prevalence of dermatographism, cholinergic urticaria, and angioedema were 0.12%, 0.025%, and 0.027%, respectively. Cholinergic urticaria was most prevalent in those aged 10 to 29 years with male predominance. The annual prevalence of all-type urticaria, dermatographism, and angioedema increased over the 5 years. Conclusions: The prevalence of urticaria has increased annually in Korea. Cholinergic urticaria showed unique distribution in its age and gender, and angioedema showed remarkable increases in annual prevalence, although the prevalence estimation is still exploratory and diagnosis of urticaria based on ICD-10 codes need to be validated. © 2019 The Korean Association of Internal Medicine.

Erroneous and excessive treatment anomaly detection based on unsupervised learning

Item Type Journal Article

Author S. Zhu

Author W. Liu

Abstract To provide an effective way to optimize the diagnosis and treatment process, in this research, our model of erroneous medical diagnosis is developed from the association rule learning by Apriori algorithm in order to correlate diseases and symptoms, and further expanded with an innovative numerical quantification method of prescription therapeutic function (called “Treatment Weight Effect Approach”). This is the first time an optimal expert prescription can be discovered from a large scale set of similar prescriptions without requiring explicit labels of training data. In this study, the idea of Hamming distance in K-Modes clustering algorithm is used to calculate the similarity of drugs, and then new prescriptions are compared with the best expert prescription to detect excess treatment. Additional experiments are conducted to verify the feasibility of the program with diagnosis and prescription treatment data. The testing results have shown that the model is successful in providing detection of erroneous and excessive treatments from the existing prescriptions and treatments. We address the critical issue of Treatment Anomalies due to Erroneous and Excessive Medications. We have overcome the traditional medical anomaly detection methods using data mining, Bayesian classification, decision trees and other supervised learning detection methods that were limited in scale and lacked data labels. © 2020, Politecnica University of Bucharest. Abstract Deployed machine learning (ML) models often encounter new user data that differs from their training data. Therefore, estimating how well a given model might perform on the new data is an important step toward reliable ML applications. This is very challenging, however, as the data distribution can change in flexible ways, and we may not have any labels on the new data, which is often the case in monitoring settings. In this paper, we propose a new distribution shift model, Sparse Joint Shift (SJS), which considers the joint shift of both labels and a few features. This unifies and generalizes several existing shift models including label shift and sparse covariate shift, where only marginal feature or label distribution shifts are considered. We describe mathematical conditions under which SJS is identifiable. We further propose SEES, an algorithmic framework to characterize the distribution shift under SJS and to estimate a model's performance on new data without any labels. We conduct extensive experiments on several real-world datasets with various ML models. Across different datasets and distribution shifts, SEES achieves significant (up to an order of magnitude) shift estimation error improvements over existing approaches. © 2022 Neural information processing systems foundation. Estimating belowground plant abundance with DNA metabarcoding

Item Type Journal Article**Author** S. Matesanz**Author** D.S. Pescador**Author** B. Pías**Author** A.M. Sánchez**Author** J. Chacón-Labela**Author** A. Illuminati**Author** M. de la Cruz**Author** J. López-Angulo**Author** N. Marí-Mena**Author** A. Vizcaíno**Author** A. Escudero

Abstract Most work on plant community ecology has been performed above ground, neglecting the processes that occur in the soil. DNA metabarcoding, in which multiple species are computationally identified in bulk samples, can help to overcome the logistical limitations involved in sampling plant communities belowground. However, a major limitation of this methodology is the quantification of species' abundances based on the percentage of sequences assigned to each taxon. Using root tissues of five dominant species in a semi-arid Mediterranean shrubland (*Bupleurum frutescens*, *Helianthemum cinereum*, *Linum suffruticosum*, *Stipa pennata* and *Thymus vulgaris*), we built pairwise mixtures of relative abundance (20%, 50% and 80% biomass), and implemented two methods (linear model fits and correction indices) to improve estimates of root biomass. We validated both methods with multispecies mixtures that simulate field-collected samples. For all species, we found a positive and highly significant relationship between the percentage of sequences and biomass in the mixtures ($R^2 = .44-.66$), but the equations for each species (slope and intercept) differed among them, and two species were consistently over- and under-estimated. The correction indices greatly improved the estimates of biomass percentage for all five species in the multispecies mixtures, and reduced the overall error from 17% to 6%. Our results show that, through the use of post-sequencing quantification methods on mock communities, DNA metabarcoding can be effectively used to determine not only species' presence but also their relative abundance in field samples of root mixtures. Importantly, knowledge of these aspects will allow us to study key, yet poorly understood, belowground processes. © 2019 John Wiley & Sons Ltd

Abstract Accurately estimating performance accuracy of machine learning classifiers is of fundamental importance in biomedical research with potentially societal consequences upon the deployment of bestperforming tools in everyday life. Although classification has been extensively studied over the past decades, there remain understudied problems when the training data violate the main statistical assumptions relied upon for accurate learning and model characterization. This particularly holds true in the open world setting where observations of a phenomenon generally guarantee its presence but the absence of such evidence cannot be interpreted as the evidence of its absence. Learning from such data is often referred to as positive-unlabeled learning, a form of semi-supervised learning where all labeled data belong to one (say, positive) class. To improve the best practices in the field, we here study the quality of estimated performance in positive-unlabeled learning in the biomedical domain. We provide evidence that such estimates can be wildly inaccurate, depending on the fraction of positive examples in the unlabeled data and the fraction of negative examples mislabeled as positives in the labeled data. We then present correction methods for four such measures and demonstrate that the knowledge or accurate estimates of class priors in the unlabeled data and noise in the labeled data are sufficient for the recovery of true classification performance. We provide theoretical support as well

as empirical evidence for the efficacy of the new performance estimation methods. © 2018 The Authors.

Estimating distributed autumn irrigation water use in a large irrigation district by combining machine learning with water balance models

Item Type Journal Article

Author X. Qian

Abstract Autumn irrigation (AI) after crop harvesting is vital for agricultural production in cold arid regions, typically requiring more water than regular irrigation during crop growth phases. Understanding distributed AI water use (AIWU) is key to optimizing irrigation strategies and refining agro-hydrological simulations. However, field-scale monitoring of irrigation water use is challenging, particularly in large districts, and quantification methods for distributed AIWU have seldom been investigated. Given this, we proposed a remote sensing-based model to estimate AIWU from water balance analysis, with key components derived through machine learning algorithms. Specifically, to address the unique challenge of short water ponding duration during AI, we selected MODIS as the primary data source, supplemented with Sentinel-2 data to enrich field-level details. A Sentinel-2 empirical bathymetry model, informed by in-situ measurements, served as a foundation for constructing a MODIS bathymetry model using random forest. This MODIS bathymetry model was essential for determining water ponding depths, which allowed for accurate estimation of infiltration rates when applied to the MODIS-based water index time series. By integrating these estimates into the water balance framework, we achieved a more precise estimate of AIWU. The proposed model was applied to Hetao Irrigation District (HID), the largest irrigation district in the arid region of China. The estimated steady infiltration rate and canal efficiency align with similar studies. The results indicate that the average AIWU per unit AI area in the HID remains stable during 2010–2020 with substantial spatial variability at the pixel level, providing new insights into the local hydrological cycle. The AIWU of HID has been decreasing by 19 million m³ per year during this period mainly due to the reduction in AI area, with a more prominent trend from 2010 to 2017. Our study deepens insights into the spatial–temporal dynamics of AIWU in arid regions, contributing to better irrigation management. © 2024 Elsevier B.V.

Abstract We consider the problem of obtaining unbiased estimates of group properties in social networks when using a classifier for node labels. Inference for this problem is complicated by two factors: The network is not known and must be crawled, and even high-performance classifiers provide biased estimates of group proportions. We propose and evaluate AdjustedWalk for addressing this problem. This is a three step procedure which entails: (1) walking the graph starting from an arbitrary node; (2) learning a classifier on the nodes in the walk; and (3) applying a post-hoc adjustment to classification labels. The walk step provides the information necessary to make inferences over the nodes and edges, while the adjustment step corrects for classifier bias in estimating group proportions. This process provides de-biased estimates at the cost of additional variance. We evaluate AdjustedWalk on four tasks: The proportion of nodes belonging to a minority group, the proportion of the minority group among high degree nodes, the proportion of within-group edges, and Coleman's homophily index. Simulated and empirical graphs show that this procedure performs well compared to optimal baselines in a variety of circumstances, while indicating that variance increases can be large for low-recall classifiers. © Springer Nature Switzerland AG 2018.

Abstract Purpose: Limb-girdle muscular dystrophies (LGMD) are a genetically heterogeneous category of autosomal inherited muscle diseases. Many genes causing LGMD have been identified, and clinical trials are beginning for treatment of some genetic subtypes. However, even with the gene-level mechanisms known, it is still difficult to get a robust and generalizable prevalence estimation for each subtype due to the limited amount of epidemiology data and the low incidence of LGMDs. Methods: Taking advantage of recently published exome and genome sequencing data from the general population, we used a Bayesian method to develop a robust disease prevalence estimator. Results: This method was applied to nine recessive LGMD subtypes. The estimated disease prevalence calculated by this method was largely comparable with published estimates from epidemiological studies; however, it highlighted instances of possible underdiagnosis for LGMD2B and 2L. Conclusion: The increasing size of aggregated population variant databases will allow for robust and reproducible prevalence estimates of recessive disease, which is critical for the strategic design and prioritization of clinical trials. © 2019, American College of Medical Genetics and Genomics.

Estimating probabilities of peptide database identifications to LC-FTICR-MS observations

Item Type Journal Article

Author K.K. Anderson

Author M.E. Monroe

Author D.S. Daly

Abstract Background: The field of proteomics involves the characterization of the peptides and proteins expressed in a cell under specific conditions. Proteomics has made rapid advances in recent years following the sequencing of the genomes of an increasing number of organisms. A prominent technology for high throughput proteomics analysis is the use of liquid chromatography coupled to Fourier transform ion cyclotron resonance mass spectrometry (LC-FTICR-MS). Meaningful biological conclusions can best be made when the peptide identities returned by this technique are accompanied by measures of accuracy and confidence. Methods: After a tryptically digested protein mixture is analyzed by LC-FTICR-MS, the observed masses and normalized elution times of the detected features are statistically matched to the theoretical masses and elution times of known peptides listed in a large database. The probability of matching is estimated for each peptide in the reference database using statistical classification methods assuming bivariate Gaussian probability distributions on the uncertainties in the masses and the normalized elution times. Results: A database of 69,220 features from 32 LC-FTICR-MS analyses of a tryptically digested bovine serum albumin (BSA) sample was matched to a database populated with 97% false positive peptides. The percentage of high confidence identifications was found to be consistent with other database search procedures. BSA database peptides were identified with high confidence on average in 14.1 of the 32 analyses. False positives were identified on average in just 2.7 analyses. Conclusion: Using a priori probabilities that contrast peptides from expected and unexpected proteins was shown to perform better in identifying target peptides than using equally likely a priori probabilities. This is because a large percentage of the target peptides were similar to unexpected peptides which were included to be false positives. The use of triplicate analyses with a "2 out of 3" reporting rule was shown to have excellent rejection of false positives. © 2006 Anderson et al; licensee BioMed Central Ltd.

Estimating the class prior and posterior from noisy positives and unlabeled data

Item Type Conference Paper**Author** S. Jain**Author** M. White**Author** P. Radivojac**Editor** Garnett R.**Editor** Lee D.D.**Editor** von Luxburg U.**Editor** Guyon I.**Editor** Sugiyama M.

Abstract We develop a classification algorithm for estimating posterior distributions from positive-unlabeled data, that is robust to noise in the positive labels and effective for high-dimensional data. In recent years, several algorithms have been proposed to learn from positive-unlabeled data; however, many of these contributions remain theoretical, performing poorly on real high-dimensional data that is typically contaminated with noise. We build on this previous work to develop two practical classification algorithms that explicitly model the noise in the positive labels and utilize univariate transforms built on discriminative classifiers. We prove that these univariate transforms preserve the class prior, enabling estimation in the univariate space and avoiding kernel density estimation for high-dimensional data. The theoretical development and parametric and nonparametric algorithms proposed here constitute an important step towards wide-spread use of robust classification algorithms for positive-unlabeled data. © 2016 NIPS Foundation - All Rights Reserved.

Estimating the class prior for positive and unlabelled data via logistic regression

Item Type Journal Article

Author M. Łazęcka

Author J. Mielniczuk

Author P. Teisseyre

Abstract In the paper, we revisit the problem of class prior probability estimation with positive and unlabelled data gathered in a single-sample scenario. The task is important as it is known that in positive unlabelled setting, a classifier can be successfully learned if the class prior is available. We show that without additional assumptions, class prior probability is not identifiable and thus the existing non-parametric estimators are necessarily biased in general if extra assumptions are not imposed. The magnitude of their bias is also investigated. The problem becomes identifiable when the probabilistic structure satisfies mild semi-parametric assumptions. Consequently, we propose a method based on a logistic fit and a concave minorization of its (non-concave) log-likelihood. The experiments conducted on artificial and benchmark datasets as well as on a large clinical database MIMIC indicate that the estimation errors for the proposed method are usually lower than for its competitors and that it is

robust against departures from logistic settings. © 2021, The Author(s).

Estimating the class prior from positive and unlabeled data

Item Type Journal Article

Author F. Shang

Author Q. Zhang

Author R. Sun

Abstract Positive and unlabeled (PU) learning is an important branch of semi-supervised learning. In the setting of positive and unlabeled learning, if the class prior is known, the classifier would be successfully learned. However, in practical applications, the class prior is unknown, and it can only be obtained from the PU data through the estimation method. In this paper, we proposed a novel method HDBEL (Hierarchical Division Based on Ensemble Learning) for estimating the label frequency from PU data. Label frequency serves as a proxy for the class prior. First, HDBEL algorithm looks for the attribute subdomains with large label probability through the hierarchical partition method based on ensemble learning and then estimates the

lower bound of label frequency by combining with the approximation formula of Hoeffding inequality. Finally, experiments on ten benchmark datasets showed that the HDBEL algorithm had higher accuracy than the existing technical methods, and the speed is seven times higher than the TICe algorithm. © 2020, Asian Association for Agricultural Engineering. Estimating the class prior in positive and unlabeled data through decision tree induction

Item Type Conference Paper

Author J. Bekker

Author J. Davis

Abstract For tasks such as medical diagnosis and knowledge base completion, a classifier may only have access to positive and unlabeled examples, where the unlabeled data consists of both positive and negative examples. One way that enables learning from this type of data is knowing the true class prior. In this paper, we propose a simple yet effective method for estimating the class prior, by estimating

the probability that a positive example is selected to be labeled. Our key insight is that subdomains of the data give a lower bound on this probability. This lower bound gets closer to the real probability as the ratio of labeled examples increases. Finding such subsets can naturally be done via top-down decision tree induction. Experiments show that our method makes estimates which are equivalently accurate as those of the state of the art methods, and is an order of magnitude faster. Estimating the clinical prevalence of Wilson's disease in the UK

Item Type Journal Article

Abstract Background & Aims: The clinical prevalence of Wilson's disease (WD) in the UK remains unknown. The estimated genetic prevalence in the UK, 142/million, is higher than the clinical prevalence (15/million) reported in other European studies. The aim of this study was to estimate the clinical prevalence of WD utilising readily available laboratory and clinical data. Method: Patients with WD who attended Nottingham University Hospital NHS Trust (NUH) between 2011 and 2018 were identified using multiple sources of case ascertainment: serum ceruloplasmin, 24-hour urinary copper, 'Wilson' in liver biopsy report, hospital prescription for penicillamine/trientine/zinc and admission coded with ICD-10 Code E83.0 (disorder of copper metabolism). Potential cases were identified using the Leipzig score, diagnosis was confirmed in hospital records and the point prevalence was calculated using the Office for National Statistics mid-2017 population estimates. Results: A total of 1,794 patients were identified from ≥ 1 source; 19 patients had WD, of whom 11 were from within the study catchment area and alive at the time of point prevalence estimation. Twenty-nine patients had a Leipzig score ≥ 2 without a diagnosis of WD, but none had WD on screening ($n = 16$). The overall prevalence of WD was 15.5/million; males 16.9/million and females 14.1/million. Conclusion: This is the first UK population-based study to assess the clinical prevalence of WD. The reported clinical prevalence is lower than the UK genetic prevalence, but comparable to the clinical prevalence reported in Europe. The case ascertainment approach used in this study may be cost-effective, and similar practises could be adopted nationally. Lay summary: Our study estimates the clinical prevalence of Wilson's disease, a rare genetic disorder of copper metabolism, in the UK. The estimated clinical prevalence in this study is markedly lower than the estimated UK genetic prevalence. © 2021

Estimating the Density Ratio between Distributions with High Discrepancy using Multinomial Logistic Regression

Item Type Journal Article

Author A. Srivastava

Author S. Han

Author K. Xu

Author B. Rhodes

Author M.U. Gutmann

Abstract Functions of the ratio of the densities p/q are widely used in machine learning to quantify the discrepancy between the two distributions p and q . For high-dimensional distributions, binary classification-based density ratio estimators have shown great promise. However, when densities are well separated, estimating the density ratio with a binary classifier is challenging. In this work, we show that the state-of-the-art density ratio estimators perform poorly on well separated cases and demonstrate that this is due to distribution shifts between training and evaluation time. We present an alternative method that leverages multi-class classification for density ratio estimation and does not suffer from distribution shift issues. The method uses a set of auxiliary densities $\{m_k\}_{K=1}$ and trains a multi-class logistic regression to classify the samples from p , q and $\{m_k\}_{K=1}$ into $K + 2$ classes. We show that if these auxiliary densities are constructed such that they overlap with p and q , then a multi-class logistic regression allows for estimating $\log p/q$ on the domain of any of the $K + 2$ distributions and resolves the distribution shift problems of the current state-of-the-art methods. We compare our method to state-of-the-art density ratio estimators on both synthetic and real datasets and demonstrate its superior performance on the tasks of density ratio estimation, mutual information estimation, and representation learning. Estimating the minority class proportion with the ROC curve using Military Personality Inventory data of the ROK Armed Forces

Item Type Journal Article

Author M. Sun

Author K. Choi

Author S. Cho

Abstract The Republic of Korea Armed Forces includes maladjusted conscripts such as the mentally ill, the suicidal, the imprisoned, and those determined by the military commander to be maladjusted. To counteract these problems, it is necessary to identify the maladjusted conscripts to determine who among them would qualify for exemption from active military service or need special attention. We use the Military Personality Inventory (MPI) to make this prediction. Such a prediction presents a kind of class imbalance and class overlap problem, where the majority fulfil active service and the minority are maladjusted, the latter being discharged early from active service. Therefore, most classification algorithms are likely to show low classification performance. As an alternative, this study demonstrates the effective utilization of the receiver operating characteristics curve using MPI data to estimate the maladjusted proportion of persons sharing similar MPI test results. We confirm that the suggested method performs well using the real-world MPI data set. The suggested method is very useful to estimate the proportion of conscripts maladjusted to military life and can help in the management of such persons subject to conscription. © 2015 Taylor & Francis.

Estimation of a priori probabilities of sleep stages: A cycle-based approach

Item Type Conference Paper

Author A. Tataraidze

Author L. Anishchenko

Author L. Korostovtseva

Author M. Bochkarev

Author Y. Sviryayev

Author S. Ivashov

Abstract This paper presents a model for the estimation of a priori probabilities of sleep epoch classes based on the epoch location in a sleep cycle. These probabilities are used as additional features for sleep stage classification based on the analysis of respiratory effort. The model was validated with data of 685 subjects selected from the Sleep Heart Health Study dataset. The model improves a base algorithm by 8 percent points and demonstrates Cohen's kappa of 0.56 ± 0.12 . Our results will contribute to the development of screening tools for unobtrusive sleep structure estimation. © 2017 IEEE.

Estimation of brain amyloid accumulation using deep learning in clinical [11C]PiB PET imaging

Item Type Journal Article**Author** C.N. Ladefoged**Author** L. Anderberg**Author** K. Madsen**Author** O.M. Henriksen**Author** S.G. Hasselbalch**Author** F.L. Andersen**Author** L. Højgaard**Author** I. Law

Abstract Introduction: Estimation of brain amyloid accumulation is valuable for evaluation of patients with cognitive impairment in both research and clinical routine. The development of high throughput and accurate strategies for the determination of amyloid status could be an important tool in patient selection for clinical trials and amyloid directed treatment. Here, we propose the use of deep learning to quantify amyloid accumulation using standardized uptake value ratio (SUVR) and classify amyloid status based on their PET images. Methods: A total of 1309 patients with cognitive impairment scanned with [11C]PiB PET/CT or PET/MRI were included. Two convolutional neural networks (CNNs) for reading-based amyloid status and SUVR prediction were trained using 75% of the PET/CT data. The remaining PET/CT (n = 300) and all PET/MRI (n = 100) data was used for evaluation. Results: The prevalence of amyloid positive patients was 61%. The amyloid status classification model reproduced the expert reader's classification with 99% accuracy. There was a high correlation between reference and predicted SUVR ($R^2 = 0.96$). Both reference

and predicted SUVR had an accuracy of 97% compared to expert classification when applying a predetermined SUVR threshold of 1.35 for binary classification of amyloid status. Conclusion: The proposed CNN models reproduced both the expert classification and quantitative measure of amyloid accumulation in a large local dataset. This method has the potential to replace or simplify existing clinical routines and can facilitate fast and accurate classification well-suited for a high throughput pipeline. © 2023, The Author(s).

Estimation of class priors for improving classification accuracy during deployment

Item Type Journal Article**Author** B. McIntosh**Author** N. Daba**Author** A. Mahalanobis

Abstract Conventional classifiers are trained and evaluated using “balanced” data sets, in which all classes are equally present. However, it is unlikely that the prior probability of occurrence will be the same for the classes that are encountered in each deployment scenario. Unfortunately, the exact class priors are generally unknown and can vary spatially and over time. We explore different methods for estimating the class priors based on the response of the classifier itself. We observe that the distribution of classifier's decisions made in response to a collection test image can be expressed as a linear combination of the distribution of its decisions made in response to each individual class. The weights of the linear combination are the prior probabilities with which the different classes occur in the test set. This can be used along with the classifier's precision and recall for each class to estimate the class priors. We then show that incorporating the estimated class priors in the overall decision scheme improves the classifier's accuracy in the context of the deployment. We first illustrate the potential improvements in classification accuracy using the CIFAR-100 and Tiny ImageNet data sets and then demonstrate the application of this technique for improving the classification and recognition of objects in satellite imagery using the well-known Xview dataset. © 2024 Elsevier Inc. Estimation of the number of Anisakis larvae in commercial fish using a descriptive model based on real-time PCR

Item Type Journal Article**Author** C. Godínez-González**Author** X. Roca-Geronès**Author** I. Montoliu**Author** R. Fisa

Abstract BACKGROUND: Seafood parasitization by Anisakis (Anisakidae) larvae has been reported in most of the oceans and seas worldwide. The presence of these nematodes in commonly consumed fish represents a potential hazard for consumers as they can provoke gastrointestinal symptoms and allergic reactions. In the present work, the capacity of a SYBR Green qPCR protocol to quantify Anisakis larvae in commercial fish was evaluated using experimentally spiked samples with different numbers (0–50) of *A. simplex* third-stage larvae (L3). To verify the agreement of the obtained results, 25 naturally infected fish specimens of Atlantic blue whiting underwent a parallel visual inspection. RESULTS: The logarithmic behavior of the Cq data obtained from the experimentally spiked samples allowed the development of a descriptive mathematical model that correlates the Cq value with the number of Anisakis larvae ($R^2 = 0.9908$, $CV = 2.37\%$). In the commercial blue whiting specimens there was a high correlation between the results of the molecular technique and the visual inspection ($R^2 = 0.9912$); the Bland–Altman analysis showed that 94% of the differences were within the limits of agreement (−4.98 and 6.68), indicating the reliability of the descriptive mathematical model based on the SYBR Green qPCR technique. CONCLUSION: The descriptive function presented based on the SYBR Green qPCR assay is promising as a sensitive and accurate tool for measuring the Anisakis larval load in commercial fish, with a potential application not only in the food industry but also in prevention programs for public health. © 2020 Society of Chemical Industry. © 2020 Society of Chemical Industry

Evaluating a Targeted Minimum Loss-Based Estimator for Capture-Recapture Analysis: An Application to HIV Surveillance in San Francisco, California

Item Type Journal Article**Author** P. Wesson**Author** M. Das**Author** M. Chen**Author** L. Hsu**Author** W. McFarland**Author** E. Kennedy**Author** N.P. Jewell

Abstract The capture-recapture method is a common tool used in epidemiology to estimate the size of "hidden" populations and correct the underascertainment of cases, based on incomplete and overlapping lists of the target population. Log-linear models are often used to estimate the population size yet may produce implausible and unreliable estimates due to model misspecification and small cell sizes. A novel targeted minimum loss-based estimation (TMLE) model developed for capture-recapture makes several notable improvements to conventional modeling: "targeting" the parameter of interest, flexibly fitting the data to alternative functional forms, and limiting bias from small cell sizes. Using simulations and empirical data from the San Francisco, California, Department of Public Health's human immunodeficiency virus (HIV) surveillance registry, we evaluated the performance of the TMLE model and compared results with those of other common models. Based on 2,584 people observed on 3 lists reportable to the surveillance registry, the TMLE model estimated the number of San Francisco residents living with HIV as of December 31, 2019, to be 13,523 (95% confidence interval: 12,222, 14,824). This estimate, compared with a "ground truth" of 12,507, was the most accurate and precise of all models examined. The TMLE model is a significant advancement in capture-recapture studies, leveraging modern statistical methods to improve estimation of the sizes of hidden populations. © 2024 The Author(s) 2023. Evaluating child-friendliness in the 15-minute community living circle: An example from Shanghai’s Dongyuan I Village

Item Type Journal Article
Author M. Liu
Author Y. Xu
Author Y. Chen
Author W. Yan

Abstract Under the pressing challenges posed by urbanization, such as road traffic, limited activity spaces, and environmental inequalities, ensuring children’s well-being in urban environments has become a critical issue. Children’s physical, cognitive, and social development is significantly influenced by their living environments, yet traditional urban planning often overlooks their unique needs. To address this gap, this study focuses on integrating child-friendliness into urban community planning, particularly through the lens of the “15-minute community living circle” model. This model emphasizes the creation of urban spaces where essential facilities are within a

15-minute walk, aligning with children's physical capabilities and daily needs. The study develops a comprehensive and quantitative evaluation system for assessing child-friendliness living circles, focusing on safety, comfort, and fun in travel and stay spaces. Using Shanghai's Dongyuan I Village as a case study, the research uses online questionnaires, field surveys, and machine learning to quantify child-friendliness. Results demonstrate the model's ability to provide micro-level evaluations and actionable insights for optimizing urban spaces. This research highlights the importance of prioritizing child-friendly principles in urban planning, offering valuable guidance for fostering safe, inclusive, and vibrant environments that support children's growth and contribute to sustainable urban development. © 2025 Urban Affairs Association.

Evaluating classifiers: Relation between area under the receiver operator characteristic curve and overall accuracy

Item Type Conference Paper

Author M.A. Mazurowski

Author G.D. Tourassi

Abstract In this study, we investigated the relation between two popular classifier performance measures: area under the receiver operator characteristic curve and overall accuracy. We also evaluated the impact of class imbalance and number of examples in test set on this relation. We perform a set of experiments in which we train multiple neural networks and test them in various, well controlled conditions. The experimental results show that given a large and balanced test set, increase in one performance measure is a very good indicator of increase in the other measure. Furthermore increasing the total number of examples, while keeping the positive class prevalence constant generally increases the correlation between the two measures. Our results also indicate that increasing the extent of class imbalance in the test set has a detrimental effect on this correlation. ©2009 IEEE.

Evaluating methods for distinguishing between human-readable text and garbled text

Item Type Conference Paper

Author J. Henderson

Author N. Siegel
Author C. Martin
Author A. Liu
Editor Markov Z.
Editor Russell I.

Abstract In some cybersecurity applications, it is useful to differentiate between human-readable text and garbled text (e.g., encoded or encrypted text). Automated methods are necessary for performing this task on large volumes of data. Which method is best is an open question that depends on the specific problem context. In this paper, we explore this open question via empirical tests of many automated categorization methods for differentiating human-readable versus garbled text under a variety of conditions (e.g., different class priors, different problem contexts, concept drift, etc.). The results indicate that the best approaches tend to be either variants of naïve Bayes or classifiers that use low-dimensional, structural features. The results also indicate that concept drift is one of the most problematic issues when classifying garbled text. © 2016, Association for the Advancement of Artificial Intelligence (www.aaai.org). Evaluating Sentiment Quantification Methods in Brazilian Portuguese Corpora

Item Type Conference Paper

Author L.N. dos Santos Silva
Author D.F. Silva
Author H. de Medeiros Caseli
Editor Paes A.
Editor Verri F.A.N.

Abstract This paper evaluates sentiment quantification methods applied to Brazilian Portuguese corpora. Sentiment quantification, distinct from sentiment classification, estimates the distribution of sentiment classes (positive and negative) within a dataset. We investigate several quantification techniques, including the family Classify and Count (CC) and more sophisticated methods, such as Kernel Density Estimation (KDE) and Distribution y-Similarity (DyS). Our analysis uses five datasets, each containing different distributions of sentiment classes. Our experimental results indicate that KDE and DyS methods consistently outperform others, achieving the best average ranks in terms of quantification accuracy. Statistical tests, including the Friedman and Nemenyi tests, confirm significant performance differences among the methods, with KDE and DyS showing statistically significant improvements over the baseline CC method. These findings highlight the importance of choosing robust quantification techniques for accurate sentiment quantification in corpora across different domains. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2025.

Abstract Introduction: To evaluate the effect pegcetacoplan, a C3 and C3b inhibitor, on the rate of progression of geographic atrophy (GA) as assessed by spectral domain optical coherence tomography (SD-OCT) using a split-person study design and deep-learning quantification. Methods: A post hoc analysis of phase 2 FILLY trial data comparing study (treated monthly, treated every other month and sham-treated) and fellow (untreated) eyes in a split-person study design was performed. This analysis included 288 eyes from 144 patients with bilateral GA from the FILLY phase 2 trial (Clinical Trials identifier: NCT02503332). Only patients with bilateral GA and without evidence of choroidal neovascularisation in either eye were included. Patient study eyes were treated with sham injections or with pegcetacoplan monthly (PM) or every other month (PEOM) for 12 months. SD-OCT scans of study and fellow eyes taken at baseline and 12 months were used for the analysis. The main outcomes were the annual change in the area of retinal pigment epithelial and outer retinal atrophy (RORA), its constituent features (photoreceptor degeneration [PRD], retinal pigment epithelium [RPE] loss, hypertransmission) and intact macula as compared to the untreated fellow eye. Results: Annual GA growth was reduced in eyes treated with PM versus untreated fellow eyes for OCT features, including RORA (study eye 0.792 vs. fellow eye 1.13 mm²; P = 0.003), PRD (0.739 vs. 1.23 mm²; P = 0.015), RPE-loss (0.789 vs. 1.17 mm²; P = 0.007) and intact macula (− 0.735 vs. − 1.29 mm²; P = 0.011). Similar (but not statistically significant) trends were observed with the PEOM treatment or when GA was quantified with fundus autofluorescence (FAF). The sham treatment demonstrated no effect. Pearson correlation coefficients showed concordance in the enlargement rate of GA between the study and fellow eyes in the

sham ($R = 0.64$) and PEOM ($R = 0.68$) groups, but not in the PM group ($R = 0.21$).
Conclusions: Pegcetacoplan-treated eyes demonstrated a reduction in spatial GA progression compared to their untreated counterparts. This effect was more evident on OCT than with FAF. Trial Registration: Clinical Trials identifier: NCT02503332.

Evaluation and Optimization of Sample Handling Methods for Quantification of Short-Chain Fatty Acids in Human Fecal Samples by GC-MS

Item Type Journal Article

Author M.-S. Wu
Author C.-H. Kuo

Abstract The gut microbiota has attracted a great deal of interest in recent years due to its association with many diseases. Short-chain fatty acids (SCFAs), the end products of dietary fiber fermentation by the intestinal microbiota, are among the most frequently discussed gut metabolites. As the sample handling method greatly affects the integrity of data, this study investigated the most important parameters that affect the bias of SCFA comparisons in human fecal studies. An accurate gas chromatography-mass spectrometry (GC-MS) method was first established and validated for quantifying six SCFAs, including acetic, propionic, butyric, isobutyric, isovaleric, and valeric acids. To remove interfering species, we used butanol to extract SCFAs from acidified fecal suspensions. The validated quantification method was then applied to evaluate fecal sample handling protocols. We found that lyophilization of fecal samples can not only minimize bias due to the water content but also provide better stability of SCFAs. Six SCFAs were stable and that their recoveries were higher than 90% after lyophilization. Lyophilization of a large fecal sample is extremely time-consuming, and 1 g of fecal sample is suggested for lyophilization to minimize sampling bias. The interindividual difference was significantly higher than the intra-individual difference when using 1 g of fecal sample to study SCFAs. Finally, an effective protocol from sample collection to GC-MS analysis was proposed. As SCFAs have been shown to play an important role in health maintenance and disease development, the proposed protocol is anticipated to be applicable to clinical studies to delineate the biological functions of each SCFA. © Copyright 2019 American Chemical Society.

Evaluation measures for quantification: an axiomatic approach

Item Type Journal Article

Author F. Sebastiani

Abstract Quantification is the task of estimating, given a set σ of unlabelled items and a set of classes $C = \{c_1, \dots, c_l \mid C\}$, the prevalence (or “relative frequency”) in σ of each class $c_i \in C$. While quantification may in principle be solved by classifying each item in σ and counting how many such items have been labelled with c_i , it has long been shown that this “classify and count” method yields suboptimal quantification accuracy. As a result, quantification is no longer considered a mere byproduct of classification, and has evolved as a task of its own. While the scientific community has devoted a lot of attention to devising more accurate quantification methods, it has not devoted much to discussing what properties an evaluation measure for quantification (EMQ) should enjoy, and which EMQs should be adopted as a result. This paper lays down a number of interesting properties that an EMQ may or may not enjoy, discusses if (and when) each of these properties is desirable, surveys the EMQs that have been used so far, and discusses whether they enjoy or not the above properties. As a result of this investigation, some of the EMQs that have been used in the literature turn out to be severely unfit, while others emerge as closer to what the quantification community actually needs. However, a significant result is that no existing EMQ satisfies all the properties identified as desirable, thus indicating that more research is needed in order to identify (or synthesize) a truly adequate EMQ. © 2019, Springer Nature B.V.

Evaluation of a computerized method for denture biofilm quantification: Inter-examiner reproducibility

Item Type Journal Article

Author C.H. Silva-Lovato

Author A.M.G. Totti

Author H.F.O. Paranhos

Author V.G. Totti

Abstract Purpose: The objective of this work was to evaluate the accuracy and inter-examiner reproducibility of the computerized method Image Tool 2.02 (Windows, version 2.02, University of Texas Health Science Center, San Antonio, TX) in the quantification of complete denture biofilm. Materials and Methods: Two hundred digital photographs of the internal surface of complete upper dentures with biofilm dyed in 1% neutral red were used. The photographs were burned to a CD and sent to two researchers who received practical training and written instructions on how to use the method; then, in a 20-day period, the stained biofilm on the internal surface was measured, and ten photographs were analyzed daily. Each examiner independently quantified the percentage of stained area on each photograph. The inter-examiner reproducibility (i.e., agreement) was estimated by calculating an intra-class correlation coefficient (ICC) based on an ANOVA mixed model (SPSS software, Chicago, IL). Results: The ICC showed excellent agreement (ICC = 0.993, $p < 0.001$). The difference in the percentage of the stained area recorded by the two examiners was ≤ 1 point for 187 (93.5%) of the 200 photographs. Conclusions: The obtained results suggest that the computerized method aided by the Image Tool software (2.0) can be employed to quantify complete denture biofilm, seeing that it demonstrated inter-examiner reproducibility of the results. © 2009 by The American College of Prosthodontists.

Evaluation of a Concept for Classification of Micromobility Vehicles Based on Thermal-Infrared Imaging and Neuromorphic Processing

Item Type Conference Paper

Author B. Stahl

Author R. Lange

Author J. Apfelbeck

Editor Kimata M.

Editor Shaw J.A.

Editor Valenta C.R.

Abstract Current trends of environmental awareness combined with a focus on personal fitness and health, motivates many people to switch from cars and public transport to micromobility solutions, namely bicycles, electric bicycles, cargo bikes, or scooters. To accommodate urban planning for these changes, cities, and communities need to know how many (micromobility) vehicles are on the road.

In this work, we design a concept for a compact, mobile, and energy-efficient system to classify and count micromobility vehicles. We aim for a battery-powered system, which can be installed in a short time by a single person and is non-invasive for the ground or traffic. For this purpose, we investigate a system architecture consisting of uncooled long-wave infrared (LWIR) imaging sensors and a neuromorphic co-processor. This processor can perform classifications in a fixed time of 16,2 μ s without requiring additional hardware for learning. It can adapt its knowledge base to new environments without external updates. Our system is aimed to achieve adequate accuracy only using a low-resolution sensor and moderate processing power. We will show that an object representation of only 256 Bytes is sufficient to achieve a four-class classification accuracy higher than 80%, with an overall power consumption of less than 7mW. We estimate a total operating time of at least two weeks using a common 12V 17Ah lead battery. © 2021 SPIE. All rights reserved.

Abstract Psychiatric evaluation relies on subjective symptoms and behavioral observation, which sometimes leads to misdiagnosis. Despite previous efforts to utilize plasma proteins as objective markers, the depletion method is time-consuming. Therefore, this study aimed to enhance previous quantification methods and construct objective discriminative models for major psychiatric disorders using nondepleted plasma. Multiple reaction monitoring-mass spectrometry (MRM-MS) assays for quantifying 453 peptides in nondepleted plasma from 132 individuals [35 major depressive disorder (MDD), 47 bipolar disorder (BD), 23 schizophrenia (SCZ) patients, and 27 healthy controls (HC)] were developed. Pairwise discriminative models for MDD, BD, and SCZ, and a discriminative model between patients and HC were constructed by machine learning approaches. In addition, the proteins from nondepleted plasma-based discriminative models were compared with previously developed depleted plasma-based discriminative models. Discriminative models for MDD versus BD, BD versus SCZ, MDD versus SCZ, and patients versus HC were constructed with 11 to 13 proteins and showed reasonable performances (AUROC = 0.890-0.955). Most of the shared proteins between nondepleted and depleted plasma models had consistent directions of expression levels and were associated with neural signaling, inflammatory, and lipid metabolism pathways. These results suggest that multiprotein markers from nondepleted plasma have a potential role in psychiatric evaluation. © 2023 American Chemical Society

Evaluation of a Novel Automated Method for the Quantification of Inflammation in Renal Biopsies

Item Type Conference Paper**Author** V. Mattioli**Author** A. Bocchi**Author** E. Martinelli**Author** C. Pala

Author M. Delsante

Author U. Maggiore

Author R. Raheli

Abstract The development of robust software-based technologies for objective image interpretation has facilitated the integration of Artificial Intelligence (AI) tools into digital pathology workflows for diagnostic applications. In this work, a novel automated method for quantifying inflammation in renal tissue biopsies is presented. To this purpose, the open-source QuPath software is exploited to design a custom classifier specifically trained to handle images stained with a novel combination of Periodic Acid-Schiff (PAS) and Leukocyte Common Antigen (LCA) techniques. This dual-staining approach enhances the visualization of both extracellular structures and inflammatory cells, enabling a more accurate assessment of the inflammation status. The performance of the presented quantification method is compared against measurements performed by two expert professionals, also referred to as observers, employing statistical metrics including the correlation coefficient and the normalized Mean Squared Error (MSE). For a thorough inspection, a Passing-Bablok regression analysis is also performed, showing a good agreement between outcomes obtained from the proposed method and one of the two observers. Discrepancies between the measurements performed by the two observers are also highlighted. © 2025 IEEE.

Evaluation of a Urine Pooling Strategy for the Rapid and Cost-Efficient Prevalence Classification of Schistosomiasis

Item Type Journal Article

Author J.R. Andrews

Abstract Background: A key epidemiologic feature of schistosomiasis is its focal distribution, which has important implications for the spatial targeting of preventive chemotherapy programs. We evaluated the diagnostic accuracy of a urine pooling strategy using a point-of-care circulating cathodic antigen (POC-CCA) cassette test for detection of *Schistosoma mansoni*, and employed simulation modeling to test the classification accuracy and efficiency of this strategy in determining where preventive chemotherapy is needed in low-endemicity settings. Methodology: We performed a cross-sectional study involving 114 children aged 6–15 years in six neighborhoods in Azaguié Ahoua, south Côte d’Ivoire to characterize the sensitivity and specificity of the POC-CCA cassette test with urine samples that were tested individually and in pools of 4, 8, and 12. We used a Bayesian latent class model to estimate test characteristics for individual POC-CCA and quadruplicate Kato-Katz thick smears on stool samples. We then developed a microsimulation model and used lot quality assurance sampling to test the performance, number of tests, and total cost per school for each pooled testing strategy to predict the binary need for school-based preventive chemotherapy using a 10% prevalence threshold for treatment. Principal Findings: The sensitivity of the urine pooling strategy for *S. mansoni* diagnosis using pool sizes of 4, 8, and 12 was 85.9%, 79.5%, and 65.4%, respectively, when POC-CCA trace results were considered positive, and 61.5%, 47.4%, and 30.8% when POC-CCA trace results were considered negative. The modeled specificity ranged from 94.0–97.7% for the urine pooling strategies (when POC-CCA trace results were considered negative). The urine pooling strategy, regardless of the pool size, gave comparable and often superior classification performance to stool microscopy for the same number of tests. The urine pooling strategy with a pool size of 4 reduced the number of tests and total cost compared to classical stool microscopy. Conclusions/Significance: This study introduces a method for rapid and efficient *S. mansoni* prevalence estimation through examining pooled urine samples with POC-CCA as an

alternative to widely used stool microscopy. © 2016 Lo et al.

Evaluation of an automatic lean meat percentage quantification method based on a partial volume model from computed tomography scans

Item Type Journal Article

Author P. Xiberta

Author A. Bardera

Author I. Boada

Author M. Gispert

Author A. Brun

Author M. Font-i-Furnols

Abstract The quality of a pig carcass is mainly measured by the lean meat percentage (LMP), which can be virtually estimated from computed tomography (CT) scans. Different strategies exist to classify the CT voxels into tissues such as fat, lean and bone, being the thresholding-based methods the most commonly used. However, these methods are usually affected by the partial volume effect, and also by data variability, which is implicit from different CT scanners and protocols, since no standard behaviour has been defined. The aim of this paper is to extend an LMP quantification method which uses a partial volume model by adding a new step to detect the animal skin, and thoroughly evaluate the new approach by analysing each of its steps. The evaluation is performed by comparing the whole pipeline of the proposed approach with a simple thresholding method and a thresholding method with bone filling and skin detection, which is an intermediate step of the new pipeline. Five experiments have been designed to test how accurate are the results of the method regarding the LMP values computed from the manual dissection, as well as the robustness to data variability. Two different manual dissection methodologies have been tested: the partial dissection, which estimates the LMP using the lean of the four main cuts of the carcass plus the tenderloin, and the total dissection, which uses the lean of the twelve main cuts. A total of 146 half carcasses have been used for this study (105 using the partial dissection methodology, and 41 using the total dissection one). To evaluate the experiments, the LMP values virtually obtained from the three methods have been compared mostly with the LMP values from the manual dissection, computing the coefficient of determination R^2 from the correlations, as well as the root mean square error of prediction by means of leave-one-out cross-validation. A statistical analysis is performed to resolve if two correlations are significantly different. The experiments' results confirm the high accuracy of the proposed approach for the LMP estimation, and mainly its high robustness to data variability. The experiments also disclose that the detection of the animal skin and its classification as a new tissue, instead of classifying it as lean, improve the results. The evaluated method has demonstrated to be as effective as the thresholding method with bone filling and skin detection, and more robust to data variability than the other evaluated methods. © 2018 Elsevier B.V.

Evaluation of an average numerator relationship matrix model and a Bayesian hierarchical model for growth traits in Nellore cattle with uncertain paternity

Item Type Journal Article

Author L. Shiotsuki

Author F.F. Cardoso

Author J.A.I.I.V. Silva

Author G.J.M. Rosa

Author L.G. Albuquerque

Abstract The objective of this work was to compare a model based on the use of an average numerator relationship matrix (ANRM) and a hierarchical animal model (HIER) to indicate the most appropriate statistical procedure to better estimate the genetic value of Nellore animals that have unknown paternity. The data set contained records of 62,212 Nellore animals. The pedigree file contained a total of 75,088 animals. Two approaches were adopted for the treatment of uncertain paternity. In the model based on the use of the ANRM probabilities were attributed to each of the possible parents of the animals with uncertain paternity. The other method adopted in the present study, i.e., the HIER, considers uncertainty in the assignment of paternity of animals participating in the multiple-sire (MS) system. Within this context, a priori probabilities are assigned to each possible sire of animals with uncertain paternity, which are altered according to information present in the data for the generation of posterior probabilities. Univariate analyses were carried out under Bayesian approach via Markov Chain Monte Carlo (MCMC) methods, implementing a chain of 400,000 rounds where the first 10,000 rounds were discarded (burn-in period). Models were compared by deviance information criteria (DIC) and pseudo Bayes factors (PBF). The model that best fits the data for estimating genetic parameter of animals with uncertain paternity is the Bayesian hierarchical model. Nevertheless, for genetic evaluation, the choice between these models would have no impact on genetic value classification of animals for selection. © 2011 Elsevier B.V.

Evaluation of broken steel wire rope using magnetic flux leakage and optimised convolutional neural network

Item Type Journal Article

Author G. Li

Author B. Cao

Author Y. Zhou

Author M. Fan

Author L. Yang

Abstract Wire rope has become a common component in mines because of its advantages such as high strength and flexibility. Nevertheless, prolonged utilisation in severe environments can result in damage due to breakage. To address this problem, this paper proposes a damage quantification method for multi-objective optimised convolutional neural networks incorporating tiny damage signal enhancement. Firstly, the signal characteristics of wire rope breakage damage are analysed by constructing a magnetic dipole model and exploring the applicability of axial and radial signals for quantitative identification. Secondly, an algorithm to enhance the radial damage signal of a small broken wire is proposed, which can enhance the peak-to-peak value of 1 broken wire by about 2.4 times, and improve the detection ability of small broken wire damage. Finally, a convolutional neural network (CNN) was constructed, and the structural parameters of the network were optimised using the crown

porcupine optimisation (CPO) algorithm for quantifying wire rope breakage damage. The experimental results show that the model proposed in this study exhibits excellent performance in terms of accuracy, precision, recall, and F1 score compared to multiple models. The accuracy is augmented to 99.17%, thereby enhancing the quantisation precision of broken wire defects. © 2025 Informa UK Limited, trading as Taylor & Francis Group.

Evaluation of method bias for determining bacterial populations in bacterial community analyses

Item Type Journal Article

Author M. Takahashi

Author Y. Kita

Author A. Mizuno

Author N. Goto-Yamamoto

Abstract Various methods are used for analyzing a bacterial community. We recently developed a method for quantifying each bacterium constituting the microbiota by combining a next-generation sequencing (NGS) analysis with a quantitative polymerase chain reaction (NGS-qPCR) assay. Our NGS-qPCR method is useful for analyzing a comprehensive bacterial community because it enables the easy calculation of the amounts of each bacterium constituting the microbiota. However, it has not been confirmed whether the estimated bacterial community obtained using this NGS-qPCR method corresponds to the results obtained using conventional methods. Accordingly, we prepared model bacterial community samples and analyzed them by several methods (NGS-qPCR, species-specific qPCR, flow cytometry, total direct counting by epifluorescent microscopy [TDC], and plate count). The total bacterial cell densities determined by the PCR-based methods were largely consistent with those determined by the TDC method. There was a difference between the amounts of each bacterium analyzed by NGS-qPCR and species-specific qPCR, although the same trend was shown by both species-specific qPCR and NGS-qPCR. Our findings also demonstrated that there is a strong positive correlation between the cell densities of a specific bacterial group in craft beer samples determined by group-specific qPCR and NGS-qPCR, and there were no significant differences among quantification methods (we tested two bacterial groups: lactic acid bacteria and acetic acid bacteria). Thus, the NGS-qPCR method is a practical method for analyzing a comprehensive bacterial community based on a bacterial cell density. © 2017 The Society for Biotechnology, Japan

Abstract Purpose: Positron emission tomography (PET) provides in vivo quantification of amyloid- β (A β) pathology. Established methods for assessing A β burden can be affected by physiological and technical factors. Novel, data-driven metrics have been developed to account for these sources of variability. We aimed to evaluate the performance of four of these amyloid PET metrics against conventional techniques,

using a common set of criteria. Methods: Three cohorts were used for evaluation: Insight 46 (N=464, [18F]florbetapir), AIBL (N=277, [18F]flutemetamol), and an independent test-retest data (N=10, [18F]flutemetamol). Established metrics of amyloid tracer uptake included the Centiloid (CL) and where dynamic data was available, the non-displaceable binding potential (BPND). The four data-driven metrics computed were the amyloid load (A β load), the A β -PET pathology accumulation index (A β index), the Centiloid derived from non-negative matrix factorisation (CLNMF), and the amyloid pattern similarity score (AMPSS). These metrics were evaluated using reliability and repeatability in test-retest data, associations with BPND and CL, variability of the rate of change and sample size estimates to detect a 25% slowing in A β accumulation. Results: All metrics showed good reliability. A β load, A β index and CLNMF were strong associated with the BPND. The associations with CL suggest that cross-sectional measures of CLNMF, A β index and A β load are robust across studies. Sample size estimates for secondary prevention trial scenarios were the lowest for CLNMF and A β load compared to the CL. Conclusion: Among the novel data-driven metrics evaluated, the A β load, the A β index and the CLNMF can provide comparable performance to more established quantification methods of A β PET tracer uptake. The CLNMF and A β load could offer a more precise alternative to CL, although further studies in larger cohorts should be conducted. © 2023

Abstract Surface water resources are subject to climate change, particularly in arid zones such as Morocco's central plateau, and to the massive demand placed on water by human activities, which calls for equitable management of water potential, In this sense, hydraulic engineering is a solution for better storage and management of surface water, as well as for mitigating and adapting to climate variability. This is the aim of the Ain Kwaachia dam on the Ykem river in the northwestern part of the central plateau of Morocco. While the use of remote sensing technology, based on the acquisition of satellite images, is a kind of machine learning to quantify spatio-temporal variations in water potential, so the processing and the analysis of these image data, based on a GIS geographic information system, and this, from the Land Use index for land cover, with an unsupervised classification from 2008, the year of commissioning of the dam subject of this research, and a supervised classification around the year 2021. The results obtained show that the variations affecting the study area have been noticeable in recent years, from 9.78 km² for 2016, to 4.23 km² for 2021, as a result of the repercussions of climate change, with falling rainfall on the one hand, and in the other hand rising temperatures. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2024.

Abstract Artificial Intelligence (AI) use in automated Electrocardiogram (ECG) classification has continuously attracted the research community's interest, motivated by their promising results. Despite their great promise, limited attention has been paid to the robustness of their results, which is a key element for their implementation in clinical

practice. Uncertainty Quantification (UQ) is a critical for trustworthy and reliable AI, particularly in safety-critical domains such as medicine. Estimating uncertainty in Machine Learning (ML) model predictions has been extensively used for Out-of-Distribution (OOD) detection under single-label tasks. However, the use of UQ methods in multi-label classification remains underexplored. This study goes beyond developing highly accurate models comparing five uncertainty quantification methods using the same Deep Neural Network (DNN) architecture across various validation scenarios, including internal and external validation as well as OOD detection, taking multi-label ECG classification as the example domain. We show the importance of external validation and its impact on classification performance, uncertainty estimates quality, and calibration. Ensemble-based methods yield more robust uncertainty estimations than single network or stochastic methods. Although current methods still have limitations in accurately quantifying uncertainty, particularly in the case of dataset shift, incorporating uncertainty estimates with a classification with a rejection option improves the ability to detect such changes. Moreover, we show that using uncertainty estimates as a criterion for sample selection in active learning setting results in greater improvements in classification performance compared to random sampling. © 2023 The Author(s)

Evidence Mapping of ctDNA Reporting in Pancreatic Ductal Adenocarcinoma: Toward a Shared Quantitative Language for ctDNA

Item Type Journal Article

Author D. Croagh

Author S. Aslani

Abstract Background/Objectives: Circulating tumour DNA (ctDNA) assays enable non-invasive assessment of tumour burden and treatment response in oncology. However, quantitative ctDNA outputs (such as variant allele frequency, tumour fraction, and aggregate burden scores) remain difficult to interpret and compare across platforms. This evidence-mapping review evaluates current quantitative reporting approaches in pancreatic ductal adenocarcinoma (PDAC) and examines the potential role of KRAS mutant ctDNA as a biologically grounded reference metric. Methods: A systematic literature search was conducted across PubMed/MEDLINE and Scopus to identify studies reporting quantitative ctDNA metrics in PDAC. Eligible studies included those measuring plasma KRAS mutations and/or reporting variant allele frequency, tumour fraction, or multi-locus aggregate metrics. Additional relevant primary studies identified through broader manual searching of PubMed were assessed against the same prespecified eligibility and classification criteria before inclusion. Data were synthesised narratively, focusing on reporting frameworks, units of measurement, assay characteristics, and the interpretability of quantitative outputs across platforms. Results: Substantial heterogeneity was observed in ctDNA quantification methods and reporting standards. Ratio-based metrics such as variant allele frequency and tumour fraction were commonly used but varied according to assay design, plasma input volume, and background cell-free DNA levels. Few studies reported absolute mutant molecule counts per unit volume. Given that approximately 90–95% of PDACs harbour truncal activating KRAS mutations, plasma KRAS was consistently represented across platforms and demonstrated potential as a shared quantitative anchor. Limited standardisation was noted in distinguishing detectability from quantifiability based on sampling depth and counting statistics. Conclusions: Current ctDNA reporting in PDAC lacks a shared quantitative reference, limiting cross-study comparability. Reporting KRAS mutant molecules per millilitre and adopting an assay-agnostic framework distinguishing detection from quantification may improve interpretability, support harmonisation across platforms, and facilitate cumulative learning in pancreatic cancer ctDNA research. © 2026 by the authors.

Evidence-based medicine and electrophysiology in schizophrenia

Item Type Journal Article

Author S. Galderisi

Author A. Mucci

Author U. Volpe

Author N. Boutros

Abstract In research on schizophrenia electrophysiological measures have been investigated to identify biomarkers of the disorder, indices enabling differential diagnosis among psychotic disorders, prognostic indicators or endophenotypes. The present systematic review will focus on the most largely studied electrophysiological indices, i.e., qualitative or quantitative (limited to spectral analysis) EEG and the P300 event-related potential. The PubMed clinical query was used with research methodology filters for each of the following categories: diagnosis/prognosis/aetiology and a broad sensitive search strategy. The key-words: SCHIZOPHRENIA AND EEG/P3/P300 were used. The search results were then narrowed by including the terms "human" and "English language", and cross-referenced. Systematic reviews and meta-analyses, when available, were also used for cross-referencing. Case reports and studies irrelevant to the topics and methodologies under examination were excluded. The remaining papers were screened to verify the eligibility for this systematic review. Inclusion criteria were: a) a diagnosis of schizophrenia confirmed by DSM-III/ICD-9 criteria (or later editions of the same classification systems); b) the inclusion of both a schizophrenia study group and an healthy control group (when appropriate, i.e., for P300 and quantitative EEG); c) qualitative or spectral EEG findings and amplitude measures for P300. The included studies were then reviewed to verify homogeneity of the results, as well as the presence of the information needed for the present systematic review and meta-analysis. Previous reviews and studies meeting the above requirements (n=22 for qualitative EEG; n=45 for spectral EEG and n=132 for P300) were classified according to the Oxford Centre for Evidence-based Medicine (EBM) levels of evidence criteria. For qualitative EEG as a diagnostic test, the majority of studies predated the introduction of DSM-III and were excluded from the review. Few post DSM-III studies investigated the usefulness of qualitative EEG in the differential

diagnosis between schizophrenia and psychosis due to general medical condition. None of them was Oxford CEBM level 3b (non-consecutive-study or cohort-study without consistently-applied reference standard) or better (exploratory or validating cohort-study). No meta-analysis could be conducted due to the lack of reliable quantification methods in the reviewed studies. For spectral EEG as a diagnostic test, most studies qualified as level 4 (case-control study with poor reference standard), and only 24% as level 3b or better. An increase of slow activity in patients is reported by most of these studies. As to meta-analyses examining 29 studies, with 32 independent samples for the delta band and 35 for the theta band, a moderate effect size was found and only 1 study yielded findings in the opposite direction for both measures. There was no identified source for the discrepancy. The analysis of moderator factors included medication, band frequency limits, spectral parameters and disease stage. The medication status was significant for the theta band but the effect was unclear as findings for drug-naïve and drug-free patients were in a different direction. Chronicity had a significant effect on both delta and theta bands, with slow activity increase larger in chronic than in first episode patients. For P3 amplitude reduction as a diagnostic index, 63% of the studies qualified as level 3b or better. Meta-analysis (52 studies, 60 independent samples) results demonstrated a large effect size. None of the studies reported opposite findings. The analysis of moderator factors, including medication status and disease stage, revealed no significant effect on data heterogeneity. In conclusion, the examined indices are good candidates but are not ready yet for clinical applications aimed to improve present diagnostic standards for schizophrenia. Further research carried out according to adequate methodological standards and based on large scale multi-center studies is mandatory.

Abstract Machine learning interatomic potentials have been widely used to facilitate large-scale molecular simulations with accuracy comparable to ab initio methods. To ensure the reliability of the simulation, the training dataset is iteratively expanded through active learning, where uncertainty serves as a critical indicator for identifying and collecting out-of-distribution data. However, existing uncertainty quantification methods tend to involve either expensive computations or compromise prediction accuracy. Here we show an evidential deep learning framework for interatomic potentials with a physics-inspired design. Our method provides uncertainty quantification without significant computational overhead or decreased prediction accuracy, consistently outperforming other methods across a variety of datasets. Furthermore, we demonstrate applications in exploring diverse atomic configurations, using examples including water and universal potentials. These results highlight the potential of our method as a robust and efficient alternative for uncertainty quantification in molecular simulations. © The Author(s) 2025.

Abstract Deterministic neural nets have been shown to learn effective predictors on a wide range of machine learning problems. However, as the standard approach is to train the network to minimize a prediction loss, the resultant model remains ignorant to its prediction confidence. Orthogonally to Bayesian neural nets that indirectly infer prediction uncertainty through weight uncertainties, we propose explicit modeling of the same using the theory of subjective logic. By placing a Dirichlet distribution on the class probabilities, we treat predictions of a neural net as subjective opinions and learn the function that collects the evidence leading to these opinions by a deterministic neural net from data. The resultant predictor for a multi-class classification problem is another Dirichlet distribution whose parameters are set by the continuous output of a neural net. We provide a preliminary analysis on how the peculiarities of our new loss function drive improved uncertainty estimation. We observe that our method achieves unprecedented success on detection of out-of-distribution queries and endurance against adversarial perturbations. © 2018 Curran Associates Inc. Evidential Fuzzy Rule-Based Machine Learning to Quantify Classification Uncertainty

Item Type Conference Paper

Author H. Shiraishi

Author H. Ishibuchi

Author M. Nakata

Editor Ochoa G.

Abstract Learning Fuzzy-Classifier Systems (LFCSSs), also known as evolutionary fuzzy rule-based machine learning, combine evolutionary algorithms with fuzzy rules to create interpretable models. However, traditional inference schemes lack mechanisms to quantify uncertainty in predictions. This paper introduces a novel class inference scheme based on the Dempster-Shafer Theory of Evidence that explicitly models epistemic uncertainty through an “I don’t know” state. By calculating belief masses for each class hypothesis and uncertainty, our approach enhances robustness in real-world applications. Experiments on real-world datasets demonstrate statistically significant improvements in classification performance compared to conventional approaches. Our method forms smoother decision boundaries and provides quantitative measures of prediction confidence, addressing a critical gap in reliable decision-making for fuzzy rule-based machine learning. © 2025 Copyright held by the owner/author(s).

Evolutionary optimization of weights of a neuro-fuzzy classifier and the effects on benchmark data and complex chemical data

Item Type Conference Paper**Author** J. Paetz

Abstract The integral part of adaptive systems are learning algorithms that are often based on heuristics. Such algorithms are used for neural network, fuzzy system and neuro-fuzzy system training. The performance can be measured on benchmark data. In this contribution we evaluate the performance of a neuro-fuzzy system with respect to the adapted weights. A comparison is given between the performance using the trained set of weights and two sets of optimized weights. Evolutionary algorithms can be used for optimizing the trained weights and for optimizing the weights directly without using the adapted weights as a basis. Additionally, all weights are set to one to measure the influence of the weight values. The results show that the weights have only a small impact on performance using benchmark data, but a high impact when using more complex, higher dimensional chemical data with skewed a priori probabilities. © 2005 IEEE.

Evolving Intelligent Network Attack Classifier Under Label Distribution Shift

Item Type Journal Article**Author** M. Kim**Author** M. Joe**Author** M. Kwon

Abstract The next-generation internet is being reshaped by the growing intelligence and connectivity of artificial intelligence of things (AIoT) devices. This evolution emphasizes the importance of AI-enabled network intrusion detection systems (NIDS) in intelligent network environments. Two major technical challenges in developing such systems are addressing class imbalance and adapting to label distribution shifts after deployment. Class imbalance, caused by the dominance of normal traffic and the scarcity and uneven distribution of attack types, often results in low performance for minority attack type classes. In addition, evolving attack patterns necessitate efficient and continuous model post-training, despite the limited and unlabeled data available in the post-deployment phase. This study proposes a unified training framework consisting of a two-step pre-training scheme and an adaptive post-training scheme. In Step I of pre-training, balanced contrastive pair selection is performed to account for class imbalance, while Step II refines the representations of hard-to-distinguish samples located near decision boundaries using latent features. In the post-training phase, the framework leverages both model outputs and latent representations to generate reliable pseudo-labels for learning. A key insight of this work is that a well-structured latent representation space enables reliable pseudo-labeling during post-training. Extensive simulations across eight online label shift scenarios with three datasets demonstrate that the proposed method achieves up to an 8.6% improvement in accuracy and F1-score over eight state-of-the-art approaches, along with a significant reduction in post-training complexity. © 2026 IEEE.

Expand and Shrink: Federated Learning with Unlabeled Data Using Clustering

Item Type Journal Article

Author A. Kumar

Author A.K. Singh

Author S.S. Ali

Author B.J. Choi

Abstract The amalgamation of the Internet of Things (IoT) and federated learning (FL) is leading the next generation of data usage due to the possibility of deep learning with data privacy preservation. The FL architecture currently assumes labeled data samples from a client for supervised classification, which is unrealistic. Most research works in the literature focus on local training, update receiving, and global model updates. However, by principle, the labeling must be performed on the client side because the data samples cannot leave the source under the FL principle. In the literature, a few works have proposed methods for unlabeled data for FL using “class-prior probabilities” or “pseudo-labeling”. However, these methods make either unrealistic or uncommon assumptions, such as knowing class-prior probabilities are impractical or unavailable for each classification task and even more challenging in the IoT ecosystem. Considering these limitations, we explored the possibility of performing federated learning with unlabeled data by providing a clustering-based method of labeling the sample before training or federation. The proposed work will be suitable for every type of classification task. We performed different experiments on the client by varying the labeled data ratio, the number of clusters, and the client participation ratio. We achieved accuracy rates of (Formula presented.) and (Formula presented.) by using (Formula presented.) and (Formula presented.) of the truth

labels, respectively. © 2023 by the authors.

Experiential Equity: Reconstructing Cities Through Intersecting Theories

Item Type Journal Article

Author R. Mazumder

Abstract Considering the unprecedented rate of global urbanisation, attention must be paid to the implications of city environments on human health. Urban infrastructures, like parks, greenspace, active transportation, and other forms of public space, are seen as health amenities. The concept of distributional equity acknowledges the disparities in

access to these health-supporting spaces; however, more granularity is needed in understanding how these spaces themselves are experienced, and the impact of marginalisation and other forms of oppression on the health benefits must be examined. Experiential equity is a framework that can be used to conceptualise and quantify the energetic cost of experiencing unpredictable urban environments, using the free energy principle to unite the energetic costs of the emotional and cognitive burden of marginalisation, and views these costs through an Intersectional Theoretical lens to establish the energetic disparities that exist depending on aspects of identity. The cognitive and emotional costs of uncertainty in urban environments can be understood through the Theory of Constructed Emotion, the model is also informed by environmental prediction and provides a link to the psychophysiology of Racism-Related Vigilance and Stereotype Threat. Applying the Person-Environment-Occupation Model and Affordance Theory, in conjunction, we can conceptualise the environment and examine the ways in which it can constrain or enable engagement with it. Leveraging machine learning to quantify aspects of the built environment and using neuroscientific methodologies like electroencephalography, electrodermal activity, and heart rate variability, we can attempt to metricise the energetic costs of societal and systemic oppression; the consideration of the environment allows potential insights into how spatial variables mediate these experiences and can have implications on road, park, and general urban policy and design. © The Editor(s) (if applicable) and The Author(s), under exclusive license to Springer Nature Switzerland AG 2024, Corrected Publication 2024, 2025.

Experimental analysis of feature selection stability for high-dimension and low-sample size gene expression classification task

Item Type Conference Paper

Author D. Dernoncourt

Author B. Hanczar

Author J.-D. Zucker

Abstract Gene selection is a crucial step when building a classifier from microarray or metagenomic data. As the number of observations is small, the gene selection tends to be unstable. It is common that two gene subsets, obtained from different datasets but dealing with the same classification problem, do not overlap significantly. Although it is a crucial problem, few works have been done on the selection stability. In this paper, we first present some stability quantification methods, then we study the variations of those measures with various parameters (dimensionality, sample size, feature distribution, selection threshold) on both artificial and real data, as well as the resulting classification performance. Feature selection was performed with t-test and classification with linear discriminant analysis. We point out a strong empiric correlation between the dimensionality/sample size ratio and selection instability. © 2012 IEEE.

Abstract Every subject and course has a learning goal that we work towards during the teaching-learning process, whether it be online or offline. Under the current system, assignments, project analysis, semester exams, and internal exams are used to evaluate students' learning. Several factors, including participation in class, prior knowledge, engagement time, activity logs, forum posts, understanding level, etc., influence how well students learn throughout a course or session. All these factors will be difficult to analyze in offline mode. All of these activities determine whether or not the learning objective is met. This study examines an experiment that provided blended learning data on students' academic details, learning behaviors, and evaluation modules to determine the success of the two subjects. It discussed the details of each phase involved in the experiment. Students enrolled in integrated courses, MTech(PG-1) and MCA(PG-2) were analyzed in this study procedure through 4 weeks of offline classes. Moodle Gnomio was used for the online processes related to the Registration process, Quizzes, and discussion forums. A total of 6 quizzes for PG-1(M-Tech) and PG-2(MCA) were organized, and learning resources were provided before the exam. This study discusses detailed experiment setup, and Statistical analysis involving difficulty level of quizzes. This study proposed a framework for the dashboard that utilize this dataset and involves analysis related to student performance, grade distribution, inferring learning patterns, and course success. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2024.

Abstract Application of clinical gait analysis (CGA) in the evaluation of Hip Osteoarthritis (HOA) is a crucial step in the identification of functional abnormalities and surgical planning through total hip arthroplasty (THA). Measured kinematic

parameters provide understanding of the gait patterns that can be used for accurate diagnostics and personalized rehabilitation. Streamlined approach is essential for efficient assessment due to the substantial amount of data generated. This study aims to explore the use of Deep Learning (DL) methodology in the classification of gait patterns before and after THA. All kinematic parameters of both lower limbs are aggregated, and a 2-dimensional data representation is acquired as input to the DL model. The best classification accuracy is 98.2% from the test subset. Consequently, model prediction is explained through Local Interpretable Model-Agnostic Explanation (LIME) to determine input features that best distinguish between gait classes. Features are ranked in terms of their relevancy, and only the most common discriminating features are considered for further analysis. Generally, the sagittal hip angle is the most significant kinematic parameter across classes, albeit from different gait cycle events. All healthy and 75% of the HOA gaits in the test subset exhibit discrimination on the single limb support towards the swing phase. The sagittal angles of the knee and ankle during the same gait events are also discriminatory for HOA with 72% of the gaits exhibiting such feature. Additionally, the same kinematic angles are important for THA class prior to heel rise of the stance phase with 85% of the gaits examined. With features acquired directly from the input data, explanation is more transparent promoting trust and understanding of the DL model. High accuracy scores coupled with explainability showcases clinical relevance and a potential for aiding medical experts in crucial decision making for HOA patients before and after THA. © 2025 Elsevier B.V.. Explainable long-term building energy consumption prediction using QLattice

Item Type Journal Article

Author S. Wenninger

Author C. Kaymakci

Author C. Wiethe

Abstract The global building sector is responsible for nearly 40% of total carbon emissions, offering great potential to move closer to set climate goals. Energy performance certificates designed to increase the energy efficiency of buildings require accurate predictions of building energy performance. With significant advances in information and communication technology, data-driven methods have been introduced into building energy performance research demonstrating high computational efficiency and prediction performance. However, most studies focus on prediction performance without considering the potential of explainable artificial intelligence. To bridge this gap, the novel QLattice algorithm, designed to satisfy both aspects, is applied to a dataset of over 25,000 German residential buildings for predicting annual building energy performance. The prediction performance, computation time, and explainability of the QLattice is compared to the established machine learning algorithms artificial neural network, support vector regression, extreme gradient boosting, and multiple-linear regression in a case study, variable importance analyzed, and appropriate applications proposed. The results show quite strongly that the QLattice should be further considered in the research of energy performance certificates and may be a potential alternative to established machine learning algorithms for other prediction tasks in energy research. © 2021 Elsevier Ltd

Explainable machine learning to quantify the value of proximal remote sensing in latent energy flux estimation

Item Type Journal Article

Author S. Gaur

Author G. Aslan-Sungur (Rojda)

Author A. VanLoocke

Author D.T. Drewry

Abstract Proximal remote sensing has the potential to provide critical information on vegetation biophysical factors that can predict land-atmosphere exchange of water and energy. Latent energy (LE) flux is traditionally estimated using process-based models which rely on vegetation parameters that change during the growing season. Data-driven models have the potential to address these issues by offering flexible predictor selection and more efficient utilization of the information in predictor sets. These models require careful choice of predictors to avoid redundancy and allow robust cross-validation. In this study we present a systematic and comprehensive evaluation of machine learning (ML) models to assess the capability of meteorological and proximal sensing data for predicting LE at a half-hourly temporal resolution across multiple growing seasons for an agricultural system. The results presented here demonstrate that a model using four environmental predictors in combination with two proximal sensing variables can capture 88 % of the variability in LE. ML models using only three predictors (one meteorological and two proximal remote sensing) captured 81 % of LE variability, offering the best trade-off between performance and complexity. An ML model utilizing only two predictors, one proximal remote sensing variable and downwelling radiation, captured 77 % of LE variability. These results demonstrate the power of proximal remote sensing and meteorological observations to estimate land-atmosphere water vapor exchange, providing a solution where more direct methods such as eddy covariance are not available and for evaluations of agronomic management and genotypic variations. © 2025 The Authors

Explainable multi-sensor geospatial modeling of forest biomass dynamics under compound climate extremes in subtropical monsoon regions

Item Type Journal Article**Author** B. Xu**Author** T. Dang**Author** X. Wu

Abstract Climate extremes are intensifying worldwide, yet the mechanisms by which forest biomass responds to compound climatic and anthropogenic pressures remain poorly resolved. Here, we integrate multi-sensor remote sensing with explainable machine learning to quantify the interactions between multiple drivers and changes in aboveground biomass density (Δ AGBD) across a subtropical monsoon region of China during 2000–2019. Annual Δ AGBD maps were derived from Landsat and GEDI, and hotspots of climatic extremes were delineated using ETCCDI (Expert Team on Climate Change Detection and Indices). Across 92 predictors, attribution indicates that—even within areas exposed to extremes—AGBD is not driven by extreme events alone. Bioclimatic and extreme-climate variables dominate overall variability, whereas topography and human disturbance strongly modulate their effects. Gradient analyses further show that climatic influences intensify with elevation and heat load, whereas anthropogenic impacts remain pronounced at low population densities and in areas distant from impervious surfaces. Collectively, these findings demonstrate that biomass dynamics under climatic extremes do not arise from a single climatic forcing but from the mutual regulation of climate, topography, and human pressure. This nonlinear, compound-mechanism framework provides a transferable basis for assessing ecosystem vulnerability and designing adaptive, resilience-oriented management strategies under intensifying climate extremes. © 2026 The Author(s). Explainable uncertainty quantifications for deep learning-based molecular property prediction

Item Type Journal Article

Author C.-I. Yang

Author Y.-P. Li

Abstract Quantifying uncertainty in machine learning is important in new research areas with scarce high-quality data. In this work, we develop an explainable uncertainty quantification method for deep learning-based molecular property prediction. This method can capture aleatoric and epistemic uncertainties separately and attribute the uncertainties to atoms present in the molecule. The atom-based uncertainty method provides an extra layer of chemical insight to the estimated uncertainties, i.e., one can analyze individual atomic uncertainty values to diagnose the chemical component that introduces uncertainty to the prediction. Our experiments suggest that atomic uncertainty can detect unseen chemical structures and identify chemical species whose data are potentially associated with significant noise. Furthermore, we propose a post-hoc calibration method to refine the uncertainty quantified by ensemble models for better confidence interval estimates. This work improves uncertainty calibration and provides a framework for assessing whether and why a prediction should be considered unreliable. Explanations and a new objective function of the minimum error thresholding based on the Rayleigh distribution

Item Type Journal Article

Author B. Lei

Author Y. Ma

Author L. He

Author Z. Yang

Author Y. Tang

Abstract The minimum error thresholding (MET) method is based on the Bayes minimum classification error principle. Under different assumptions of the initial grayscale distribution of an image, MET criterion functions based on the mixed Gaussian distribution, mixed Poisson distribution, and shifted Rayleigh distribution have been proposed. Mathematical explanations have been presented for the MET criterion functions of mixed Gaussian and Poisson distributions from relative entropy and the joint maximum likelihood principle. However, the explanations for the MET criterion function of the shifted Rayleigh distribution (RMET) have not been presented. In this paper, the detailed joint maximum likelihood principle and relative entropy interpretations of the RMET method were presented, and the principles for calculating the class parameters in the RMET method were also explained. Moreover, since the class prior probability is unknown, it is more reasonable to use conditional likelihood estimation. Therefore, a new MET method of the shifted Rayleigh distribution is proposed based on the conditional maximum likelihood function. Performance tests on synthetic images, synthetic aperture radar (SAR) images, and natural images in the experiments confirm the effectiveness of the proposed new MET algorithm. © 2025 Elsevier Ltd

Exploiting Feature Interactions for Malicious Website Detection with Overhead-accuracy Tradeoff

Item Type Conference Paper

Author S. Shen

Author C. Yu

Author K. Zhang

Author S. Ci

Abstract Malicious websites attempt to install malware on user's devices without permission, which can disrupt device operation, steal personal information, and even acquire access to the device for future attacks. Accurate detection of malicious website behaviors is crucial for network security but still faces challenges. Firstly, various types and semantics of website features are required to identity the wide range of malicious characteristics, leading to massive training data and computational overhead. Secondly, to reduce model dimensionality, a proper selection of website features is essential but difficult due to the complex relations among features that can affect each other's contribution to detection outcomes. In this paper, we propose a lightweight feature-based detection scheme against malicious websites considering the interaction measures among features and the overhead-accuracy tradeoff. Specifically, we systematically characterize the interactions among website features in a non-additive manner to indicate the aggregated impacts of feature subsets. Then we propose a quantification method to measure the feature interactions based on multivariate regression. With this method, important features are selected to substantially reduce the model dimension and computational complexity while maintaining desirable accuracy. Meanwhile, the proposed scheme provides an interpretable model that preserves the physical meanings of original features. It allows users to balance the overhead-accuracy tradeoff for detection model training through feature subset selection to fit the requirements and constraints of real applications. © 2021

Exploiting physics-based machine learning to quantify geodynamic effects – insights from the Alpine region

Item Type Journal Article**Author** D. Degen**Author** A. Kumar**Author** M. Scheck-Wenderoth**Author** M. Cacace

Abstract Geodynamical processes are important to understand and assess the evolution of the Earth system as well as its natural resources. Given the wide range of characteristic spatial and temporal scales of geodynamic processes, their analysis routinely relies on computer-assisted numerical simulations. To provide reliable predictions such simulations need to consider a wide range of potential input parameters, material properties as they vary in space and time, in order to address associated uncertainties. To obtain any quantifiable measure of these uncertainties is challenging both because

of the high computational cost of the forward simulation and because data is typically limited to direct observations at the near surface and for the present-day state. To account for both of these challenges, we present how to construct efficient and reliable surrogate models that are applicable to a wide range of geodynamic problems using a physics-based machine learning method. In this study, we apply our approach to the case study of the Alpine region, as a natural example for a complex geodynamic setting where several subduction slabs as imaged by tomographic methods interact below a heterogeneous lithosphere. We specifically develop surrogates for two sets of observables, topography and surface velocity, to provide models that can be used in probabilistic frameworks to validate the underlying model structure and parametrization. We additionally construct models for the deeper crustal and mantle domains of the model, to improve the system understanding. For this last family of models, we highlight different construction methods to develop models to either allow evaluations in the entirety of the 3D model or only at specific depth intervals. © 2025 Denise Degen et al.

Exploration of genomic, proteomic, and histopathological image data integration methods for clinical prediction

Item Type Conference Paper

Author A. Poruthoor

Author J.H. Phan

Author S. Kothari

Author M.D. Wang

Abstract The emergence of large multi-platform and multi-scale data repositories in biomedicine has enabled the exploration of data integration for holistic decision making. In this research, we investigate multi-modal genomic, proteomic, and histopathological image data integration for prediction of ovarian cancer clinical endpoints in The Cancer Genome Atlas (TCGA). Specifically, we study two data integration techniques, simple data concatenation and ensemble classification, to determine whether they can improve prediction of ovarian cancer grade or patient survival. Results indicate that integration via ensemble classification is more effective than simple data concatenation. We also highlight several key factors impacting data integration outcome such as predictability of endpoint, class prevalence, and unbalanced representation of features from different data modalities. © 2013 IEEE.

Explore the RNA-sequencing and the next-generation sequencing in crops responding to abiotic stress

Item Type Journal Article**Author** A. Kido**Author** J.R.C. Ferreira-Neto**Author** E. Binneck**Author** M. da Silva**Author** W. da Silva**Author** A.M. Benko-Iseppon

Abstract Most of the environmental stresses damage crops provoking economic losses. Molecular characterization of genotypes identifying suitable genes helps breeders to develop abiotic stress-tolerant crops. Among the omics technologies, transcriptomics represents the most informative techniques for global gene expression profiling of an organism, organ/tissue, or even cell at a given snapshot in time. In this context the next-generation sequencing technologies revolutionized plant transcriptomics, particularly nonmodel plants of economic interest, enhancing the high-throughput data generated from biological samples. This chapter shows an updated RNA-Seq (sequencing of RNA) overview covering scientific reports published in the last 5 years. The assortment of the data-mined RNA-Seq studies concerning relevant issues identified the most studied crops, abiotic stresses, plant organs/tissues, stress-treatment exposition time, global or specific gene expression profiling, noncoding RNA approach, extra omics data, supplementary physiological data, studied accession(s), transcriptome assembly approach, gene expression validation process, relative quantification method, and reference gene(s) in the qPCR assays. Besides, an overall RNA-Seq analysis workflow, covering data generation, raw data processing, and data analysis, was provided, together with some information involving transcriptome assembly, quality of the transcriptome assembly, transcript quantification, differential expression analysis, and annotation/functional analysis. Finally, in the functional genomics topic, the integration of multiomic data stands out, improving our understanding of genetic networks, which helps us to envision machine learning strategies and genome editing applications involving agronomic characteristics. These approaches may help plant breeders identify new genes and related metabolic subpathways associated with relevant agronomic traits. © 2022 Elsevier Inc. All rights reserved.

Exploring federated learning in optical music recognition

Item Type Journal Article

Author E. Ayllon

Author B. Serrano Sánchez

Author J. Calvo-Zaragoza

Abstract Optical Music Recognition (OMR) technology plays a crucial role in the preservation of cultural heritage by automating the digitization of music documents, enabling their storage in symbolic formats and their subsequent analysis through digital tools. Progress in this field is, however, constrained by limited data availability: access to or distribution of music collections is frequently restricted due to legal or ownership barriers. This work investigates a potential mitigation of this issue through Federated Learning (FL) strategies, which enable decentralized training and eliminate the need to release restricted collections. Our methodology assumes a setting in which client nodes operate on small, heterogeneous corpora, while evaluation is conducted on established OMR benchmark collections. We examine widely used FL aggregation techniques, such as FedAvg, FedProx, and SCAFFOLD; as well as modern methodologies, such as FedKT. In addition, we introduce two modules specifically designed for OMR: FedClassPrior, which integrates class-prior information to improve symbol balance, and FedNGram, which supports decentralized language modelling to exploit notational regularities during decoding. Experimental results show consistent accuracy improvements when using FL compared to purely local training. Furthermore, the proposed modules substantially narrow the performance gap between standard FL and the ideal scenario in which centralized training is feasible. © 2026 The Authors

Exploring Label Correlations for Quantification of ICD Codes

Item Type Conference Paper

Author I. Coutinho

Author B. Martins

Editor Bifet A.

Editor Lorena A.C.

Editor Ribeiro R.P.

Editor Gama J.

Editor Abreu P.H.

Abstract The International Classification of Diseases (ICD) has been adopted worldwide in the healthcare domain, e.g. to summarize the key information in clinical documents. Since manual ICD coding is very expensive, time-consuming, and error-prone, deep learning algorithms have been proposed to automate this task. However, the final goal of ICD coding often lays not in determining the codes associated with individual documents, but instead in quantifying the prevalence of each code within sets of documents. In this work, we experimentally assess different quantification methods in connection to ICD coding, including a simple learning-based approach that leverages associations between the codes, in order to predict their relative frequencies more accurately. Experiments show that the proposed approach can effectively explore existing associations between ICD codes, improving the quantification performance over baseline methods that deal

with each code independently. © 2023, The Author(s), under exclusive license to Springer Nature Switzerland AG.

Author E. Diaz-Mohedo

Abstract Background: Pelvic floor dysfunctions (PFDs) encompass an array of conditions with discrepant classification systems, hampering accurate prevalence estimation. Despite potentially affecting up to 25% of women during their lifetime, many remain undiagnosed, underestimating the true extent. Objectives: This cross-sectional study aimed to examine the impacts of the menstrual cycle on PFDs and dysfunctions. Secondary objectives included investigating differences between athletic and nonathletic women. Methods: An online questionnaire examined the effects of the menstrual cycle (MC) on 477 women's pelvic symptoms (aged 16–63 years), stratified by athletic status. This ad hoc instrument built upon a validated screening tool for female athletes. Results: Most participants reported symptom fluctuations across menstrual phases, with many modifying or reducing exercise participation. A concerning number experienced daily undiagnosed pelvic floor symptoms, emphasizing needs for comprehensive medical evaluation. Conclusions: Exacerbated pelvic symptoms showed complex relationships with menstruation, highlighting the importance of considering the MC in customized clinical management approaches. Symptoms demonstrated differential links to menstruation, indicating needs for individualized evaluation and tailored treatment plans based on symptom profiles and hormonal interactions. Educating professionals and patients remains essential to enhancing awareness, detection, and therapeutic outcomes. Further controlled longitudinal research should elucidate intricate relationships between menstrual cycles and pelvic symptom variability. © 2024 by the authors.

Exploring the Impact of Alternatives of Object-Oriented Cohesion Measures on Machine Learning-Based Predictions of Inheritance Reusability

Item Type Journal Article

Author J. Al Dallal

Author B. Alkhazi

Abstract The cohesion of an object-oriented class refers to the relatedness of its methods and attributes. Constructors, destructors, and access methods are special types of methods featuring unique characteristics that can artificially affect class cohesion quantification. Methods within a class can also directly or transitively invoke each other, representing another cohesion aspect not considered by most existing cohesion measures. The impact of considering special methods (SPs) and transitive relations (TRs) in cohesion measurement on the abilities of the measures to predict inheritance reusability has yet to be investigated. In this paper, we empirically explored this effect. We applied a statistical technique to test the significance of the cohesion value changes across seven scenarios of ignoring or considering SPs and TRs. In addition, we applied a machine learning-based technique to build inheritance reusability prediction models using each of the considered measures and scenarios, evaluated the classification performance of the prediction models, and statistically compared the inheritance reusability prediction results. The results show that for most of the considered measures, the ignorance/consideration of SPs and TRs changed the cohesion values and the corresponding prediction significantly. Based on the study findings, when building inheritance reusability prediction models, software engineers are advised to 1) combine cohesion with other quality factors; 2) exclude the TRs from cohesion quantification; and 3) decide whether to consider or ignore SPs in cohesion quantification based on the selected measure(s) to be used in the prediction model, as this decision differs from one measure to another. © 2024 The Authors.

Exploring the Trade-Off between generalist and specialized Models: A center-based comparative analysis for glioblastoma segmentation

Item Type Journal Article

Author F. Javier Gil-Terrón

Author P. Ferri

Author V. Montosa-i-Micó

Author M. Gómez Mahiques

Author C. Lopez-Mateu

Author P. Martí

Author J.M. García-Gómez

Author E. Fuster-Garcia

Abstract Introduction: Inherent variations between inter-center data can undermine the robustness of segmentation models when applied at a specific center (dataset shift). We investigated whether specialized center-specific models are more effective compared to generalist models based on multi-center data, and how center-specific data could enhance the performance of generalist models within a particular center using a fine-tuning transfer learning approach. For this purpose, we studied the dataset shift at center level and conducted a comparative analysis to assess the impact of data source on glioblastoma segmentation models. Methods & Materials: The three key components of dataset shift were studied: prior probability shift—variations in tumor size or tissue distribution among centers; covariate shift—inter-center MRI alterations; and concept shift—different criteria for tumor segmentation. BraTS 2021 dataset was used, which includes 1251 cases from 23 centers. Thereafter, 155 deep-learning models were developed and compared, including 1) generalist models trained with multi-center data, 2) specialized models using only center-specific data, and 3) fine-tuned generalist models using center-specific data. Results: The three key components of dataset shift were characterized. The amount of covariate shift was substantial, indicating large variations in MR imaging between different centers. Glioblastoma segmentation models tend to perform best when using data from the application center. Generalist models, trained with over 700 samples, achieved a

median Dice score of 88.98%. Specialized models surpassed this with 200 cases, while fine-tuned models outperformed with 50 cases. Conclusions: The influence of dataset shift on model performance is evident. Fine-tuned and specialized models, utilizing data from the evaluated center, outperform generalist models, which rely on data from other centers. These approaches could encourage medical centers to develop customized models for their local use, enhancing the accuracy and reliability of glioblastoma segmentation in a context where dataset shift is inevitable. © 2024 The Authors

Exploring Turbulence and micro-scale mixing mechanisms for enhancing jet impingement heat transfer using micro-roughness elements: A data-driven and numerical analysis

Item Type Journal Article

Author K. Nagesha

Abstract This study uses machine learning to quantify micro-scale mixing mechanisms that enhance jet impingement heat transfer. Experiments and computational fluid dynamics (CFD) simulations tested flat, discrete protrusion, and continuous V-groove surfaces under Reynolds numbers(ReN) from 10,000 to 27,500 and nozzle-to-plate distances(NPD) between 2 and 5 times the diameter of the nozzle. An integrated approach combining experimental data, CFD, and four neural network models was used for comprehensive turbulence analysis. The neural networks, trained on the combined sixty datasets, showed high predictive accuracy with R-squared over 0.999 and Mean Absolute Error over 1e-7. The results highlight that micro-scale turbulence, characterized by Reynolds stress, dominates over operating parameters such as ReN and NPD in enhancing heat transfer. Discrete protrusions actively disrupt the thermal boundary layer, promoting vigorous mixing, while weaker turbulence and insulation effects in V-grooves contribute less. Percentage change analysis shows protrusions are more effective at extracting energy from jet and generating turbulence at smaller NPDs, but V-groove performance increases more strongly with rising distance. This data-driven analysis provides insight into surface roughness-induced mixing mechanisms and compares key turbulence parameters to assess thermal performance. The advanced understanding will aid in developing optimized designs for improved heat transfer in practical applications. © 2025 Elsevier Ltd

Extended a Priori Probability (EAPP): A Data-Driven Approach for Machine Learning Binary Classification Tasks

Item Type Journal Article

Author V.O. Castello

Author F.J. Perez-Benito

Author O.D.T. Catala

Author I.S. Igual

Author R. Llobet

Author J.-C. Perez-Cortes

Abstract The a priori probability of a dataset is usually used as a baseline for comparing a particular algorithm's accuracy in a given binary classification task. ZeroR is the simplest algorithm for this, predicting the majority class for all examples. However, this is an extremely simple approach that has no predictive power and does not describe other dataset features that could lead to a more demanding baseline. In this paper, we present the Extended A Priori Probability (EAPP), a novel semi-supervised baseline metric for binary classification tasks that considers not only the a priori probability but also some possible bias present in the dataset as well as other features that could provide a relatively trivial separability of the target classes. The approach is based on the area under the ROC curve (AUC ROC), known to be quite insensitive to class imbalance. The procedure involves multiobjective feature extraction and a clustering stage in the input space with autoencoders and a subsequent combinatory weighted assignation from clusters to classes depending on the distance to nearest clusters for each class. Class labels are then assigned to establish the combination that maximizes AUC ROC for each number of clusters considered. To avoid overfit in the combined feature extraction and clustering method, a cross-validation scheme is performed in each case. EAPP is defined for different numbers of clusters, starting from the inverse of the minority class proportion, which is useful for a fair comparison among diversely imbalanced datasets. A high EAPP usually relates to an easy binary classification task, but it also may be due to a significant coarse-grained bias in the dataset, when the task is previously known to be difficult. This metric represents a baseline beyond the a priori probability to assess the actual capabilities of binary classification models. © 2013 IEEE.

Extending Adversarial Attacks to Produce Adversarial Class Probability Distributions

Item Type Journal Article**Author** J. Vadillo**Author** R. Santana**Author** J.A. Lozano

Abstract Despite the remarkable performance and generalization levels of deep learning models in a wide range of artificial intelligence tasks, it has been demonstrated that these models can be easily fooled by the addition of imperceptible yet malicious perturbations to natural inputs. These altered inputs are known in the literature as adversarial examples. In this paper, we propose a novel probabilistic framework to generalize and extend adversarial attacks in order to produce a desired probability distribution for the classes when we apply the attack method to a large number of inputs. This novel attack paradigm provides the adversary with greater control over the target model, thereby exposing, in a wide range of scenarios, threats against deep learning models that cannot be conducted by the conventional paradigms. We introduce four different strategies to efficiently generate such attacks, and illustrate our approach by extending multiple adversarial attack algorithms. We also experimentally validate our approach for the spoken command classification task and the Tweet emotion classification task, two exemplary machine learning problems in the audio and text domain, respectively. Our results demonstrate that we can closely approximate any probability distribution for the classes while maintaining a high fooling rate and even prevent the attacks from being detected by label-shift detection methods. ©2023 Jon Vadillo, Roberto Santana and Jose A. Lozano.

Extensions of transductive learning for distributed ensemble classification and application to biometric authentication

Item Type Journal Article

Author D.J. Miller

Author S. Pal

Author Y. Wang

Abstract We consider ensemble classification when there is no common labeled data for designing the function which aggregates classifier decisions. In recent work, we dubbed this problem distributed ensemble classification, addressing when local classifiers are trained on different (e.g., proprietary, legacy) databases or operate on different sensing modalities. Typically, fixed (untrained) rules of classifier combination such as voting methods are used in this case. However, these may perform poorly, especially when (i) the local class priors, used in training, differ from the true (test batch) priors and (ii) classifier decisions are statistically dependent. Alternatively, we proposed several transductive methods, optimizing the combining rule for objective functions measured on the test batch. We proposed both maximum likelihood (ML) and constraint-based (CB) objectives and found that CB achieved superior performance. Here, we develop CB extensions (i) for sequential

decisionmaking and (ii) exploiting additional class information contained in the local classifier feature vectors. The new sequential method is applied to biometric authentication. We demonstrate these new CB methods achieve better ensemble decision accuracy than methods which apply fixed rules in combining classifier decisions. © 2008 Elsevier B.V. All rights reserved.

Author F.A.P. Rizzante

Abstract Introduction: The aim of this study was to assess the temporal evolution of external cervical resorption (ECR) defects using a volumetric quantification method. Methods: Cone-beam computed tomographic (CBCT) images of patients diagnosed with ECR who chose not to receive treatment and attended recalls were collected. ECR defects were segmented in CBCT images at baseline and recall, and their volumes were quantified. The volumetric ratio of resorption defects/teeth was calculated. Three-dimensional classification of defects at baseline and recall and the prevalence of root surface perforations ≥ 1 mm were determined. The Wilcoxon matched pairs signed rank test, chi-square test, and linear regression models were used to analyze the data. Results: Fifteen patients with 20 teeth diagnosed with ECR and an average recall time of 21 months were included. Nine (45%) teeth showed a change in 3-dimensional classification at recall. The volume of resorption defects ($P = .0001$) and the volumetric ratio of resorption defects/teeth ($P = .0001$) increased over time. The prevalence of root surface perforations ≥ 1 mm was higher at recall ($n = 17$, 85%) compared with baseline ($n = 9$, 45%) ($P = .008$). Linear regression models showed significant associations between the resorption defect volume at recall compared with baseline ($P < .0001$; 95% confidence interval, 0.053–0.081) and the volumetric ratio of resorption defects/teeth at recall compared with baseline ($P < .0001$; 95% confidence interval, 0.205–0.356). There was no association between the volume of resorption defects at recall with the length of the recall period, sex, or age ($P > .05$). Conclusions: When left untreated, ECR defects can increase in size and develop more root surface perforations. ECR has a dynamic nature, and its volumetric increase over time does not result from uniform/linear expansion of the defects. © 2022 American Association of Endodontists

Abstract Background context: A machine learning (ML) model was recently developed to predict massive intraoperative blood loss ($>2,500$ mL) during posterior decompressive surgery for spinal metastasis that performed well on external validation within the same region in China. Purpose: We sought to externally validate this model across new geographic regions (North America and Europe) and patient cohorts. Study design: Multiinstitutional retrospective cohort study. Patient sample: We retrospectively included patients 18 years or older who underwent decompressive surgery for spinal metastasis across three institutions in the United States, the United Kingdom and the Netherlands between 2016 and 2022. Inclusion and exclusion criteria were consistent with the development study with additional inclusion of (1) patients undergoing palliative decompression without stabilization, (2) patients with multiple myeloma and lymphoma, and (3) patients who continued anticoagulants perioperatively. Outcome measures: Model performance was assessed by comparing the incidence of massive intraoperative blood loss ($>2,500$ mL) in our cohort to the predicted risk generated by the ML model. Blood loss was quantified in 7 ways (including the formula from the development study) as no gold standard exists, and the method in the development paper was not clearly defined. We estimated blood loss using the anesthesia report, and calculated it using transfusion data, and preoperative and postoperative hematocrit levels. Methods: The following five input variables necessary for risk calculation by the ML model were manually collected: tumor type, smoking status, ECOG score, surgical process, and preoperative platelet count. Model performance was assessed on overall fit (Brier score), discriminatory

ability (area under the curve (AUC)), calibration (intercept & slope), and clinical utility (decision curve analysis)) for the total validation cohort, and for the North American and European cohorts separately. A subanalysis, excluding the additional included patient groups, assessed the predictive model's performance with the same inclusion and exclusion criteria as the development cohort. Results: A total of 880 patients were included with a massive blood loss incidence ranging from 5.3% to 18% depending on the quantification method used. Using the most favorable quantification method, the predictive model overestimated risk in our total validation cohort and scored poorly on overall fit (Brier score: 0.278), discrimination (AUC: 0.631 [95%CI: 0.583, 0.680]), calibration, (intercept: -2.082, [95%CI: -2.285, -1.879]), slope: 0.283 [95%CI: 0.173, 0.393]), and clinical utility, with net harm observed in decision curve analysis from 20%. Similar poor performance results were observed in the subanalysis excluding the additional included patients (n=676) and when analyzing the North American (n=539) and European (n=341) cohorts separately. Conclusions: To our knowledge, this is the first published external validation of a predictive ML model within orthopedic surgery to demonstrate poor performance. This poor performance might be attributed to overfitting and sampling bias as the development cohort had an insufficient sample size, and distributional shift as our cohort had key differences in predictive variables used by the model. These findings emphasize the importance of extensive validation in different geographical areas and addressing biases and pitfalls of ML model development before clinical implementation, as untested models may do more harm than good. © 2025 The Author(s)

Abstract Extracellular vesicles (EVs) are lipid nano-to-micro-sized vesicles increasingly studied for their role in intercellular communication and their potential as minimally invasive molecular indicators in various diseases. However, challenges remain in characterizing specific surface molecules on EVs due to cargo heterogeneity and the lack of convenient quantification methods. In this study, we show the isolation, characterization, detection, and quantification of Trop2-carrying EVs (EV-Trop2) in serum of prostate cancer patients. This work combines the unique advantages of our

EV isolation method with ELISA to enable surface-protein-specific EV analysis directly from serum. This is, to our knowledge, the first demonstration to isolate and quantify EV-Trop2 from prostate cancer patient serum to study its expression patterns in relation to prostate cancer status. Analysis of serum samples from three patient groups: high-risk prostate cancer (n = 22), low-risk prostate cancer (n = 23), and cancer-free groups (n = 21), revealed significantly different levels of EV-Trop2 expression between the high-risk and low-risk patient groups ($p = 0.0015$) and between high-risk patient and cancer-free groups ($p < 0.0001$). Multivariate modeling further showed that EV-Trop2 contributed to improved classifier metrics across the three sample groups. These findings highlight a strategy for probing EV-associated surface targets and suggest broader applicability of this approach across multiple cancers. © 2025 The Author(s). Extraction of landcover themes out of aerial orthoimages in mountainous areas using external information

Item Type Conference Paper

Author A. Le Bris

Author D. Boldo

Abstract In mountainous areas, the landcover extraction out of orthoimages through semi-automatic classification is limited by several factors (such as large shadow areas, radiometric similarities between different themes, inhomogeneous radiometry among regions of the same class...). Image information is not sufficient to separate the different classes. Nevertheless, good results can be obtained by dividing each landcover class "c" into two subclasses "c in shadow" / "c not in shadow" and introducing external information in the classification process. This information can be an older or more generalized database, geographic knowledge concerning the links between relief and landcover, or prior information concerning shadows. This external knowledge is then interpreted in terms of a priori probabilities and merged with radiometric information from the image in a MAP per region classification process. Besides, the results can also be improved by the use of combinations of channels calculated from the initial image.

Abstract In this paper, a quantification method for sub-surface crack evaluation based on extreme learning machine (ELM) neural network is proposed to the application of alternating current field measurement (ACFM). According to simulation results of finite element model, the dimensions of cracks can be described by four features of the Bz and Bx curves. An optimized ELM feasible for ACFM detection is trained and validated based on the selected features. Taking the advantage of our proposed sub-surface crack sizing method, the experimental results indicate that the detection and quantification for sub-surface crack is conducted readily. The maximum errors of length and depth predicted by ELM can be limited to 5.65 % and 6.27 %, respectively. © 2021 Elsevier B.V.

Abstract A game changing innovation that delivers swift, precise eye care - protecting vision beforehand. The conventional approaches to diagnosing eye diseases are often inefficient and require expert intervention as well as financially burdensome, thus not optimal for widespread implementation. This study aims to discover a logical solution through the application of advanced intelligence approaches on a publicly available dataset containing 21,577 images categorized into ten classes. Prior to analysis, the dataset was processed and partitioned into training, testing and validation sets. However, the previous outcomes reached an accuracy of 89.64%, employing MobileNet model with Adam optimizer. On the contrary, our applied EfficientNetV2-M (92.50%) and ConvNeXt-Small (92.27%) with an attention mechanism to boost the accuracy through the ensemble of the models, obtained an accuracy of 93.5%, surpassing previous findings in effectiveness. Our method has the potential to be refined for clinical applications, assisting in prompt detection and intervention to prevent vision impairment. © 2025 IEEE.

Facial image analysis for fully automatic prediction of difficult endotracheal intubation

Item Type Journal Article**Author** G.L. Cuendet**Author** P. Schoettker**Author** A. Yüce**Author** M. Sorci**Author** H. Gao**Author** C. Perruchoud**Author** J.-P. Thiran

Abstract Goal: Difficult tracheal intubation is a major cause of anesthesia-related injuries with potential life threatening complications. Detection and anticipation of difficult airway in the preoperative period is, thus, crucial for the patients' safety. We propose an automatic face-analysis approach to detect morphological traits related to difficult intubation and improve its prediction. Methods: For this purpose, we have collected a database of 970 patients including photos, videos, and ground truth data. Specific statistical face models have been learned using the faces in our database providing an automated parametrization of the facial morphology. The most discriminative morphological features are selected through the importance ranking provided by the random forest algorithm. The random forest approach has also been used to train a classifier on these selected features. We compare a threshold tuning method based on class prior with two methods, which learn an optimal threshold on a training set for tackling the inherent imbalanced nature of the database. Results: Our fully automated method achieves an AUC of 81.0% in a simplified experimental setup, where only easy and difficult patients are considered. A further validation on the entire database has proven that our method is applicable for real-world difficult intubation prediction, with AUC = 77.9%. Conclusion: The system performance is in line with the state-of-

the-art medical diagnosis, based on ratings provided by trained anesthesiologists, whose assessment is guided by an extensive set of criteria. Significance: We present the first completely automatic and noninvasive difficult intubation detection system that is suitable for use in clinical settings. © 2015 IEEE.

Abstract The facial nerve is an array that encompasses motor and sensory fibers. It is one of the most common cranial nerves involved in disorders that considers congenital, traumatic, inflammatory and neoplastic disorders. Facial palsy is a common disease that results from the abnormal state of the facial nerve. In order to understand the full behavior, a quantification method for facial palsy is developed. The method that we propose uses the muscle trajectory information in order to perform a comparison between the right and left side of the face starting from the sagittal plane. To obtain such information, we developed an algorithm that will read a sensor array distributed across the face in order to read the state of the muscle in real time. Moreover, a statistical analysis is performed allowing us to know the state of the facial nerve. Accurate facial palsy measurement are key in the disorder treatment. According to the results found by our system, healthy faces must show a high correlation as well as a large standard deviation, correlation coefficient and a statistical mean. © 2021 American Institute of Physics Inc.. Facilitating objective forest land use decisions by site classification and tree growth modeling: A case study from Vietnam

Item Type Journal Article

Author N.D. Cuong

Author M. Volker

Author M. Köhl

Abstract Onsite information pertaining to forest growth potential is a significant prerequisite for selecting suitable forest plantation locations and safeguards sustainable timber production and income generation. In the scope of forest landscape restoration, the selection of the most suitable sites for reforestation remains a major issue. The current study introduces an operational, objective, and straightforward methodology for the identification and prioritization of sites that are suitable for forest plantations. The methodology is based on an approach that combines land use suitability assessment with site-specific growth and yield predictions. The land use suitability assessment is based on a methodological framework presented by the Food and Agriculture Organization (FAO). In a study area in Vietnam four different suitability classes are defined for the species *Acacia mangium* (*A. mangium*). Field assessments in existing *A. mangium* plantations were utilized to develop yield models. Among the Korf, Gompertz, and Chapman-Richards growth equations Korf performed the best for all suitability classes. Prioritization of sites is realized by the analytical hi-erarchy process (AHP). Our study offers a pragmatic approach for selecting the most suitable sites for large-scale forest restoration activities. Integrating growth and yield predictions supports reforestation practices and promotes sustainable timber production. © SISEF.

Factorizable Joint Shift in Multinomial Classification

Item Type Journal Article

Author D. Tasche

Abstract Factorizable joint shift (FJS) was recently proposed as a type of dataset shift for which the complete characteristics can be estimated from feature data observations on the test dataset by a method called Joint Importance Aligning. For the multinomial (multiclass) classification setting, we derive a representation of factorizable joint shift in terms of the source (training) distribution, the target (test) prior class probabilities and the target marginal distribution of the features. On the basis of this result, we propose alternatives to joint importance aligning and, at the same time, point out that factorizable joint shift is not fully identifiable if no class label information on the test dataset is available and no additional assumptions are made. Other results of the paper include correction formulae for the posterior class probabilities both under general dataset shift and factorizable joint shift. In addition, we investigate the consequences of assuming factorizable joint shift for the bias caused by sample selection. © 2022 by the author.

Fairness and AI generalizability in medical image analysis

Item Type Conference Paper

Author N.D. Forkert

Editor Yang X.

Editor Hsu W.

Abstract The rapid evolution of artificial intelligence (AI) and in particular machine learning (ML) for healthcare applications has opened many new exciting opportunities to automatically analyze increasingly complex clinical data, especially related to medical imaging, one of the biggest data contributors in health care. However, while machine learning models have demonstrated considerable potential in the research setting to improve and accelerate diagnostic accuracy, reduce clinician workload, and enable integration of multi-modal data, their real-world deployment in clinical settings remains limited in many cases. A major obstacle is that ML models trained on medical images consistently fail to generalize well and perform poorly when applied to data from institutions, scanners, and patient populations that were not or poorly represented in the training set. These performance gaps often stem from biological and non-biological variations and biases that are only spuriously but not causally correlated with the medical task of interest. However, it still remains an open question how such biases propagate through deep learning model architectures and shape learned representations. This invited paper summarizes our recent efforts to address these challenges through controlled bias experiments and distributed learning methods. More precisely, the Simulated Bias in Artificial Medical Images (SimBA) framework is introduced, which enables the generation of realistic brain MRI datasets with known and fully controllable morphological and intensity-based biases, thereby facilitating counterfactual analyses of how biases are encoded and used by deep learning models. Using SimBA, we demonstrate that standard convolutional neural networks encode biases across all layers and that shortcut learning depends on various factors, including spatial proximity, bias salience, and class prevalence. We further discuss distributed training strategies as a scalable solution to overcome structural barriers to data sharing and enhance deep learning model generalizability. Together, this work provides foundational insights toward developing robust, interpretable, and equitable ML solutions for the analysis of medical imaging data and downstream computer-aided diagnosis tasks. © 2026 SPIE. Author G. Xu

Abstract With the wide application of recommender systems, the potential impacts of recommender systems on customers, item providers and other parties have attracted increasing attention. Fairness, which is the quality of treating people equally, is also becoming important in recommender system evaluation and algorithm design. Therefore, in the past years, there has been a growing interest in fairness measurement and assurance in recommender systems. Although there are several reviews on related topics, such as fairness in machine learning and debias in recommender systems, they do not present a systematic view on fairness in recommender systems, which is context aware and has a multi-sided meaning. Therefore, in this review, the concept of fairness is discussed in detail in the various

contexts of recommender systems. Specifically, a comprehensive framework to classify fairness metrics is proposed from four dimensions, i.e., Fairness for Whom, Demographic Unit, Time Frame, and Quantification Method. Then the strategies for eliminating unfairness in recommendations, fairness in different recommendation tasks and datasets are reviewed and summarized. Finally, the challenges and future work are discussed. © 2023 Copyright held by the owner/author(s). Publication rights licensed to ACM.

Fairness through the lens of proportional equality

Item Type Conference Paper

Author A. Biswas

Author S. Mukherjee

Abstract Today, automated algorithms, such as machine learning classifiers, are playing an increasingly pivotal role in important societal decisions such as hiring, loan allocation, and criminal risk assessment. This motivates the need to probe the outcomes of a prediction model for discriminatory traits towards specific groups of individuals. In this context, one of the crucial challenges is to formally define a satisfactory notion of fairness. Our contribution in this paper is to formalize

Proportional Equality (PE) as a fairness notion. We additionally show that it is a more appropriate criterion than the existing popular notion called Disparate Impact (DI), which is used for evaluating the fairness of a classifier's outcomes.

Abstract Given an algorithmic predictor that is “fair” on some source distribution, will it still be fair on an unknown target distribution that differs from the source within some bound? In this paper, we study the transferability of statistical group fairness for machine learning predictors (i.e., classifiers or regressors) subject to bounded distribution shift. Such shifts may be introduced by initial training data uncertainties, user adaptation to a deployed predictor, dynamic environments, or the use of pre-trained models in new settings. Herein, we develop a bound that characterizes such transferability, flagging potentially inappropriate deployments of machine learning for socially consequential tasks. We first develop a framework for bounding violations of statistical fairness subject to distribution shift, formulating a generic upper bound for transferred fairness violations as our primary result. We then develop bounds for specific worked examples, focusing on two commonly used fairness definitions (i.e., demographic parity and equalized odds) and two classes of distribution shift (i.e., covariate shift and label shift). Finally, we compare our theoretical bounds to deterministic models of distribution shift and against real-world data, finding that we are able to estimate fairness violation bounds in practice, even when simplifying assumptions are only approximately satisfied. © 2022 Neural information processing systems foundation. Fast Inner-Product Algorithms and Architectures for Deep Neural Network Accelerators

Item Type Journal Article

Author T.E. Pogue

Author N. Nicolici

Abstract We introduce a new algorithm called the Free-pipeline Fast Inner Product (FFIP) and its hardware architecture that improve an under-explored fast inner-product algorithm (FIP) proposed by Winograd in 1968. Unlike the unrelated Winograd minimal filtering algorithms for convolutional layers, FIP is applicable to all machine learning (ML) model layers that can mainly decompose to matrix multiplication, including fully-connected, convolutional, recurrent, and attention/transformer layers. We implement FIP for the first time in an ML accelerator then present our FFIP algorithm and generalized architecture which inherently improve FIP's clock frequency and, as a consequence, throughput for a similar hardware cost. Finally, we contribute ML-specific optimizations for the FIP and FFIP algorithms and architectures. We show that FFIP can be seamlessly incorporated into traditional fixed-point systolic array ML accelerators to achieve the same throughput with half the number of multiply-accumulate (MAC) units, or it can double the maximum systolic array size that can fit onto devices with a fixed hardware budget. Our FFIP implementation for non-sparse ML models with 8 to 16-bit fixed-point inputs achieves higher throughput and compute efficiency than the best-in-class prior solutions on the same type of compute platform. © 1968-2012 IEEE.

Fast LCNN ica for unsupervised hyperspectral image classifier

Item Type Journal Article

Author I. Kopriva

Author H. Szu

Abstract Since in remote sensing each pixel could have its own unique radiation source s including man-made objects associated with different spectral reflectance matrix A , we could not average over neighborhood pixels. Instead, we solve pixel-by-pixel independent classes analysis (ica) without pixel average by Lagrange Constraint of the data measurement model and Gibbs' equal a priori probability assumption based on Shannon's Entropy $-\sum_{j=1}^M s_j \ln(s_j)$ with probability normalization condition $\sum_{j=1}^M s_j = 1$ for an arbitrary number of M classes that is bounded by the spectral data components N . We formulate the Fast Lagrangian method to maximize the Shannon entropy with the equality constraints in order to achieve $O(N)$ numerical complexity contrary to the $O(N^2)$ numerical complexity associated with the solution of the inverse problem required in the classical Lagrangian formulation. Trivial equal probability solution with uniformly distributed class vector s is avoided by introducing additional set of the inequality constraints. The unknown spectral reflectance matrix A is estimated blindly in non-parameterized form minimizing an LMS energy function $E(A)$. We apply the Riemannian metric to the gradient learning for $(\partial E / \partial A) A^T A$ reproducing the biological Hebbian rule in terms of a full rank vector outer product formula and demonstrate faster convergence than standard Euclidean gradient. Since the proposed Fast Lagrangian method has $O(N)$ numerical complexity we have achieved a real time hyperspectral remote sensing capability as platform moves, samples and processes. A FPGA firmware implementation for massive pixel parallel algorithm has been filed for patent. © Society of Photo-Optical Instrumentation Engineers.

Fast nonparametric estimation of class proportions in the positive-unlabeled classification setting

Item Type Conference Paper

Author D. Zeiberg

Author S. Jain

Author P. Radivojac

Abstract Estimating class proportions has emerged as an important direction in positive-unlabeled learning. Well-estimated class priors are key to accurate approximation of posterior distributions and are necessary for the recovery of true classification performance. While significant progress has been made in the past decade, there remains a need for accurate strategies that scale to big data. Motivated by this need, we propose an intuitive and fast nonparametric algorithm to estimate class proportions. Unlike any of the previous methods, our algorithm uses a sampling strategy to repeatedly (1) draw an example from the set of positives, (2) record the minimum distance to any of the unlabeled examples, and (3) remove the nearest unlabeled example. We show that the point of sharp increase in the recorded distances corresponds to the desired proportion of positives in the unlabeled set and train a deep neural network to identify that point. Our distance-based algorithm is evaluated on forty datasets and compared to all currently available methods. We provide evidence that this new approach results in the most accurate performance and can be readily used on large datasets. Fast Recognition and Counting Method of Dragon Fruit Flowers and Fruits Based on Video Stream

Item Type Journal Article

Author X. Li

Author X. Wang

Author P. Ong

Author Z. Yi

Author L. Ding

Author C. Han

Abstract Dragon fruit (*Hylocereus undatus*) is a tropical and subtropical fruit that undergoes multiple ripening cycles throughout the year. Accurate monitoring of the flower and fruit quantities at various stages is crucial for growers to estimate yields, plan orders, and implement effective management strategies. However, traditional manual counting methods are labor-intensive and inefficient. Deep learning techniques have proven effective for object recognition tasks but limited research has been conducted on dragon fruit due to its unique stem morphology and the coexistence of flowers and fruits. Additionally, the challenge lies in developing a lightweight recognition and tracking model that can be seamlessly integrated into mobile platforms, enabling on-site quantity counting. In this study, a video stream inspection method was proposed to classify and count dragon fruit flowers, immature fruits (green fruits), and mature fruits (red fruits) in a dragon fruit plantation. The approach involves three key steps: (1) utilizing the YOLOv5 network for the identification of different dragon fruit categories, (2) employing the improved ByteTrack object tracking algorithm to assign unique IDs to each target and track their movement, and (3) defining a region of interest area for precise classification and counting of dragon fruit across categories. Experimental results demonstrate recognition accuracies of 94.1%, 94.8%, and 96.1% for dragon fruit flowers, green fruits, and red fruits, respectively, with an overall

average recognition accuracy of 95.0%. Furthermore, the counting accuracy for each category is measured at 97.68%, 93.97%, and 91.89%, respectively. The proposed method achieves a counting speed of 56 frames per second on a 1080ti GPU. The findings establish the efficacy and practicality of this method for accurate counting of dragon fruit or other fruit varieties.

Abstract The prognostic relevance of tumor-infiltrating lymphocytes (TILs) in non-small cell Lung cancer (NSCLC) is well-established. However, manual TIL quantification in hematoxylin and eosin (H&E) whole slide images (WSIs) is laborious and prone to variability. To address this, we aim to develop and validate an automated computational pipeline for the quantification of TILs in WSIs of NSCLC. Such a

solution in computational pathology can accelerate TIL evaluation, thereby standardizing the prognostication process and facilitating personalized treatment strategies. We develop an end-to-end automated pipeline for TIL estimation in Lung cancer WSIs by integrating a patch extraction approach based on hematoxylin component filtering with a machine learning-based patch classification and cell quantification method using the HoVer-Net model architecture. Additionally, we employ randomized patch sampling to further reduce the processed patch amount. We evaluate the effectiveness of the patch sampling procedure, the pipeline's ability to identify informative patches and computational efficiency, and the clinical value of produced scores using patient survival data. Our pipeline demonstrates the ability to selectively process informative patches, achieving a balance between computational efficiency and prognostic integrity. The pipeline filtering excludes approximately 70% of all patch candidates. Further, only 5% of eligible patches are necessary to retain the pipeline's prognostic accuracy (c-index = 0.65), resulting in a linear reduction of the total computational time compared to the filtered patch subset analysis. The pipeline's TILs score has a strong association with patient survival and outperforms traditional CD8 immunohistochemical scoring (c-index = 0.59). Kaplan–Meier analysis further substantiates the TILs score's prognostic value. This study introduces an automated pipeline for TIL evaluation in Lung cancer WSIs, providing a prognostic tool with potential to improve personalized treatment in NSCLC. The pipeline's computational advances, particularly in reducing processing time, and clinical relevance demonstrate a step forward in computational pathology. © 2025 The Authors

Fault detection in batch processes through variable selection integrated to multiway principal component analysis

Item Type Journal Article

Author F.A.P. Peres

Author T.N. Peres

Author F.S. Fogliatto

Author M.J. Anzanello

Abstract The main purpose of fault detection in batch process monitoring is to identify batches displaying atypical behavior in comparison to normal operating data. The current growth in the number of measurable variables due to process automation yields datasets in which the number of variables is much larger than the number of batches. That may compromise the performance of Multiway Principal Component Analysis (MPCA), which is the most popular quality control approach used in batch processes. To overcome that, new strategies to handle high-dimensional datasets become necessary. In this paper we propose the Pareto Variable Selection (PVS) – MPCA method to monitor batch processes described by high-dimensional datasets. The main idea of PVS-MPCA is to select process variables that promote the best classification of production batches in conforming or non-conforming classes, prior to the construction of T2 and Q control charts used to monitor batch performance. Our proposition was applied to a real dataset from a chocolate conching batch operation and compared to classical MPCA-based monitoring. PVS-MPCA promoted a reduction of 85.18% in false alarm rate retaining only 5 unfolded variables, in opposition to 2,864 unfolded variables used in classical MPCA. The missed detection rate was null, ensuring that only conforming batches were released to the production line. © 2019 Elsevier Ltd

FCP-Pro: Federated conformal prediction algorithm based on prototype similarity

Item Type Journal Article

Author G. Li

Author Y. Zhang

Author Y. Wang

Author C. Wang

Abstract Research on trustworthy federated learning (FL) is still in its nascent stages, which severely limits the potential for FL to be applied in high-stakes scenarios, such as medical diagnosis, financial computing, and autonomous driving. To quantify uncertainty for the federated classification task, we extend conformal prediction to the federated learning system. First, we design the prototype-based adaptive prediction set (PAPS) score function for FL to compute the integrated prototype-based non-conformity score. It utilizes prototypes as proxies to protect privacy and reduce the size of the prediction set. Subsequently, we propose the federated conformal prediction algorithm based on prototype similarity (FCP-Pro) to overcome the data non-exchangeability and improve the prediction efficiency. It simultaneously enforces label shift correction and similarity calibration adjustment to the empirical distribution of federated calibration samples. The coverage guarantee of the proposed FCP-Pro algorithm is proved theoretically. To validate the effectiveness of the FCP-Pro algorithm, extensive experiments have been conducted on the CIFAR-10, CIFAR-100, and ImageNet datasets. The experimental results demonstrate that FCP-Pro significantly outperforms other state-of-the-art federated conformal prediction algorithms in terms of both empirical coverage and efficiency. © 2025 Elsevier Ltd

Feasibility of single-beat detection of ventricular late potentials on standard ECG leads via interpretable gradient boosting

Item Type Journal Article

Author A. Novak

Author D. Barić

Author I. Zeljković

Author B. Penayo

Author N. Pavlović

Author Š. Manola

Abstract Background: Ventricular late potentials (VLPs) are markers of arrhythmogenic substrate, but conventional assessment using signal-averaged ECG (SAECG) requires prolonged acquisition and operator-dependent artifact handling, limiting scalability and ambulatory use. Single-beat detection of VLP-like activity from standard surface ECG remains insufficiently validated. Objective: To evaluate the technical feasibility of interpretable single-beat detection of VLP-like perturbations from standard ECG leads without signal averaging. Methods: Using the MIMIC-IV-ECG database, we analyzed 120,000 beats from leads II, V2, and V6. Because large public datasets with beat-level clinically adjudicated VLP labels are not currently available, physiologically constrained synthetic VLP-like signals were injected into a subset of

beats to create a controlled feasibility benchmark. For each beat, more than 200 features were extracted, including time-domain statistics, frequency-domain measures, wavelet coefficients, autocorrelation features, and localized windowed summaries. Ten classifiers were optimized using nested patient-wise cross-validation and evaluated in five settings: single-lead detection, cross-lead generalization, mixed-lead training, reduced training size, and class-imbalance robustness. Results: Gradient-boosted ensembles, particularly XGBoost and CatBoost, achieved strong discrimination on held-out single-beat data ($AUC > 0.99$; $F1 > 0.93$), while remaining stable with 10% of the training data and 5% positive-class prevalence. Performance was also robust in lead-transfer experiments. SHAP analysis identified localized entropy, dispersion, and related high-frequency descriptors in late post-R windows as the dominant predictors. Conclusion: These findings support the methodological feasibility of interpretable single-beat detection of VLP-like signatures from routine surface ECG under controlled synthetic conditions. Validation on clinically adjudicated cohorts and external datasets is required before clinical translation. © 2026 Elsevier B.V.

Feature selection for high-dimensional imbalanced data

Item Type Journal Article**Author** L. Yin**Author** Y. Ge**Author** K. Xiao**Author** X. Wang**Author** X. Quan

Abstract Given its importance, the problem of classification in imbalanced data has attracted great attention in recent years. However, few efforts have been made to develop feature selection techniques for the classification of imbalanced data. This paper thus fills this critical void by introducing two approaches for the feature selection of high-dimensional imbalanced data. To this end, after introducing three traditional methods, we study and illustrate the challenges of feature selection in imbalanced data with Bayesian learning. Indeed, we reveal that the samples in the larger classes have a dominant influence on these feature selection methods. However, the samples in rare classes are essential for the learning performances of rare classes. Based on these observations, we provide a new feature selection approach based on class decomposition. Specifically, we partition the large classes into relatively smaller pseudo-subclasses and generate the pseudo-class labels accordingly. Feature selection is then performed on the new decomposed data for computing the goodness measurement of features. In addition, we also introduce a Hellinger distance-based method for feature selection. Hellinger distance is a measure of distribution divergence, which is strongly skew insensitive as the class prior information is not involved for computing the distance. Finally, we theoretically show the effectiveness of these two approaches with Bayesian learning on synthetic data. We also test and compare the performances of the proposed feature-selection methods on some real-world data sets. The experimental results show that both decomposition-based and Hellinger distance-based methods can outperform existing feature-selection methods with a clear margin on imbalanced data. © 2012 Elsevier B.V.

Feature-based classification and segmentation of mitral regurgitation echocardiography images quantification using PISA method

Item Type Journal Article

Author P.A. Khayum

Author R.S. Babu

Abstract Echocardiography is the enormously admired scientific specification for the evaluation of valvular regurgitation and gives significant knowledge on the bareness of mitral regurgitation MR). MR is a general heart disease which does not cause indications till its final phase. A technique is advanced for jet area separation and quantification in MR assessment in arithmetical expressions. Previous to this separation method count preprocessing and some attributes are mined from the record to arrangement method. From the cataloguing method, support vector machine SVM) classifier developed to confidential echocardiogram images. Entire abnormal images to the modified region growing MRG) separation method to segment jet area of MR. This segmented jet area in MR quantification process passed out with the support of proximal isovelocity surface area PISA). This procedure is based on mass diverse limitations like blood flow rate, regurgitant fraction, EROA, etc. From the outcomes, this projected effort associated with the current method fuzzy with PISA quantification process, the projected work attained accuracy rate 99.05% in the study of jet area segmenting and quantification method. © 2019 Inderscience Enterprises Ltd..

Author J. Xu

Abstract Second-coordination-shell effects have emerged as a crucial factor in regulating the performance of single-atom catalysts for the nitrogen reduction reaction (NRR), but quantifying their impact remains challenging due to their spatial distribution and lack of a unique descriptor. Here, we propose a feature-center-based spatial–physicochemical quantification method to describe second-coordination-shell effects in terms of composition and effective distribution, using a carbene-coordinated single-atom catalyst platform with varying ratios of N-heterocyclic carbene (NHC) and cyclic (alkyl)(amino)carbene (CAAC) ligands. High-throughput screening of 203 designed systems identified 32 computationally screened candidate systems, four of which exhibited low calculated limiting potentials of -0.15 to -0.17 V. Machine-learning analysis identified the first-ionization-energy feature-center-based descriptor (dIE) as an important catalyst-intrinsic descriptor for quantifying second-coordination-shell effects, highlighting the relevance of spatially distributed electronic characteristics to catalytic performance. The proposed representation further shows transferability to chemically related coordination environments. These results demonstrate the potential of the proposed framework for quantifying second-coordination-shell effects in carbene-coordinated single-atom catalysts and provide insights into the design of coordination-sensitive electrocatalysts. © 2026 Elsevier B.V.

FEDERATED LEARNING FROM ONLY UNLABELED DATA WITH CLASS-CONDITIONAL-SHARING CLIENTS

Item Type Conference Paper

Author N. Lu

Author Z. Wang

Author X. Li

Author G. Niu

Author Q. Dou

Author M. Sugiyama

Abstract Supervised federated learning (FL) enables multiple clients to share the trained model without sharing their labeled data. However, potential clients might even be reluctant to label their own data, which could limit the applicability of FL in practice. In this paper, we show the possibility of unsupervised FL whose model is still a classifier for predicting class labels, if the class-prior probabilities are shifted while the class-conditional distributions are shared among the unlabeled data owned by the clients. We propose federation of unsupervised learning (FedUL), where the unlabeled data are transformed into surrogate labeled data for each of the clients, a modified model is trained by supervised FL, and the wanted model is recovered from the modified model. FedUL is a very general solution to unsupervised FL: it is compatible with many supervised FL methods, and the recovery of the wanted model can be theoretically guaranteed as if the data have been labeled. Experiments on benchmark and real-world datasets demonstrate the effectiveness of FedUL. FedERFT: Improving federated learning through feature-enriched regularization and post-aggregation fine-tuning

Item Type Journal Article

Author S. Zhu

Author C. Qiu

Author G. Sun

Abstract Federated learning (FL) is a privacy-preserving distributed machine learning paradigm that enables collaborative model training through local updates and model sharing. However, in realistic deployments the data are typically non-independent and identically distributed (non-IID), and in particular label shift severely limits the generalization ability and convergence efficiency of the global model. Existing model-averaging-based algorithms struggle in such heterogeneous settings, making them insufficient for many practical applications. To address these issues, we propose FedERFT, a federated learning framework with server-side staged optimization, which systematically improves model stability and generalization by combining feature generation with progressive fine-tuning. In the first stage, the server aggregates client models to obtain an initial global model. In the second stage, the global encoder is frozen and only the classification head is fine-tuned, allowing rapid adaptation to the feature distributions of different clients. In the final stage, both the global encoder and the classification head are jointly fine-tuned to further enhance overall performance. In addition, we design a feature generation strategy based on bidirectional Kullback-Leibler (KL) divergence minimization. This strategy applies random dropout and rescaling to client parameter increments to generate diversified feature representations, effectively aligning client feature distributions and substantially mitigating the training instability caused by data heterogeneity. Experiments on CIFAR-10, CIFAR-100, and Tiny-ImageNet show that FedERFT achieves a 1.5%-4.5% accuracy improvement across various non-IID scenarios, and exhibits particularly strong generalization and cross-client robustness under extreme heterogeneity. These results demonstrate that FedERFT provides an efficient, robust, and widely applicable solution for federated learning in non-IID environments. © 2026 Elsevier B.V.

FedIIC: Towards Robust Federated Learning for Class-Imbalanced Medical Image Classification

Item Type Conference Paper**Author** N. Wu**Author** L. Yu**Author** X. Yang**Author** K.-T. Cheng**Author** Z. Yan**Editor** Greenspan H.**Editor** Greenspan H.**Editor** Madabhushi A.**Editor** Mousavi P.**Editor** Salcudean S.**Editor** Duncan J.**Editor** Syeda-Mahmood T.**Editor** Taylor R.

Abstract Federated learning (FL), training deep models from decentralized data without privacy leakage, has shown great potential in medical image computing recently. However, considering the ubiquitous class imbalance in medical data, FL can exhibit performance degradation, especially for minority classes (e.g. rare diseases). Existing methods towards this problem mainly focus on training a

balanced classifier to eliminate class prior bias among classes, but neglect to explore better representation to facilitate classification performance. In this paper, we present a privacy-preserving FL method named FedIIC to combat class imbalance from two perspectives: feature learning and classifier learning. In feature learning, two levels of contrastive learning are designed to extract better class-specific features with imbalanced data in FL. In classifier learning, per-class margins are dynamically set according to real-time difficulty and class priors, which helps the model learn classes equally. Experimental results on publicly-available datasets demonstrate the superior performance of FedIIC in dealing with both real-world and simulated multi-source medical imaging data under class imbalance. FedMCLA: Multi-Cluster Label-Shift-Aware Backdoor Defense for Heterogeneous IoT Federations

Item Type Journal Article

Author X. Zhang

Author J. Kang

Abstract Federated intelligence enables heterogeneous Internet of Things (IoT) gateways to train without sharing raw data, but non-IID label skew lets malicious updates hide among overlapping benign modes. FedMCLA uses a client-specific label-shift signature to jointly drive fuzzy multi-reference consensus and client-conditioned benign-update reconstruction. The defense runs at a compute-capable aggregation coordinator with visible client updates. Vision models use their native classifier bias; the decoder-only federated large language model (FLLM) path requires a persistent vocabulary-sized output-bias augmentation, so it is not purely coordinator-side. FedMCLA is also incompatible with standard secure aggregation that reveals only an aggregate. Experiments cover vision and FLLM attacks, matched method-specific white-box attacks, contamination stressors, and deployment envelopes. Under matched defense-specific attacks on CIFAR-10, FedMCLA obtains 23.14% ASR, 63.36% benign accuracy (BA), and 7.53% benign error rate (BER), versus the next-lowest ASR of 42.68% for FedDLAD; with 50% same-round update exposure, Attack-MCLA+-E reaches 34.26% ASR. Across seven standard CIFAR-10 attacks, FedMCLA reduces mean ASR from 18.65% with DoBlock to 7.33%. On three Alpaca attacks, it achieves 9.12%–12.45% ASR while keeping MMLU within 1.2 percentage points of the undefended model. © 2014 IEEE.

FedR2G: Federated long-tailed learning via geometric structure correction and generative rebalancing

Item Type Journal Article

Author J. Ren

Author G. Ye

Author Y. Zhang

Author Y. Xin

Author A. Wu

Author Y. Yuan

Author S. Zhao

Author Y. Li

Abstract Federated long-tailed learning is difficult because the model must learn from clients that are both heterogeneous and class-imbalanced. Tail classes may appear on only a few clients, and the prototypes used by generative augmentation can therefore be shifted by sample scarcity, label skew, and classifier bias. FedR2G addresses this problem by making the generation condition reliable before generating more tail samples. It first trains clients with a class-prior-scaled ETF directional classifier, which maintains a stable inter-class angular reference while strengthening weak tail-class responses. Clients then upload normalized class prototypes and local class counts. On the server, FedR2G uses these counts to calibrate latent class centers and performs tail-aware generation from the calibrated anchors. A latent consistency loss returns the public generative prior to client training. Experiments on CIFAR-10-LT, CIFAR-100-LT, and TinyImageNet-LT show consistent gains, especially in severe long-tailed settings. On CIFAR-100-LT with IF = 100, FedR2G reaches 37.64% Top-1 accuracy, improves Few-class accuracy by 3.28 percentage points over RUCR, and raises Macro-F1 by 2.69 percentage points. Ablations under a fixed StyleGAN-XL generator further show that the gains come from corrected semantic anchors and count-aware calibration, not only from the generator prior. FedR2G thus provides a practical way to connect geometric correction with generative rebalancing under federated long-tailed constraints. © 2026 Elsevier B.V.

FedSea: Federated Learning via Selective Feature Alignment for Non-IID Multimodal Data

Item Type Journal Article

Author M. Tan

Author Y. Feng

Author L. Chu

Author J. Shi

Author R. Xiao

Author H. Tang

Author J. Yu

Abstract The growing demands for privacy protection challenge the joint training of one model by leveraging multiple datasets. Federated learning (FL) provides a new way to

overcome this challenge and has attracted many research interests, which enables multiple parties to collaboratively train a machine learning model without exchanging their local data. Despite some success, the non-independent and identically distributed (non-IID) data distributions in different parties remain challenging and easily damage the performance of FL methods, specifically for the heterogeneous multimodal data. Existing FL studies on non-IID data settings are often dedicated to the label space, neglecting the non-IID issues in feature space, thus limiting their performance when the parties with non-IID multimodal data. This paper proposes a new Federated learning method via Selective feature Alignment (FedSea) to align representations across multiple parties in the feature space. FedSea uses a domain adversarial learning framework consisting of an affine-transform-based generator and a gradient-reversal-based client discriminator to perform IID transformation and reduce data source distinguishability, respectively. An attention-based mask module and a feature IID confidence quantification method are introduced to effectively address the diverse feature non-IID levels across multimodal data. Comprehensive experiments are conducted on three widely-used public datasets and one large-scale industrial dataset, showing FedSea has: 1) better performance than state-of-the-art FL methods on both multimodal and single-modal datasets; 2) superior feature alignment ability on non-IID datasets, and 3) good model interpretability. © 1999-2012 IEEE.

FedShift: Federated Learning with Classifier Shift for Class Imbalance

Item Type Conference Paper

Author Y. Shen

Author H. Wang

Author H. Lv

Abstract Federated learning enables collaborative model training without sharing raw data, but its performance degrades significantly under non-IID data. A particularly challenging case is label distribution skew, where clients have different class proportions and local updates drift away from the global objective. Existing methods such as FedProx, SCAFFOLD, FedDC, and FedDyn mitigate this issue only indirectly through regularization or variance reduction. We propose FedShift, a simple method that adds a client-specific shift to the classifier logits during local training to correct the mismatch between local and global label distributions. We show that, under label shift, this modification aligns the local optimum with the global optimum, and we further establish convergence guarantees under the strongly convex assumption. Experiments on CIFAR-10, CINIC-10, and Tiny-ImageNet show that FedShift consistently outperforms strong baselines in accuracy and improves communication efficiency by up to 4.34×. These results demonstrate that FedShift is an effective and practical solution for federated learning under label distribution skew. © 2026 IEEE.

FedUA: An Uncertainty-Aware Distillation-Based Federated Learning Scheme for Image Classification

Item Type Journal Article

Author S.-M. Lee

Author J.-L. Wu

Abstract Recently, federated learning (FL) has gradually become an important research topic in machine learning and information theory. FL emphasizes that clients jointly engage in solving learning tasks. In addition to data security issues, fundamental challenges in this type of learning include the imbalance and non-IID among clients' data and the unreliable connections between devices due to limited communication bandwidths. The above issues are intractable to FL. This study starts from the uncertainty analysis of deep neural networks (DNNs) to evaluate the effectiveness of FL, and proposes a new architecture for model aggregation. Our scheme improves FL's performance by applying knowledge distillation and the DNN's uncertainty quantification methods. A series of experiments on the image classification task confirms that our proposed model aggregation scheme can effectively solve the problem of non-IID data, especially when affordable transmission costs are limited. © 2023 by the authors.

FedUV: Uniformity and Variance for Heterogeneous Federated Learning

Item Type Conference Paper

Author H.M. Son

Author M.-H. Kim

Author T.-M. Chung

Author C. Huang

Author X. Liu

Abstract Federated learning is a promising framework to train neural networks with widely distributed data. However, performance degrades heavily with heterogeneously distributed data. Recent work has shown this is due to the final layer of the network being most prone to local bias, some finding success freezing the final layer as an orthogonal classifier. We investigate the training dynamics of the classifier by applying SVD to the weights motivated by the observation that freezing weights results in constant singular values. We find that there are differences when training in IID and non-IID settings. Based on this finding, we introduce two regularization terms for local training to continuously emulate IID settings: (1) variance in the dimension-wise probability distribution of the classifier and (2) hyperspherical uniformity of representations of the encoder. These regularizations promote local models to act as if it were in an IID setting regardless of the local data distribution, thus off-setting proneness to bias while being flexible to the data. On extensive experiments in both label-shift and feature-shift settings, we verify that our method achieves highest performance by a large margin especially in highly non-IID cases in addition to being scalable to larger models and datasets. © 2024 IEEE.

Abstract In recent decades, few-shot object detection in SAR imagery has gained prominence as a major research focus. The unique imaging mechanism of SAR causes the model to suffer from foreground–background imbalance and inaccurate extraction of class prototypes for novel class instances. Therefore, we propose an innovative few-shot object detection algorithm for SAR images via context-aware and robust Gaussian flow representation. First, we design the Context-Aware Enhancement module to address the foreground–context imbalance problem by refining representative support features into fine-grained prototypes, which are deeply fused with query features based on the prototype matching paradigm. Second, we devise the Manifold Class Distribution Estimation module to address the difficulty of class distribution estimation and the fluctuation of class centers of the sparse novel class. Furthermore, we formulate the Category-Balanced Difference Aggregation module to model the relationship between the base class and the novel class, addressing the sensitivity of the model to the variance of the novel class instances. Finally, we design the Cosine Decoupling Module so that the aggregated features are executed only on the classification branch without affecting the precise localization of the target. Experiments based on SAR-AIRcraft-1.0 and the self-constructed MSAR-AIR dataset indicate that the fine-grained detection and identification performance of the novel class of airplanes can reach 32.90% and 55.26%, respectively, in the 10-shot and 50-shot cases. In addition, our method enables cross-domain detection for different scenarios and sample types and exhibits excellent generalization performance in data-sparse scenarios. © 2025 by the authors.

Few-shot Open-set Recognition by Transformation Consistency

Item Type Conference Paper

Author M. Jeong

Author S. Choi

Author C. Kim

Abstract In this paper, we attack a few-shot open-set recognition (FSOSR) problem, which is a combination of few-shot learning (FSL) and open-set recognition (OSR). It aims to quickly adapt a model to a given small set of labeled samples while rejecting unseen class samples. Since OSR requires rich data and FSL considers closed-set classification, existing OSR and FSL methods show poor performances in solving FSOSR problems. The previous FSOSR method follows the pseudo-unseen class sample-based methods, which collect pseudo-unseen samples from the other dataset or synthesize samples to model unseen class representations. However, this approach is heavily dependent on the composition of the pseudo samples. In this paper, we propose a novel unknown class sample detector, named SnaTCHer, that does not require pseudo-unseen samples. Based on the transformation consistency, our method measures the difference between the transformed prototypes and a modified prototype set. The modified set is composed by replacing a query feature and its predicted class prototype. SnaTCHer rejects samples with large differences to the transformed prototypes. Our method alters the unseen class distribution estimation problem to a relative feature transformation problem, independent of pseudo-unseen class samples. We investigate our SnaTCHer with various prototype transformation methods and observe that our method consistently improves unseen class sample detection performance without closed-set classification reduction. © 2021 IEEE

Finding rare objects and building pure samples: Probabilistic quasar classification from low-resolution Gaia spectra

Item Type Journal Article

Author C.A.L. Bailer-Jones

Author K.W. Smith

Author C. Tiede

Author R. Sordo

Author A. Vallenari

Abstract We develop and demonstrate a probabilistic method for classifying rare objects in surveys with the particular goal of building very pure samples. It works by modifying the output probabilities from a classifier so as to accommodate our expectation (priors) concerning the relative frequencies of different classes of objects. We demonstrate our method using the Discrete Source Classifier (DSC), a supervised classifier currently based on support vector machines, which we are developing in preparation for the Gaia data analysis. DSC classifies objects using their very low resolution optical spectra. We look in detail at the problem of quasar classification, because identification of a pure quasar sample is necessary to define the Gaia astrometric reference frame. By varying a posterior probability threshold in DSC, we can trade off sample completeness and contamination. We show, using our simulated data, that it is possible to achieve a pure sample of quasars (upper limit on contamination of 1 in 40 000) with a completeness of 65 per cent at magnitudes of $G = 18.5$, and 50 per cent at $G = 20.0$, even when quasars have a frequency of only 1 in every 2000 objects. The star sample completeness is simultaneously 99 per cent with a contamination of 0.7 per cent. Including parallax and proper motion in the classifier barely changes the results. We further show that not accounting for class priors in the target population leads to serious misclassifications and poor predictions for sample completeness and contamination. We discuss how a classification model prior may, or may not, be influenced by the class distribution in the training data. Our method controls this prior and so allows a single model to be applied to any target population without having to tune the training data and retrain the model. © 2008 RAS.

Fine-Grained Uncertainty Quantification via Collisions

Item Type Journal Article

Author J. Friedbaum

Author S. Adiga

Author R. Tandon

Abstract We propose a new and intuitive metric for aleatoric uncertainty quantification (UQ), the prevalence of class collisions defined as the same input being observed in different classes. We use the rate of class collisions to define the collision matrix, a novel and uniquely fine-grained measure of uncertainty. For a classification problem involving K classes, the $K \times K$ collision matrix S measures the inherent difficulty in distinguishing between each pair of classes. We discuss several applications of the

collision matrix, establish its fundamental mathematical properties, and show its relationship with existing UQ methods, including the Bayes error rate (BER). We also address the new problem of estimating the collision matrix using one-hot labeled data by proposing a series of innovative techniques to estimate S . First, we learn a pair-wise contrastive model which accepts two inputs and determines if they belong to the same class. We then show that this contrastive model (which is PAC learnable) can be used to estimate the row Gramian matrix of S , defined as $G = SST$. Finally, we show that under reasonable assumptions, G can be used to uniquely recover S , a new result on non-negative matrices which could be of independent interest. With a method to estimate S established, we demonstrate how this estimate of S , in conjunction with the contrastive model, can be used to estimate the posterior class probability distribution of any point. Experimental results are also presented to validate our methods of estimating the collision matrix and class posterior distributions on several datasets. © 2026 IEEE. All rights reserved.

Abstract Nowadays imbalanced learning represents one of the most vividly discussed challenges in machine learning. In these scenarios, one or some of the classes in the problem have a significantly lower a priori probability, usually leading to trivial or non-desirable classifiers. Because of this, imbalanced learning has been researched to a great extent by means of different approaches. Recently, the focus has switched from binary classification to other paradigms where imbalanced data also arise, such as ordinal classification. This paper tests the application of learning pairwise ranking with multiple granularity levels in an ordinal and imbalanced classification problem where the aim is to construct an accurate model for donor-recipient allocation in liver transplantation. Our experiments show that approaching the problem as ranking solves the imbalance issue and leads to a competitive performance. © Springer International Publishing AG 2017.

Author W.-L. Chao

Abstract Class activation map (CAM) has been widely used to highlight image regions that contribute to class predictions. Despite its simplicity and computational efficiency, CAM often struggles to identify discriminative regions that distinguish visually similar fine-grained classes. Prior efforts address this limitation by introducing more sophisticated explanation processes, but at the cost of extra complexity. In this paper, we propose Finer-CAM, a method that retains CAM's efficiency while achieving precise localization of discriminative regions. Our key insight is that the deficiency of CAM lies not in "how" it explains, but in "what" it explains. Specifically, previous methods attempt to identify all cues contributing to the target class's logit value, which inadvertently also activates regions predictive of visually similar classes. By explicitly comparing the target class with similar classes and spotting their differences, Finer-CAM suppresses features shared with other classes and emphasizes the unique, discriminative details of the target class. Finer-CAM is easy to implement, compatible with various CAM methods, and can be extended to multi-modal models for accurate localization of specific concepts. Additionally, Finer-CAM allows adjustable comparison strength, enabling users to selectively highlight coarse object contours or fine discriminative details. Quantitatively, we show that masking out the top 5% of activated pixels by Finer-CAM results in a larger relative confidence drop compared to baselines. The source code and demo are available at <https://github.com/Imageomics/Finer-CAM>. © 2025 IEEE.

Fish feeding intensity assessment method using deep learning-based analysis of feeding splashes

Item Type Journal Article

Author Y. Wu

Author X. Wang

Author Y. Shi

Author Y. Wang

Author D. Qian

Author Y. Jiang

Abstract Assessment of fish feeding intensity provides effective feedback on fish starvation, which is important for improving feed utilisation and reducing water pollution. The vigorous gathering, jumping, or chasing of fish during feeding produces splashes of different sizes. The size of the splash reflects the intensity of fish feeding. However, the diverse splashes, reflected light spots on the surface of the water, and ripples created by fish movement pose inevitable problems for direct quantification methods. These methods require extensive data labelling and complex pre-processing to eliminate disturbances. Hence, this study proposes a method for assessing fish feeding intensity using a workflow involving several deep learning-based techniques such as an adaptive receptive field image feature extraction network based on a multi-kernel selection structure that becomes the teacher module for a semi-supervised splash detection module that uses a class activation map to create pseudo-labels for splashes. Feature extraction is done on the detected feeding splashes using a grey-level co-occurrence matrix and a grey-gradient co-occurrence matrix, which are then used to assess fish feeding intensity using a regression multi-classification model. The experimental results show that the feeding intensity assessment method proposed in this study achieves a mean accuracy of 98.22%, a false detection rate of 1.27%, and a missed detection rate of 2.75%; these results provide practical implications for the design of effective feeding systems that can improve feed utilisation, reduce water pollution, and enhance the welfare of farmed fish. © 2024 Elsevier B.V.

Fisher consistency for prior probability shift

Item Type Journal Article

Author D. Tasche

Abstract We introduce Fisher consistency in the sense of unbiasedness as a desirable property for estimators of class prior probabilities. Lack of Fisher consistency could be used as a criterion to dismiss estimators that are unlikely to deliver precise estimates in test data sets under prior probability and more general data set shift. The usefulness of this unbiasedness concept is demonstrated with three examples of classifiers used for quantification: Adjusted Count, EM-algorithm and CDE-Iterate. We find that Adjusted Count and EM-algorithm are Fisher consistent. A counter-example shows that CDE-Iterate is not Fisher consistent and, therefore, cannot be trusted to deliver reliable estimates of class probabilities. © 2017 Dirk Tasche.

Abstract AI fitness has become a new and practical way of fitness, but most of the mainstream fitness apps focus on guiding and planning fitness activities, ignoring the detection and evaluation of users' fitness movements. Aiming at this phenomenon, this paper proposed a method to classify and count basic fitness movements based on Google Mediapipe framework. The method consists of three steps: First, a single fitness action is divided into two detection states: up and down, and the corresponding picture samples are collected and trained. Secondly, based on the generated training set (csv file), KNN algorithm was used to identify and classify different fitness actions. Finally, the classification results are processed and the fitness actions are counted. The best recognition angle and threshold are obtained through the test accuracy. Compared with the mainstream human pose recognition frameworks such as Openpose and Alphapose, Mediapipe's BlazePose algorithm has lower performance requirements, faster recognition speed and a high level of accuracy, which is more suitable for personalized needs for smart fitness on mobile devices today. © 2022 IEEE.

Flashover Detection and Anomaly Prediction in Aerial Images of Insulator Strings in Complex Environments

Item Type Journal Article

Author L. Zhang

Author X. Li

Author J. Zhao

Author Y. Zhang

Author Q. Zhang

Abstract The normal operation of insulator strings affects the safety and stability of the power system, and insulator string flashover is one of the important faults. In this paper, considering the flashover characteristics of insulator strings in complex environments, noise is added to the collected insulator strings to simulate the actual complex environment, and then the collected data are rotationally transformed and filtered using an improved non-local mean filtering algorithm. To accurately locate insulator strings in complex environments, the geodesic active contour correction algorithm is employed to locate and segment the image. This algorithm is developed based on the level set model, replaces the image target boundary finding problem with the problem of solving a weighted arc length minimum, and introduces a penalty term into the level set energy generalization that constrains the distance function of the level set, which effectively solves the edge leakage problem. For the segmented image of insulator strings, grayscale features and wavelet features are extracted, and then the optimized random forest algorithm is utilized for prediction analysis, and the

diversity of weak learners in the random forest algorithm is increased not only through sample perturbation but also through attribute perturbation, leading to excellent generalization performance. Additionally, by combining the misclassification matrix and the a priori probability optimization algorithm, the random forest algorithm is optimized to achieve a better classification effect. Finally, the simulation of flashover discharge phenomenon characteristics and simulation experiments on a large number of insulator string images demonstrate that the proposed method has high practicality. © 2013 IEEE.

Flexibility Provision From Urban Buildings to Low-Carbon Power Systems: Quantification, Aggregation and System Integration

Item Type Journal Article

Author H. Yuan

Author W. Tang

Abstract Achieving net-zero emissions requires a comprehensive transformation of energy infrastructure. The expansion of intermittent renewable generation together with increased demand, for example, from electric vehicles and heat pumps, exerts

significant stress on grid stability and reliability, making power system flexibility essential for maintaining power and energy balance and enhancing system resilience. Urban buildings, with integrated heating, cooling, on-site generation, storage and flexible demand, constitute a substantial, cost-effective flexibility resource. In this paper, building flexibility is first defined and its physical drivers are identified. Quantification methods at the individual building scale, including physics-based simulations, machine-learning models and hybrid approaches supported by recent experiments, are then surveyed. Aggregation frameworks that include Virtual Power Plants and Virtual Energy Storage Systems are examined, comparing centralised, decentralised and hierarchical control strategies, ICT requirements and market-integration pathways. The participation of aggregated building flexibility in wholesale markets and its provision of distribution-level services are analysed. Enabling measures such as dynamic tariffs, demand-response programmes, smart-readiness indicators and relevant standards are critically evaluated. Finally, future research needs in integration, standardisation and policy development are outlined. That leveraging urban building flexibility may be crucial for developing a reliable, cost-effective, low-carbon power system is suggested by our analysis. © 2025 The Author(s). Abstract Long-tailed semi-supervised learning (LTSSL) represents a practical scenario for semi-supervised applications, challenged by skewed labeled distributions that bias classifiers. This problem is often aggravated by discrepancies between labeled and unlabeled class distributions, leading to biased pseudo-labels, neglect of rare classes, and poorly calibrated probabilities. To address these issues, we introduce Flexible Distribution Alignment (FlexDA), a novel adaptive logit-adjusted loss framework designed to dynamically estimate and align predictions with the actual distribution of unlabeled data and achieve a balanced classifier by the end of training. FlexDA is further enhanced by a distillation-based consistency loss, promoting fair data usage across classes and effectively leveraging underconfident samples. This method, encapsulated in ADELLO (Align and Distill Everything All at Once), proves robust against label shift, significantly improves model calibration in LTSSL contexts, and surpasses previous state-of-the-art approaches across multiple benchmarks, including CIFAR100-LT, STL10-LT, and ImageNet127, addressing class imbalance challenges in semi-supervised learning. Our code is available at <https://github.com/emasa/ADELLO-LTSSL>. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2025.

Flow cytometric S-phase fraction measurement in breast carcinoma: Influence of software and histogram resolution

Item Type Journal Article**Author** M.-L. Jourdan**Author** M. Ferrero-Poüs**Author** F. Spyrtos**Author** S. Romain**Author** P.-M. Martin**Author** A. Chassevent

Abstract Background: S-phase fraction (SPF) measurement by flow cytometry is a clinically useful prognostic factor in patients with breast carcinoma. Standardized SPF determination is essential. As part of a multicenter study, we evaluated the influence of the choice of software and histogram resolution (256, 512, or 1,024 channels) on SPF quantification. Methods: One hundred thirty-three DNA histograms were analyzed in three laboratories with Modfit 5.2, Modfit LT, and Multicycle AV software. Strict rules for histogram interpretation and software management were

applied. The following five options were compared: MF 5.2 1024, MF 5.2 256, MF LT 256, MCAV 256, and MC AV 512. Results: In the DNA diploid and aneuploid groups, SPF distributions were not statistically different among the five options, Excellent quantitative correlations were obtained between pairs of options. When using tertiles as cutpoints for SPF classification, concordance rates ranged from 79.7% to 93.2% for DNA diploid samples and from 87.8% to 95.9% for DNA aneuploid samples, the best results being obtained with software working with a similar histogram resolution. Conclusions: Standardized use of commercially available software, including the choice of histogram resolution, provides comparable SPF results. © 2002 Wiley-Liss, Inc.

Flowcam: Quantification and classification of phytoplankton by imaging flow cytometry

Item Type Journal Article

Author N.J. Poulton

Abstract The ability to enumerate, classify, and determine biomass of phytoplankton from environmental samples is essential for determining ecosystem function and their role in the aquatic community and microbial food web. Traditional micro-phytoplankton quantification methods using microscopic techniques require preservation and are slow, tedious and very laborious. The availability of more automated imaging microscopy platforms has revolutionized the way particles and cells are detected within their natural environment. The ability to examine cells unaltered and without preservation is key to providing more accurate cell concentration estimates and overall phytoplankton biomass. The Flow Cam ® is an imaging cytometry tool that was originally developed for use in aquatic sciences and provides a more rapid and unbiased method for enumerating and classifying phytoplankton within diverse aquatic environments. © Springer Science+Business Media New York 2016.

FMAPLS: Bayesian Label Shift Estimation Based on Dynamic Dirichlet Parameter Adaptation

Item Type Journal Article

Author J. Hu

Author J.A. Barria

Abstract Label shift, a critical challenge in supervised learning, occurs when the class prior distribution of test data deviates from that of training data, leading to significant degradation in classifier performance. This issue is particularly impactful in real-world applications such as medical diagnosis and satellite imaging, where a reduction in classification accuracy can cause severe consequences. Existing methods, such as Maximum A Posterior Label Shift (MAPLS), rely on strict Dirichlet hyperparameter constraints, thereby imposing a limitation on their adaptability to dynamic learning environments and class-imbalanced scenarios. To address this problem, we propose Full Maximum A Posterior Label Shift (FMAPLS), a Bayesian label shift estimation framework that dynamically co-optimizes Dirichlet hyperparameters and class priors through Expectation-Maximization (EM) iterations. By eliminating rigid hyperparameter constraints and introducing a linear surrogate function, FMAPLS enhances both expressivity and robustness in prior estimation while reducing computational complexity. Extensive experiments on CIFAR100 under shuffled long-tail and Dirichlet imbalanced test priors demonstrate FMAPLS's superiority over state-of-the-art baselines, achieving up to 50% lower KL divergence and maintaining accuracy improvements by up to 0.5% in extreme imbalance settings. The results validate the efficacy of dynamic hyperparameter adaptation in estimating label shift, particularly under high class imbalance and distributional uncertainty. © 1994-2012 IEEE.

Food waste quantification; Methods and Benefits

Item Type Conference Paper

Author S. Anwar

Author M. Shahbaz

Author A. Saeed

Author R. Parsad

Abstract Food waste is a significant socioeconomic and environmental problem. Recent research has provided more evidence, particularly considering the UNO's sustainable development goals. Many factors accelerate food wastage, and most studies consider food waste quantification a technique to reduce food wastage, where multiple classical and manual methods have been applied. However, in most studies, food waste quantification is deployed to measure single or specific waste, not considering the additional contributing factors. Also, multiple studies highlighted the importance of different factors that helps in food waste reduction. The paper provides a comprehensive literature review linking many food waste factors for food waste quantification. In addition, we provide two diagrams that show methods and critical areas where food waste quantification helps in the policymaking process to reduce wasting food. © 2022 IEEE.

Forecasting CPU and Memory Usage in Cloud Workloads Using Task Metadata: A Machine Learning Approach on Google Cluster Data

Item Type Conference Paper

Author N. Kumar

Author S. Kukreja

Author Y. Kumar

Author Y. Choudhary

Editor Vijayan K V.K.

Editor Singh V.

Abstract Precise estimation of CPU and memory usage in cloud settings is crucial for improving resource allocation efficiency and reducing operational expenditures. The proposed machine learning framework in this work aims at predicting average CPU usage and average memory usage from task-level metadata of the Google 2019 Cluster Dataset with features of scheduling class, priority, requested resources, task duration, and failure status. Hybrid models that integrate tree-based techniques (LightGBM, Random Forest) and deep learning models (Long Short-Term Memory (LSTM), Multilayer Perceptron (MLP)) are compared to isolated models such as XGBoost and Convolutional Neural Network (CNN). Experiments prove that the hybrid LightGBM + MLP + LSTM model performs better with an RMSE of 0.08 for CPU prediction and 0.12 for memory consumption prediction and R2 scores of 0.94 and 0.91, respectively. Results indicate the importance of incorporating task metadata, especially resource requests and time, for enhancing scheduling efficiency. This eliminates provisioning errors by 25%, supports dynamic scaling of resources, and reduces infrastructure expenses in cloud data centers. © 2026 The Authors.

Forecasting the Future Development in Quality and Value of Professional Football Players

Item Type Journal Article**Author** K. van Arem**Author** F. Goes-Smit**Author** J. Söhl

Abstract Featured Application: This paper studies what models are most suitable for forecasting future values of player performance metrics in association football (soccer). The resulting forecast statistics find applications in team management and player scouting at football clubs. As transfer decisions concern whether a player should play for a club in the future, the predictions of future performance metrics offer a forward-looking improvement over the traditional backward-looking assessments. Transfers in professional football (soccer) are risky investments because of the large transfer fees and high risks involved. Although data-driven models can be used to improve transfer decisions, existing models focus on describing players' historical progress, leaving their future performance unknown. Moreover, recent developments have called for the use of explainable models combined with methods for uncertainty quantification of predictions to improve applicability for practitioners. This paper assesses explainable machine learning models in a practitioner-oriented

way for the prediction of the future development in quality and transfer value of professional football players. To this end, the methods for uncertainty quantification are studied through the literature. The predictive accuracy is studied by training the models to predict the quality and value of players one year ahead, equivalent to one season. This is carried out by training them on two data sets containing data-driven indicators describing the player quality and player value in historical settings. In this paper, the random forest model is found to be the most suitable model because it provides accurate predictions as well as an uncertainty quantification method that naturally arises from the bagging procedure of the random forest model. Additionally, this research shows that the development of player performance contains nonlinear patterns and interactions between variables, and that time series information can provide useful information for the modeling of player performance metrics. The resulting models can help football clubs make more informed, data-driven transfer decisions by forecasting player quality and transfer value. © 2025 by the authors.

Fostering knowledge transfer and learning in shift work environments

Item Type Journal Article

Author R. Bosua

Author K. Venkitachalam

Abstract Shift work is a continuous 'round-the-clock' work practice that involves rotating work schedules with a vital process of 'handover' denoting a change of teams between shifts. Handover as an activity requires that outgoing shift teams pass on insights and responsibility to incoming shift teams. Knowledge transfer in shift work environments is therefore crucial to allow for a seamless continuation of work practices between shifts. Studies in shift work indicate that knowledge transfer between shifts often fails—that is, incoming workers tend to solve problems with inadequate information, have an incomplete understanding of significant events that occurred in prior shifts, while workers often attempt to solve the same problems across different shifts. This study investigates the challenges associated with shift handover and proposes knowledge transfer enablers that can make a difference to handover. In addition, these enablers can foster learning, a process often overlooked in shift environments. A qualitative research methodology was used to study three distinctive case organisations in the manufacturing and educational sectors, where the nature of day-to-day work is shift-bound and transfer issues were present during handover processes. Our findings suggest that three enablers facilitate knowledge transfer problems associated with shift work: (1) a purposeful knowledge codification and classification culture, (2) open access to established boundary objects and boundary spanners and (3) a unified information infrastructure to facilitate knowledge transfer during shifts and handover. © 2015 John Wiley & Sons, Ltd.

Author S.G. Anavatti

Abstract As global energy systems transition to clean energy, accurate renewable generation forecasting is imperative for effective grid management. Foundation Models (FMs), which are large-scale, pre-trained neural networks capable of learning adaptable representations from large datasets, possess transformative potential for renewable energy forecasting by effectively analyzing intricate, high-dimensional time-series data and adapting to a variety of downstream tasks. This review examines FMs in renewable energy forecasting, with primary emphasis on wind and solar power generation. We systematically analyze how FMs address diverse forecasting scenarios spanning multiple temporal scales (ultra-short to long-term), spatial resolutions (individual installations to system-wide), data modalities (univariate to multi-modal), and operational contexts (zero-shot to supervised learning). The focus on generation forecasting rather than demand forecasting is motivated by the unique challenges of renewable generation, including weather dependency, spatial-temporal variability, and intermittency, which necessitate specialized multi-modal data integration (satellite imagery, numerical weather prediction, atmospheric modeling) distinct from the socioeconomic and behavioral patterns characterizing load prediction. An overview of FM architectures, pre-training strategies, fine-tuning methods, and data modalities used in renewable energy forecasting is presented. Particular emphasis is placed on large-scale, domain-specific Transformer architectures that capture spatial-temporal correlations, embed domain knowledge, and address the intermittent nature of renewable generation. Recent FM-based advancements in forecast accuracy are assessed, including multi-scale temporal prediction reconciliation and uncertainty quantification methods. Existing challenges and areas for improvement in long-term and multi-variate time series forecasting are reviewed. A distinction between theoretical developments and practical deployment considerations is established throughout the survey. The strengths and weaknesses of FMs are critically assessed, and future research directions in this rapidly emerging area are advanced. © 2025 Elsevier Ltd

Foundations of statistical mechanics for unstable interactions

Item Type Journal Article

Author R. Hilfer

Abstract Traditional Boltzmann-Gibbs statistical mechanics does not apply to systems with unstable interactions, because for such systems the conventional thermodynamic limit does not exist. In unstable systems the ground state energy does not have an additive lower bound, i.e., no lower bound linearly proportional to the number N of particles or degrees of freedom. In this article unstable systems are studied whose ground state energy is bounded below by a regularly varying function of N with index $\sigma \geq 1$. The index $\sigma \geq 1$ of regular variation introduces a classification with respect to stability. Stable interactions correspond to $\sigma = 1$. A simple example for an unstable system with $\sigma = 2$ is an ideal gas with a nonvanishing constant two-body potential. The foundations of statistical physics are revisited, and generalized ensembles are introduced for unstable interactions in such a way that the thermodynamic limit exists. The extended ensembles are derived by identifying and postulating three basic properties as extended foundations for statistical mechanics: first, extensivity of thermodynamic systems, second, divisibility of equilibrium states, and third, statistical independence of isolated systems. The traditional Boltzmann-Gibbs postulate, resp. the hypothesis of equal a priori probabilities, is identified as a special case of the extended ensembles. Systems with unstable interactions are found to be thermodynamically normal and extensive. The formalism is applied to ideal gases with constant many-body potentials. The results show that, contrary to claims in the literature, stability of the interaction is not a necessary condition for the existence of a thermodynamic limit. As a second example the formalism is applied to the Curie-Weiss-Ising model with strong coupling. This model has index of stability $\sigma = 2$. Its thermodynamic potentials [originally obtained in R. Hilfer, *Physica A* 320, 429 (2003)10.1016/S0378-4371(02)01585-6] are confirmed up to a trivial energy shift. The strong coupling model shows a thermodynamic phase transition of order 1 representing a novel mean-field universality class. The disordered high temperature phase collapses into the ground state of the system. The metastable extension of the high temperature free energy to low temperatures ends at absolute zero in a phase transition of order $1/2$. Between absolute zero and the critical temperature of the first order transition all fluctuations are absent. © 2022 American Physical Society.

Four decades of full-depth profiles reveal layer-resolved drivers of reservoir thermal regimes and episodic hypolimnetic warming

Item Type Journal Article

Abstract Thermal structure shapes ecological dynamics in lakes and reservoirs. Yet full-profile temperature records over multi-decades remain scarce, constraining mechanistic understanding of depth-resolved thermal changes and subseasonal extremes (e.g., surface heat waves and late-season hypolimnetic warming). In this study, we focused on Rappbode Reservoir, Germany's largest drinking-water reservoir, and compiled four decades of high-resolution, full-depth temperature profiles with concurrent hydro-meteorological records that are rarely available for stratified systems. Building

on these data, we developed a novel two-step analytical framework that integrates long-term monitoring and process-based modelling to yield a high-resolution, internally consistent dataset of spatiotemporal temperature dynamics. We then applied interpretable machine learning to quantify depth-specific statistical attributions of hydro-meteorological and operational drivers, using process-based interpretation to assess mechanisms associated with late-stratification hypolimnetic warming. Our results suggested that driver contributions varied markedly with depth and stratification phase: stratification-strength metrics tied to atmospheric heat exchange (i.e., surface temperature, vertical temperature difference, Schmidt stability) showed the largest SHAP contributions from the 30 d antecedent moving average of shortwave radiation and air temperature. For hypolimnetic temperature, outflow discharge accounted for the largest contribution during late stratification. Additional process-based analyses supported a link between episodic hypolimnetic warming by up to 10 °C in four specific years and intensified deep withdrawals, which weakened the density gradient and promoted downward transport of warm upper-layer water into the hypolimnion. The dual-perspective framework developed here, which integrates process-based and machine-learning approaches, is broadly transferable for analyzing ecological processes and supporting evidence-based management in stratified waters. © 2026 Chenxi Mi et al.

Framework for incorporating class priors into discriminative classification

Item Type Conference Paper

Author R. Jin

Author Y. Liu

Abstract Discriminative and generative methods provide two distinct approaches to machine learning classification. One advantage of generative approaches is that they naturally model the prior class distributions. In contrast, discriminative approaches directly model the conditional distribution of class given inputs, so the class priors are only implicitly obtained if the input density is known. In this paper, we propose a framework for incorporating class prior proportions into discriminative methods in order to improve their classification accuracy. The basic idea is to enforce that the distribution of class labels predicted on the test data by the discriminative model is consistent with the class priors. Therefore, the discriminative model has to not only fit the training data well but also predict class labels for the test data that are consistent with the class priors. Experiments on five different UCI datasets and one image database show that this framework is effective in improving the classification accuracy when the training data and the test data come from the same class proportions, even if the test data does not have exactly the same feature distribution as the training data. © Springer-Verlag Berlin Heidelberg 2005.

From manual scoring to machine learning: recent developments in image-based arbuscular mycorrhizal fungi root quantification

Item Type Journal Article**Author** A. Bouvette**Author** S. Basiru**Author** M. Hijri

Abstract Selecting an appropriate method to quantify arbuscular mycorrhizal fungi (AMF) colonization in plants can be challenging, particularly for non-experts, due to the wide diversity of available techniques, some of which date back to the 1980s. Despite rapid methodological advances, comprehensive reviews focusing specifically on recent image analysis approaches for AMF root quantification are still scarce in the scientific literature. Given the growing potential of image-based methods to improve the accuracy, reproducibility, and high throughput of AMF root colonization assessment, this review synthesizes conceptual structure and thematic map of studies focusing on AMF colonization from 2001 to 2026. In addition, we examine widely used traditional approaches, such as the gridline intersect method, and emerging tools, including Visual Basic for Application–Arbuscular Mycorrhizal Fungi (VBA-AMF), MycoPatt, WinRHIZO, ImageJ-based workflows, Zeiss Intellesis, and deep learning approaches such as Automatic Mycorrhizal Finder (AMFinder), “Tool for Analysing root images to calculate the Infection rate of arbuscular Mycorrhizal fungi” (TAIM) and Mask Region-based Convolutional Neural Network (Mask R-CNN). By critically comparing their principles, capabilities, and limitations, this review aims to guide researchers in selecting the most appropriate image analysis methods for AMF quantification according to their experimental objectives and technical constraints. © The Author(s), under exclusive licence to Springer-Verlag GmbH Germany, part of Springer Nature 2026.

From outcrop observations to dynamic simulations: an efficient workflow for generating ensembles of geologically plausible fracture networks and assessing their impact on flow and transport

Item Type Journal Article

Author E. Kamel Targhi

Author P.-O. Bruna

Author A. Daniilidis

Author G. Rongier

Author S. Geiger

Abstract Fractures are ubiquitous in geological formations and can often have an impact on subsurface applications such as geothermal energy, groundwater management or CO₂ storage. Quantifying the relationship between the uncertainties inherent to fracture networks and the corresponding flow behaviour for these applications remains an open challenge. Simulation studies that are based on outcrop analogues of fracture networks have yielded many new insights about heat and mass transfer in fractured geological formations but are restricted to a limited number of fracture network realizations, simplified assumptions about fracture network properties or deterministic models, making it difficult to analyse a wide range of uncertainties. This study introduces a flexible workflow that generates ensembles of geologically plausible fracture networks that can be based on statistical data from outcrop analogues. The fracture networks are generated using a computationally efficient approach that combines mechanical and statistical methods. The ensembles are then seamlessly linked to multi-purpose flow and transport simulations where the fractures are represented explicitly in a porous and permeable rock matrix. This approach can

enable new uncertainty quantification methods, supported by machine-learning-based emulators, to analyse how fracture network properties, such as fracture intensity, fracture aperture or fracture orientation, influence heat and mass transfer in fractured geological formations. The workflow is illustrated using two classic example applications pertinent to fracture network modelling – one based on outcrop data to assess thermal behaviour in geothermal systems, and one synthetic study to analyse the transition from matrix-dominated to fracture-dominated flow – and released as open-source code. © 2025 The Author(s). From Perception to Regulation: Frontier Advances in Structural Mechanisms, Objective Quantification, and Debitting Strategies of Bitter Peptides

Item Type Journal Article

Author J. Gao

Author Y. Yuan

Author J. Li

Abstract The bitterness of protein hydrolysates is a critical sensory defect that severely compromises consumer acceptance and limits their application in functional foods. Bitter peptides, the primary source of this undesirable taste, often possess significant bioactivity, creating a challenging “flavor-function” duality. This conflict arises fundamentally because the structural mechanisms governing peptide-bitter taste receptors (TAS2R) interactions and the correlation between bitterness and bioactivity remain incompletely understood. Consequently, objective quantification methods lack standardization, and debittering strategies often lack precision, hindering the development of palatable functional products. This review aims to systematically

analyze the structural basis of bitterness, its relationship with bioactivity, objective quantification technologies, and advanced strategies for bitter peptide removal, masking, and modification. Key findings reveal that bitterness perception is intricately linked to specific hydrophobic motifs and spatial conformation, often overlapping with bioactive features. Emerging computational resources and instruments, such as comprehensive databases, quantitative structure–activity relationship (QSAR) and machine learning models, and high-sensitivity bionic electronic tongue, offer superior high-throughput capabilities and accelerate the elucidation of peptide-TAS2R binding mechanisms compared to traditional sensory evaluation. Furthermore, distinct debittering strategies are identified: Encapsulation and masking technologies are preferred when retaining the bioactivity of functional bitter peptides is essential. Ultimately, resolving the “flavor-function” duality requires a deeper understanding of the structural mechanisms governing peptide-TAS2R binding. This fundamental insight will provide the necessary basis for standardized prediction models and the design of precision debittering technologies, thereby enabling the optimized application of bitter peptides in the development of palatable and functional protein hydrolysates. © 2026 Institute of Food Technologists.

Author C. Jiang

Abstract This paper presents a streamlined and interpretable framework for handwritten digit classification on the MNIST dataset. While deep learning models offer superior accuracy, they often function as 'black boxes' with high computational demands. To address this, we propose a modular pipeline that integrates Principal Component Analysis (PCA) as a denoising filter with mutual information-based pixel selection and nonparametric kernel density estimation (KDE). Crucially, we find ICA to be redundant within reconstruction-based pipelines, as PCA denoising provides sufficient feature preservation for KDE modeling. The framework further incorporates an optimized Jensen-Shannon divergence-based weighting scheme to resolve confusing digit pairs and a Bayesian MAP decision rule using empirical class priors. The resulting method achieves an accuracy of (83.36%) while maintaining full pixel-level transparency and high computational efficiency. This work demonstrates that efficient generative models can provide a rigorous and explainable alternative to discriminative models in scenarios where interpretability and uncertainty quantification are paramount. © 2026 IEEE.

Abstract Purpose: To compare semiquantitative striatal indices produced by two widely used quantification platforms — BasGanV2™ and NeuroTrans3D (Oasis©) — for ¹²³I-Ioflupane DAT SPECT, to evaluate their diagnostic performance for Parkinson’s disease (PD) versus non-degenerative presentations, and to determine whether supervised machine-learning (ML) classifiers can clarify relative utility of the two methods. Methods: Retrospective analysis of 90 consecutive subjects (48 PD, 42 not-PD) undergoing routine ¹²³I-Ioflupane SPECT. Striatal binding ratios (caudate and putamen, left and right) were computed with both tools. Distributional differences were tested (Mann–Whitney U and Brown–Forsythe/Levene tests). Three supervised classifiers (Gaussian naïve Bayes, k-nearest neighbours, and SVM-RBF) were trained on four regional metrics from each tool using stratified shuffle-split (60:40 train: test)

repeated 50 times; performance was summarised as mean (95% percentile CI) accuracy, sensitivity, specificity and AUC. Results: Both quantification methods discriminated PD from not-PD (all regions $p < 0.0001$). NeuroTrans3D/Oasis© produced consistently higher mean binding values and significantly greater variance than BasGanV2™. ML models trained on either tool achieved excellent AUCs (0.917–0.960) and similar accuracy (≈ 86 –91%), with overlapping confidence intervals and no single tool/classifier combination clearly outperforming the others. Conclusion: BasGanV2™ and NeuroTrans3D (Oasis©) are comparably effective for distinguishing PD from non-degenerative cases when combined with straightforward ML classifiers, despite systematic differences in absolute values and dispersion between tools. ML aids comparison by quantifying discriminative performance but, in this dataset, does not indicate a clear superiority of one quantification pipeline over the other. © The Author(s) 2026.

Full classification of permutation rational functions and complete rational functions of degree three over finite fields

Item Type Journal Article

Author A. Ferraguti

Author G. Micheli

Abstract Let q be a prime power, F_q be the finite field of order q and $F_q(x)$ be the field of rational functions over F_q . In this paper we classify and count all rational functions $\varphi \in F_q(x)$ of degree 3 that induce a permutation of $P_1(F_q)$. As a consequence of our classification, we can show that there is no complete permutation rational function of degree 3 unless $3 \mid q$ and φ is a polynomial. © 2020, Springer Science+Business Media, LLC, part of Springer Nature.

Fully automatic segmentation of multiple sclerosis lesions in brain MR FLAIR images using adaptive mixtures method and markov random field model

Item Type Journal Article

Author R. Khayati

Author M. Vafadust

Author F. Towhidkhah

Author S. Nabavi

Abstract In this paper, an approach is proposed for fully automatic segmentation of MS lesions in fluid attenuated inversion recovery (FLAIR) Magnetic Resonance (MR) images. The proposed approach, based on a Bayesian classifier, utilizes the adaptive mixtures method (AMM) and Markov random field (MRF) model to obtain and upgrade the class conditional probability density function (CCPDF) and the a priori probability of each class. To compare the performance of the proposed approach with those of previous approaches including manual segmentation, the similarity criteria of different slices related to 20 MS patients were calculated. Also, volumetric comparison of lesions volume between the fully automated segmentation and the gold standard was performed using correlation coefficient (CC). The results showed a better performance for the proposed approach, compared to those of previous works. © 2007 Elsevier Ltd. All rights reserved.

Functional surfaces in mechanical systems: Classification, fabrication, and characterisation

Item Type Journal Article

Author A. Godi

Author L. De Chiffre

Abstract This chapter deals with functional surfaces in mechanical systems. These surfaces are named in a multitude of ways; therefore, a classification is provided based on how the texture is designed. For a better clarification, a number of practical examples for each category are given. An overview of fabrication methods employed to produce such surfaces is presented. The numerous fabrication methods are classified based on the mechanism they employ for providing a texture. Three main categories (removing, moving, and adding material techniques) are identified, and for each of them, a number of processes are described with examples of the textures they can create. The last section of the chapter deals with surface metrology, a topic of central importance in the design and generation of surfaces for functional purposes. The process of surface characterisation is outlined, reviewing measuring instruments, classical and advanced filtering procedures, quantification methods, and eventually, providing traceability considerations. © 2014 by IGI Global. Fundamentals of Uncertainty Quantification for Engineers

Item Type Book

Author Y. Wang

Author A. Tran

Author D.L. McDowell

Abstract Fundamentals of Uncertainty Quantification for Engineers: Methods and Models provides a comprehensive introduction to uncertainty quantification (UQ) accompanied by a wide variety of applied examples and implementation details to reinforce the concepts outlined in the book. Sections start with an introduction to the history of probability theory and an overview of recent developments of UQ methods in the domains of applied mathematics and data science. Major concepts of copula, Monte Carlo sampling, Markov chain Monte Carlo, polynomial regression, Gaussian process regression, polynomial chaos expansion, stochastic collocation, Bayesian inference, modelform uncertainty, multi-fidelity modeling, model validation, local and global sensitivity analyses, linear and nonlinear dimensionality reduction are included. Advanced UQ methods are also introduced, including stochastic processes, stochastic differential equations, random fields, fractional stochastic differential equations, hidden Markov model, linear Gaussian state space model, as well as non-probabilistic methods such as robust Bayesian analysis, Dempster-Shafer theory, imprecise probability, and interval probability. The book also includes example applications in multiscale modeling, reliability, fatigue, materials design, machine learning, and decision making. © 2025 Elsevier Inc. Fuzzy decision tree learning for preoperative classification of adnexal masses

Item Type Conference Paper**Author** E. Ahmadi**Author** H. Javadi**Author** A. Khansefid**Author** A. Asadi**Author** M.M. Ebadzadeh**Author** D. Timmerman

Abstract The study problem was learning a fuzzy decision tree to classify patients with adnexal mass into either of benign or malignant class prior to surgery using patients' medical history, physical exam, laboratory tests, and ultrasonography. A learning algorithm was developed to learn a fuzzy decision tree in three steps. In the growing step, a binary decision tree was learned from a dataset of patients while fuzzy discretization was used in decision nodes testing continuous attributes. The best degree of fuzziness was automatically found by an algorithm based on optimization procedures. In the pruning step, the overfitted nodes were removed by an algorithm based on critical value post-pruning method. In the refitting step, the labels of the leaf nodes were optimized. The final resulted tree had 10 decision nodes and 11 leaf nodes. Performance testing of the tree gave AUC of ROC of 0.91 and mean squared error of 0.1. The tree was translated into a set of 11 fuzzy if-then rules and the clinical plausibility of the rules was assessed by domain experts. All rules were verified to be in agreement with medical knowledge in the domain. Despite the small learning set and the lack of some important input variables, this method gave accurate and, more importantly, clinically interpretable results.

G4 & the balanced metric family – a novel approach to solving binary classification problems in medical device validation & verification studies

Item Type Journal Article

Author A. Marra

Abstract Background: In medical device validation and verification studies, the area under the receiver operating characteristic curve (AUROC) is often used as a primary endpoint despite multiple reports showing its limitations. Hence, researchers are encouraged to consider alternative metrics as primary endpoints. A new metric called G4 is presented, which is the geometric mean of sensitivity, specificity, the positive predictive value, and the negative predictive value. G4 is part of a balanced metric family which includes the Unified Performance Measure (also known as P4) and the Matthews' Correlation Coefficient (MCC). The purpose of this manuscript is to unveil the benefits of using G4 together with the balanced metric family when analyzing the overall performance of binary classifiers. Results: Simulated datasets encompassing different prevalence rates of the minority class were analyzed under a multi-reader-multi-case study design. In addition, data from an independently published study that tested the performance of a unique ultrasound artificial intelligence algorithm in the context of breast cancer detection was also considered. Within each dataset, AUROC was reported alongside the balanced metric family for comparison. When the dataset prevalence and bias of the minority class approached 50%, all three balanced metrics provided equivalent interpretations of an AI's performance. As the prevalence rate increased / decreased and the data became more imbalanced, AUROC tended to overvalue / undervalue the true classifier performance, while the balanced metric family was resistant to such imbalance. Under certain circumstances where data imbalance was strong (minority-class prevalence < 10%), MCC was preferred for standalone assessments while P4 provided a stronger effect size when evaluating between-groups analyses. G4 acted as a middle ground for maximizing both standalone assessments and between-groups analyses. Conclusions: Use of AUROC as the primary endpoint in binary classification problems provides misleading results as the dataset becomes more

imbalanced. This is explicitly noticed when incorporating AUROC in medical device validation and verification studies. G4, P4, and MCC do not share this limitation and paint a more complete picture of a medical device’s performance in a clinical setting. Therefore, researchers are encouraged to explore the balanced metric family when evaluating binary classification problems. © The Author(s) 2024.

Abstract When applying supervised learning to estimate class distributions of unlabelled samples (so-called quantification), dataset shift is an expected yet challenging problem. Existing quantification methods make strong assumptions on the nature of dataset shift that often will not hold in practice. We propose a novel Gain-Some-Lose-Some (GSLS) model that accounts for more general conditions of dataset shift. We present a method for fitting the GSLS model without any labelled instances from the target sample, and experimentally demonstrate that GSLS can produce reliable quantification prediction intervals under broader conditions of shift than existing quantification methods. © 2021 IEEE.

Abstract Graph convolutional networks (GCNs) are discriminative models that directly model the class posterior $p(y|x)$ for semi-supervised classification of graph data. While being effective, as a representation learning approach, the node representations extracted from a GCN often miss useful information for effective clustering, because the objectives are different. In this work, we design normalizing flows that replace GCN layers, leading to a generative model that models both the class conditional likelihood $p(x|y)$ and the class prior $p(y)$. The resulting neural network, GCFlow, retains the graph convolution operations while being equipped with a Gaussian mixture representation space. It enjoys two benefits: it not only maintains the predictive power of GCN, but also produces well-separated clusters, due to the structuring of the representation space. We demonstrate these benefits on a variety of benchmark data sets. Moreover, we show that additional parameterization, such as that on the adjacency matrix used for graph convolutions, yields additional improvement in clustering. © 2023 Proceedings of Machine Learning Research. Abstract Background Somatostatin (SS) acts as a universal endocrine off-switch, and also inhibits the growth of neuroendocrine tumours through its specific receptors (SSTRs). Somatostatin receptors are G-protein-coupled receptors, which are encoded by five separate genes (SSTR1-5). Short peptide analogues demonstrate specific binding only for the subgroup consisting of SSTR2a, SSTR3 and SSTR5. Moreover, previous studies reported that expression of mRNA for SSTR2a correlated with therapeutic outcome in patients with carcinoid tumours treated with somatostatin analogs. Purpose To develop and apply a Real Time Quantitative PCR technique (RT-qPCR) to compare and contrast the mRNA levels of SSTR2a, SSTR3 and SSTR5 in Neuroendocrine Lung Cancer affected patients. Methods Peripheral blood samples from 21 neuroendocrine lung cancer affected patients (14 SCLC, 6 LC and 1LCNEC) subjected to scintigraphy with ¹¹¹In-DTPA-DPhe1- octreotide (OctreoScan) and 24 healthy blood donors were investigated by RT-qPCR. mRNA levels for SSTR2a, SSTR3 and SSTR5 were measured in peripheral blood samples with a relative quantification method using plasmid dilutions as calibration curves and GAPDH as reference gene. Results A statistically significant increase in target genes/ GAPDH copy number ratio was found for SSTR2a (median 38; IQR 22-141) and SSTR5 (median 51; IQR 19-499) in neuroendocrine lung cancer affected patients as compared with samples from healthy blood donors ($P \leq 0.0003$ and $P \leq 0.0005$). Since low levels of expression were detected in the control group for all three genes, optimal cut-off values were assessed using ROC curve analyses and were equal to 9.05 for SSTR2a and 16.97 for SSTR5. These cut off values resulted in a sensitivity of 86% (95%IC 65-95) for both markers and a specificity of 83% (95%IC 64-93%) and 79% (95%IC 60-91%) for SSTR2a and SSTR5 respectively. Comparison between OctreoScan results and RT-qPCR analysis demonstrated agreement in 76% of the cases. Conclusions Our results suggest that SSTR2a and SSTR5 mRNAs are detectable in peripheral blood of neuroendocrine lung cancer affected patients using real-time quantitative PCR, with a good agreement with OctreoScan. The high sensitivity of this non-invasive molecular technique suggests that this method could represent a useful tool in the clinical management of neuroendocrine lung cancers. © The Author(s) 2011.

Generalized Bayes Quantification Learning under Dataset Shift

Item Type Journal Article

Author J. Fiksel

Author A. Datta

Author A. Amouzou

Author S. Zeger

Abstract Quantification learning is the task of prevalence estimation for a test population using predictions from a classifier trained on a different population. Quantification methods assume that the sensitivities and specificities of the classifier are either perfect or transportable from the training to the test population. These assumptions are inappropriate in the presence of dataset shift, when the misclassification rates in the training population are not representative of those for the test population. Quantification under dataset shift has been addressed only for single-class (categorical) predictions and assuming perfect knowledge of the true labels on a small subset of the test population. We propose generalized Bayes quantification learning (GBQL) that uses the entire compositional predictions from probabilistic classifiers and allows for uncertainty in true class labels for the limited labeled test data. Instead of positing a full model, we use a model-free Bayesian estimating equation approach to compositional data using Kullback–Leibler loss-functions based only on a first-moment assumption. The idea will be useful in Bayesian compositional data analysis in general as it is robust to different generating mechanisms for compositional data and allows 0's and 1's in the compositional outputs thereby including categorical outputs as a special case. We show how our method yields existing quantification approaches as special cases. Extension to an ensemble GBQL that uses predictions from multiple classifiers yielding inference robust to inclusion of a poor classifier is discussed. We outline a fast and efficient Gibbs sampler using a rounding and coarsening approximation to the loss functions. We establish posterior consistency, asymptotic normality and valid coverage of interval estimates from GBQL, which to our knowledge are the first theoretical results for a quantification approach in the presence of local labeled data. We also establish finite sample posterior concentration rate. Empirical performance of GBQL is demonstrated through simulations and analysis of real data with evident dataset shift. Supplementary materials for this article are available online. © 2021 The Author(s). Published with license by Taylor & Francis Group, LLC.

Generalized Universal Domain Adaptation

Item Type Journal Article**Author** W. Su**Author** Z. Han**Author** X. Liu**Author** Y. Yin

Abstract Universal Domain Adaptation (UniDA) stands as a pivotal framework for transferring knowledge between disparate domains under the challenge of domain shifts. It uniquely caters to mismatches in class space without necessitating prior knowledge. Despite its utility, UniDA's effectiveness is often compromised in practical scenarios by the label shift, which poses significant hurdles to its generalization capabilities. Moreover, the existing UniDA approaches lack true universality, as they tend to erroneously detect “unknown” class samples even in situations where no “unknown” class are present, leading to unnecessary errors. In this paper, we propose a new framework known as Generalized Universal Domain Adaptation (GUDA) to handle the new challenges posed by both label shifts and the lack of true universality. At the core of our GUDA lies the Generalized Universal Adaptation Network (GUAN), comprising three innovative modules: the dual centroid learning module, which explores the internal structure of “unknown” classes and allows the model to determine if the “unknown” classes exist; the dual centroid employment module, which promotes cohesive clustering and emphasizes learning on minority classes to recognize “unknown” classes without prior knowledge; and the weighted multi-class adversarial alignment module, which aligns source and target samples with class-specific adjustments, preserving class boundaries amidst label shifts. These modules enable GUAN to form adaptable clusters tailored to varied target settings, enhancing classification precision and showcasing the true universality of our GUDA approach. Through extensive experimentation on benchmark datasets, we have demonstrated that our method substantially surpasses existing leading approaches in performance. © 2024 Elsevier B.V.

Generalized universal inference on risk minimizers

Item Type Journal Article

Author N. Dey

Author R. Martin

Author J.P. Williams

Abstract A common goal in statistics and machine learning is estimation of unknowns. Point estimates alone are of little value without an accompanying measure of uncertainty, but traditional uncertainty quantification methods, such as confidence sets and p-values, often require distributional or structural assumptions that may not be justified in modern applications. The present paper considers a very common case in machine learning, where the quantity of interest is the minimizer of a given risk (expected loss) function. We propose a generalization of universal inference specifically designed for inference on risk minimizers. Notably, our generalized universal inference attains finite-sample frequentist validity guarantees under a condition common in the statistical learning literature. One version of our procedure is also anytime-valid, i.e. it maintains the finite-sample validity properties regardless of the stopping rule used for the data collection process. Practical use of our proposal requires tuning, and we offer a data-driven procedure with strong empirical performance across a broad range of challenging statistical and machine learning examples. © The Royal Statistical Society 2025. Generated Preserved Adversarial Federated Learning for Enhanced Image Analysis (GPAF)

Item Type Journal Article

Author S. Lakrouni

Author S. Bah

Author M. Sebgui

Abstract Federated Learning (FL) has recently emerged as a promising paradigm that enables medical institutions to collaboratively train robust models without centralizing sensitive patient information. Data collected from different institutions represent distinct source domains. Consequently, discrepancies in feature distributions can significantly hinder a model's generalization to unseen domains. While domain generalization (DG) methods have been proposed to address this challenge, many may compromise data privacy in FL by requiring clients to transmit their local feature representations to the server. Furthermore, existing adversarial training methods, commonly used to align marginal feature distributions, fail to ensure the consistency of conditional distributions. This consistency is often critical for accurate predictions in unseen domains. To address these limitations, we propose GPAF, a privacy-preserving federated learning (FL) framework that mitigates both domain and label shifts in healthcare applications. GPAF aligns conditional distributions across clients in the latent space and restricts communication to model parameters. This design preserves class semantics, enhances privacy, and improves communication efficiency. At the server, a global generator learns a conditional feature distribution from clients' feedback. During local training, each client minimizes an adversarial loss to align its local conditional distribution with the global distribution, enabling the FL model to

learn robust, domain-invariant representations across all source domains. To evaluate the effectiveness of our approach, experiments on a medical imaging benchmark demonstrate that GPAF outperforms four FL baselines, achieving up to 17% higher classification accuracy and 25% faster convergence in non-IID scenarios. These results highlight GPAF's capability to generalize across domains while maintaining strict privacy, offering a robust solution for decentralized healthcare challenges.

Generating prior probabilities for classifiers of brain tumours using belief networks

Item Type Journal Article

Author G.M. Reynolds

Author A.C. Peet

Author T.N. Arvanitis

Abstract Background. Numerous methods for classifying brain tumours based on magnetic resonance spectra and imaging have been presented in the last 15 years. Generally, these methods use supervised machine learning to develop a classifier from a database of cases for which the diagnosis is already known. However, little has been published on developing classifiers based on mixed modalities, e.g. combining imaging information with spectroscopy. In this work a method of generating probabilities of tumour class from anatomical location is presented. Methods. The method of "belief networks" is introduced as a means of generating probabilities that a tumour is any given type. The belief networks are constructed using a database of paediatric tumour cases consisting of data collected over five decades; the problems associated with using this data are discussed. To verify the usefulness of the networks, an application of the method is presented in which prior probabilities were generated and combined with a classification of tumours based solely on MRS data. Results. Belief networks were constructed from a database of over 1300 cases. These can be used to generate a probability that a tumour is any given type. Networks are presented for astrocytoma grades I and II, astrocytoma grades III and IV, ependymoma, pineoblastoma, primitive neuroectodermal tumour (PNET), germinoma, medulloblastoma, craniopharyngioma and a group representing rare tumours, "other". Using the network to generate prior probabilities for classification improves the accuracy when compared with generating prior probabilities based on class prevalence. Conclusion. Bayesian belief networks are a simple way of using discrete clinical information to generate probabilities usable in classification. The belief network method can be robust to incomplete datasets. Inclusion of a priori knowledge is an effective way of improving classification of brain tumours by non-invasive methods. © 2007 Reynolds et al; licensee BioMed Central Ltd.

Abstract Vaccination is the most effective course of action to prevent influenza. About 150 million doses of influenza vaccines were distributed for the 2015-2016 season in the USA alone according to the Centers for Disease Control and Prevention. Vaccine dosage is calculated based on the concentration of hemagglutinin (HA), the main surface glycoprotein expressed by influenza which varies from strain to strain. Therefore yearly-updated strain-specific antibodies and calibrating antigens are required. Preparing these quantification reagents can take up to three months and significantly slows down the release of new vaccine lots. Therefore, to circumvent the need for strain-specific sera, two anti-HA monoclonal antibodies (mAbs) against a

highly conserved sequence have been produced by immunizing mice with a novel peptide-conjugate. Immunoblots demonstrate that 40 strains of influenza encompassing HA subtypes H1 to H13, as well as B strains from the Yamagata and Victoria lineage were detected when the two mAbs are combined to form a pan-HA mAb cocktail. Quantification using this pan-HA mAbs cocktail was achieved in a dot blot assay and results correlated with concentrations measured in a hemagglutination assay with a coefficient of correlation of 0.80. A competitive ELISA was also optimised with purified viral-like particles. Regardless of the quantification method used, pan-HA antibodies can be employed to accelerate process development when strain-specific antibodies are not available, and represent a valuable tool in case of pandemics. These antibodies were also expressed in CHO cells to facilitate large-scale production using bioreactor technologies which might be required to meet industrial needs for quantification reagents. Finally, a simulation model was created to predict the binding affinity of the two anti-HA antibodies to the amino acids composing the highly conserved epitope; different probabilities of interaction between a given amino acid and the antibodies might explain the affinity of each antibody against different influenza strains. © 2017 Manceur et al. Generative Calibration for In-context Learning**Item Type** Conference Paper**Author** Z. Jiang**Author** Y. Zhang**Author** C. Liu**Author** J. Zhao**Author** K. Liu

Abstract As one of the most exciting features of large language models (LLMs), in-context learning is a mixed blessing. While it allows users to fast-prototype a task solver with only a few training examples, the performance is generally sensitive to various configurations of the prompt such as the choice or order of the training examples. In this paper, we for the first time theoretically and empirically identify that such a paradox is mainly due to the label shift of the in-context model to the data distribution, in which LLMs shift the label marginal $p(y)$ while having a good label conditional $p(x|y)$. With this understanding, we can simply calibrate the in-context predictive distribution by adjusting the label marginal, which is estimated via Monte-Carlo sampling over the in-context model, i.e., generation of LLMs. We call our approach as generative calibration. We conduct exhaustive experiments with 12 text classification tasks and 12 LLMs scaling from 774M to 33B, generally find that the proposed method greatly and consistently outperforms the ICL as well as state-of-the-art calibration methods, by up to 27% absolute in macro-F1. Meanwhile, the proposed method is also stable under different prompt configurations. © 2023 Association for Computational Linguistics.

Abstract INTRODUCTION: M0 images were missing in Siemens ASL data in Alzheimer's Disease Neuroimaging Initiative (ADNI) dataset, prohibiting cerebral blood flow (CBF) quantification. METHODS: A conditional latent diffusion model was trained and evaluated on in-house datasets, then applied to the Siemens data in ADNI-3. Regional CBF differences by Alzheimer's disease (AD) stages, their accuracy for AD classification, and CBF trajectory slopes were compared between generated data (Siemens) and acquired data (General Electric). RESULTS: The diffusion model generated M0 images with high fidelity (SSIM = 0.918 ± 0.023 , PSNR = 31.361 ± 2.537) and minimal CBF bias (mean difference is 0.21 ± 1.58 mL/100 g/min). Both generated and acquired CBF showed similar spatial patterns and decreasing trends with AD progression in specific AD-related regions. Generated CBF also improved accuracy in classifying AD stages compared to qualitative perfusion images. CONCLUSION: This study shows the potential of diffusion models for imputing missing modalities in large-scale studies exploring the use of ASL as a biomarker of AD. Highlights: Using latent diffusion model, we can generate M0 image from control image in arterial spin labeling (ASL) with high fidelity. The generated M0 can be used for cerebral blood flow (CBF) quantification

in Alzheimer's Disease Neuroimaging Initiative dataset. The performance of classification between Alzheimer's disease (AD) patients and cognitive normal people is better when using generated CBF maps than using non-quantitative perfusion images. ASL CBF decreases with AD progression in key AD-related brain regions. © 2025 The Author(s). Abstract Cardiometabolic diseases are an increasing global health burden. While socioeconomic, environmental, behavioural, and genetic risk factors have been identified, a better understanding of the underlying mechanisms is required to develop more effective interventions. Magnetic resonance imaging (MRI) has been used to assess organ health, but biobank-scale studies are still in their infancy. Using over 38,000 abdominal MRI scans in the UK Biobank, we used deep learning to quantify volume, fat, and iron in seven organs and tissues, and demonstrate that imaging-derived phenotypes reflect health status. We show that these traits have a substantial heritable component (8–44%) and identify 93 independent genome-wide significant associations, including four associations with liver traits that have not previously been reported. Our work demonstrates the tractability of deep learning to systematically quantify health parameters from high-throughput MRI across a range of organs and tissues, and use the largest-ever study of its kind to generate new insights into the genetic architecture of these traits. © Liu et al.

GeneWalk identifies relevant gene functions for a biological context using network representation learning

Item Type Journal Article

Author R. Ietswaart

Author B.M. Gyori

Author J.A. Bachman

Author P.K. Sorger

Author L.S. Churchman

Abstract A bottleneck in high-throughput functional genomics experiments is identifying the most important genes and their relevant functions from a list of gene hits. Gene Ontology (GO) enrichment methods provide insight at the gene set level. Here, we introduce GeneWalk (github.com/churchmanlab/genewalk) that identifies individual genes and their relevant functions critical for the experimental setting under examination. After the automatic assembly of an experiment-specific gene regulatory network, GeneWalk uses representation learning to quantify the similarity between vector representations of each gene and its GO annotations, yielding annotation significance scores that reflect the experimental context. By performing gene- and condition-specific functional analysis, GeneWalk converts a list of genes into data-driven hypotheses. © 2021, The Author(s).

Abstract A high-throughput targeted quantification method based on GC–MS/MS was established to determine 156 trace volatile aroma compounds (TVACs) in Sauce-flavor Baijiu. The method showed good linearity over 2–10,000 µg/L ($R^2 > 0.99$), low LOQs (< 25.76 µg/L), satisfactory precision ($RSD < 3.96\%$), acceptable recoveries (82.11–118.04%), and low matrix effects ($\leq \pm 15\%$). Compared with HS-SPME-GC–MS, it allowed high-throughput, more accurate quantification with simple pretreatment. Based on orthogonal partial least squares discriminant analysis (OPLS-DA) combined with $VIP > 1$ and $p < 0.05$, 40 potential differential compounds were screened from 46 SRBB samples originating from six regions. Random forest model was subsequently established and evaluated using stratified 5-fold cross-validation to preserve class distribution, followed by validation with an independent test set, achieving an accuracy of 90.00%. SHAP (Shapley additive explanations) analysis identified compounds contributing to differences among regions, providing a useful approach for regional discrimination and flavor profiling of Baijiu. Geographical aspects of enterobiasis in Estonia

Item Type Journal Article

Author K. Remm

Author M. Remm

Abstract This paper examines the geographical pattern of the prevalence of enterobiasis among children in Estonian counties, and methods for risk modelling. The methodological questions were as follows:(1)Is the prevalence of enterobiasis related to geographical region and settlement size?(2)Is the reliability of risk estimations related to the modelling method and sample size? Case-based predictions were more liable to result in over fitting in the case of small training samples than the classification tree models. The spatial autocorrelation of the prevalence was significant up to a distance of 20 km. The main reason for the differences in the predictions might simply be the regional differences in the prevalence. © 2009 Elsevier Ltd. All rights reserved.

Geometric Continuity and Consistency Learning for Self-Supervised Point Cloud Completion

Item Type Journal Article

Author J. Ma

Author S. Wang

Author Q. Zheng

Author X. Mai

Abstract Point cloud completion aims to infer the complete point clouds from incomplete ones. In real-world scenarios, where the paired data is absent, self-supervised methods have emerged as a promising solution. Although existing self-supervised methods perform well at relatively low resolutions, they suffer significant performance degradation at

higher resolution primarily because they focus on point cloud reconstruction at patch-level or point-level. In this paper, we propose a self-supervised method based on Geometric Continuity and Consistency Learning (GCCL) at multi-scale level to improve the accuracy of predicting local details and global shapes of point clouds. Specifically, to capture local details, we employ a patch-to-point strategy and a coarse-fine manner for geometric continuity learning. To constrain the global shapes, we construct multiple branches for mutual supervision and utilize class priors to build a memory queue for contrasting current features, enhancing the network focus on geometric consistency learning. We evaluate GCCL on multiple datasets, and the results show that our method outperforms existing self-supervised methods by a 4.4 improvement in CD- ℓ_2 on the synthetic PCN dataset and can generate more uniformly distributed completion results on real-world datasets. © 1999-2012 IEEE.

GeoNet: Benchmarking Unsupervised Adaptation across Geographies

Item Type Conference Paper

Author T. Kalluri

Author W. Xu

Author M. Chandraker

Abstract In recent years, several efforts have been aimed at improving the robustness of vision models to domains and environments unseen during training. An important practical problem pertains to models deployed in a new geography that is under-represented in the training dataset, posing a direct challenge to fair and inclusive computer vision. In this paper, we study the problem of geographic robustness and make three main contributions. First, we introduce a large-scale dataset GeoNet for geographic adaptation containing benchmarks across diverse tasks like scene recognition (GeoPlaces), image classification (GeoImNet) and universal adaptation (GeoUniDA). Second, we investigate the nature of distribution shifts typical to the problem of geographic adaptation and hypothesize that the major source of domain shifts arise from significant variations in scene context (context shift), object design (design shift) and label distribution (prior shift) across geographies. Third, we conduct an extensive evaluation of several state-of-the-art unsupervised domain adaptation algorithms and architectures on GeoNet, showing that they do not suffice for geographical adaptation, and that large-scale pre-training using large vision models also does not lead to geographic robustness. Our dataset is publicly available at <https://tarun005.github.io/GeoNet>. © 2023 IEEE.

Geospatial Analysis of Land Use Changes and Its Implications on Agricultural Production

Item Type Conference Paper

Author M.D. Sree

Author V. Sarada

Author S.K. Singh

Author V. Priyadarshini

Author S.S. Vasanthi

Author V. Balasubramanian

Abstract The conversion of land use patterns generates substantial effects on food cultivation which affects the stability of both food supply and economy. Specifically, this methodology utilizes advanced satellite imagery processing and machine learning to quantify land use transformations and their impacts on agriculture, and geospatial analysis to carry out this process. The pre-analysis processes including cloud mask technique combined with georeferencing and feature extraction yield quality satellite dataset information. ReliefF algorithm serves for feature selection by finding key spectral and temporal indicators that affect agricultural productivity. The research employs CNN+LSTM deep learning techniques which use both spatial feature extraction from CNN and temporal ability of LSTM for land use change classification. The research results show accurate land classification outcomes which enable exact agricultural transition detection. Post-classification validation methods through change detection analysis and statistical assessments help show how much and what patterns in agricultural land transformations appear. The applied research offers vital data-based information for sustainable land management that helps officials and agricultural organizations reduce detrimental land use change effects. © 2025 IEEE.

GeT: Generative Target Structure Debiasing for Domain Adaptation

Item Type Conference Paper

Author C. Zhang

Author G.H. Lee

Abstract Domain adaptation (DA) aims to transfer knowledge from a fully labeled source to a scarcely labeled or totally unlabeled target under domain shift. Recently, semi-supervised learning-based (SSL) techniques that leverage pseudo labeling have been increasingly used in DA. Despite the competitive performance, these pseudo labeling methods rely heavily on the source domain to generate pseudo labels for the target domain and therefore still suffer considerably from source data bias. Moreover, class distribution bias in the target domain is also often ignored in the pseudo label generation and thus leading to further deterioration of performance. In this paper, we propose GeT that learns a non-bias target embedding distribution with high quality pseudo labels. Specifically, we formulate an online target generative classifier to induce the target distribution into distinctive Gaussian components weighted by their class priors to mitigate source data bias and enhance target class discriminability. We further propose a structure similarity regularization framework to alleviate target class distribution bias and further improve target class discriminability. Experimental results show that our proposed GeT is effective and achieves consistent improvements under various DA settings with and without class distribution bias. Abstract Background – Quantitative and reproducible microbiome analysis is limited by fragmented workflows lacking standardized anaerobic sampling, absolute quantification methods, and transparent AI inference. Patent-documented engineering integration is required for reliable microbiome analytics at population scale. Methods – Gi-MAPS was designed as an end-to-end analytical system integrating several core patented innovations, including (i) a press-activated anaerobic sample-preservation device that maintains ultra-low residual oxygen to protect obligate anaerobes during transport, (ii) a multiplex qPCR assay enabling simultaneous absolute quantification

of key HMO-utilizing *Bifidobacterium* species in a single reaction, and (iii) a CIT-Net-based digital-twin engine that supports forward simulation of gut microbiota ecological trajectories. These modules are coupled with explainable ensemble artificial intelligence models to form a fully quantitative and simulation-enabled microbiome analysis framework. Each subsystem was validated under granted patents to define engineering performance boundaries and reproducibility specifications. Results – System validation demonstrated <0.1% residual oxygen stability for anaerobic preservation, detection sensitivity down to five genomic copies per microliter, AUC > 0.97 for ecological maturity estimation, 89% accuracy for disease-risk classification, and 95% concordance for digital-twin forecasting. Execution-layer software copyright modules and filed patents extend automation, visualization, and future application domains. Conclusion – Gi-MAPS provides a patent-anchored, standardized engineering framework whose key novelties lie in oxygen-controlled anaerobic sampling, absolute microbial quantification via multiplex qPCR, and digital-twin ecological simulation, enabling quantitative, function-aware, and prospective microbiome analysis. It establishes a reproducible foundation enabling large-scale cohort deployment, longitudinal ecological monitoring, digital-twin simulation, and future multi-omics integration. Global Balanced Experts for Federated Long-Tailed Learning

Item Type Conference Paper

Author Y. Zeng

Author L. Liu

Author L. Liu

Author L. Shen

Author S. Liu

Author B. Wu

Abstract Federated learning (FL) is a prevalent distributed machine learning approach that enables collaborative training of a global model across multiple devices without sharing local data. However, the presence of long-tailed data can negatively deteriorate the model's performance in real-world FL applications. Moreover, existing re-balance strategies are less effective for the federated long-tailed issue when directly utilizing local label distribution as the class prior at the clients' side. To this end, we propose a novel Global Balanced Multi-Expert (GBME) framework to optimize a balanced global objective, which does not require additional information beyond the standard FL pipeline. In particular, a proxy is derived from the accumulated gradients uploaded by the clients after local training, and is shared by all clients as the class prior for re-balance training. Such a proxy can also guide the client grouping to train a multi-expert model, where the knowledge from different clients can be aggregated via the ensemble of different experts corresponding to different client groups. To further strengthen the privacy-preserving ability, we present a GBME-p algorithm with a theoretical guarantee to prevent privacy leakage from the proxy. Extensive experiments on long-tailed decentralized datasets demonstrate the effectiveness of GBME and GBME-p, both of which show superior performance to state-of-the-art methods. The code is available at here. © 2023 IEEE.

Abstract Microplastics (MPs) in soil can paradoxically stimulate microbial biomass in a highly context-dependent manner, potentially inducing decomposition and affecting carbon and nitrogen cycles. We conducted a global meta-analysis with 90 studies (710 observations of microbial biomass carbon (MBC), 354 of microbial biomass nitrogen (MBN)) integrated with machine learning to quantify MPs effects on soil microbial biomass. Field studies showed no significant effects, contrasting with controlled experiments where MPs increased MBC by 9.6% (95% CI: 7.2–11.9%) and MBN by

10.4% (6.8–14.0%). Biodegradable plastics (PBAT, PLA) induced stronger effects (36.1–67.6%) than conventional polymers (PE, PP, PS, PVC). Temperature emerged as the dominant factor, with a contrasting MPs effect on MBC (positive) and MBN (negative) at higher temperatures, suggesting potential decoupling of carbon and nitrogen cycles under warming conditions. Machine learning models (XGBoost, $R^2 = 0.62$) significantly outperformed linear regressions ($R^2 = 0.02–0.05$), revealing nonlinear responses and threshold effects. Stimulatory effects were most significant for medium-sized MPs (30–90 μm), at high concentrations ($>10 \text{ g kg}^{-1}$), and in soils with intermediate fertility, highlighting context-dependent risks to soil carbon and nitrogen cycling. © 2025 The Authors. Google Earth Engine-enabled Mangrove Monitoring: A Systematic Review

Item Type Journal Article

Author K. Patil

Author R. Pawar

Author N. Gangan

Author A. Kurmi

Abstract Mangrove ecosystems are central to global climate mitigation and coastal resilience, yet their monitoring remains inherently complex due to tidal inundation, spectral ambiguity and persistent cloud cover across tropical regions. The emergence of cloud-based geospatial platforms, particularly the Google Earth Engine (GEE), has transformed mangrove remote sensing from scene-based analysis to scalable, multi-sensor, time-series frameworks operating at planetary scale. This study presents a systematic review and critical synthesis of 162 peer-reviewed studies published between 2017 and 2025, examining the structural evolution, methodological foundations and ecological implications of GEE-enabled mangrove research. Bibliometric assessment indicates rapid expansion of the field, reflecting a transition from early methodological experimentation to widespread application. Thematic evolution reveals a clear shift from two-dimensional extent mapping to increasingly dynamic and process-oriented analyses, including disturbance monitoring, hydroperiod assessment, biomass estimation and blue carbon quantification. Methodologically, the literature is strongly anchored in ensemble machine learning approaches, particularly Random Forest, supported by multi-sensor integration of optical time-series (Landsat, Sentinel-2) and Synthetic Aperture Radar (SAR) to mitigate atmospheric and tidal constraints. Despite these advances, critical structural limitations persist. Research output and study-area focus remain geographically concentrated in a limited number of countries, whereas several ecologically significant mangrove regions remain underrepresented, indicating a mismatch between research capacity and ecosystem distribution. Furthermore, although classification accuracy has improved substantially, persistent uncertainties arising from tidal variability, spectral similarity, training data bias and limited model transferability constrain ecological interpretation. These findings indicate that GEE has successfully enabled large-scale mangrove monitoring but has not yet fully translated computational advances into ecological understanding or operational decision-making. Future research should prioritize cross-regional model validation, the integration of structural datasets such as spaceborne light detection and ranging (LiDAR), and the development of interpretable, process-based frameworks to better connect remote sensing outputs with ecosystem functioning. Strengthening these directions is essential to ensure that GEE-based monitoring systems effectively

contribute to global mangrove conservation, blue carbon accounting and climate-resilient coastal management. © The Author(s), under exclusive licence to Springer Nature Switzerland AG 2026.

Gossen's first law in the modeling for demand side management: a thorough heat pump case study with deep learning based partial time series data generation

Item Type Journal Article

Author V. Hagenmeyer

Abstract Gossen's First Law describes the law of diminishing marginal utility. This paper aims to further verify the proposed hypothesis that Gossen's First Law also holds in the modeling for Demand Side Management (DSM) with a thorough heat pump case study. The proposed hypothesis states that in general the complexity-utility relationship in the field of DSM modeling could be represented by a diminishing marginal utility curve. On the other hand, in data based modeling, when utilizing a large dataset for validation, the data integrity is critical to the reliability of the results. However, the absence of partial time series data may occur during the measurement due to missing sensors or IT related issues. In this work, an extensive real-world open dataset of a ground source heat pump is utilized for the case study. In the raw data, one key variable namely the flow rate is missing. Thus, three different algorithms based on machine learning and deep learning architectures namely Random Forest (RF), Long Short-Term Memory (LSTM) and Transformer are applied to predict the flow rate by utilizing an open loop forecasting. The raw data are first pre-processed with a time interval of one hour and then used for training, validation and forecast. Furthermore, a modified persistence model as the baseline is also defined. The predicted flow rate using LSTM yields the lowest error of 7.47% nMAE and 10.56% nRMSE respectively. The forecast results are then utilized in the following step of modeling of a heat pump use case. With the introduced quantification method for complexity and a modified version for utility, we further verify the proposed hypothesis with a longer time horizon of 7 days. © The Author(s) 2024.

Gradient-Based Quantification of Epistemic Uncertainty for Deep Object Detectors

Item Type Conference Paper

Author T. Riedlinger

Author M. Rottmann

Author M. Schubert

Author H. Gottschalk

Abstract The majority of uncertainty quantification methods for deep object detectors are based on the network output, such as sampling strategies like Monte-Carlo dropout or deep ensembles with straight-forward transfers to object detection. Here, we study gradient-based uncertainty features for object detection. We show that they contain information orthogonal to that of common, output-based uncertainty approximation methods. Meta classification and meta regression are used to produce confidence estimates using gradient features and other methods which are applicable to numerous object detection architectures. Our results show that gradient uncertainty itself performs on par with state-of-the-art methods across different detectors and datasets. We find that combined meta classifiers outperform standalone models. This suggests that sampling strategies may be supplemented by gradient-based uncertainty to obtain improved confidences, contributing to the probabilistic reliability of object detectors in down-stream applications. © 2023 IEEE.

Graph positive-unlabeled learning via Bootstrapping Label Disambiguation

Item Type Journal Article

Author C. Liang

Author Y. Cheng

Author M. Li

Author S. Pan

Author H. Zhang

Abstract Graph positive-unlabeled learning is an important task that tries to learn binary classification models from only positive and unlabeled (PU) nodes. While state-of-the-art methods focus on training graph neural networks, they frequently rely on weak objective functions derived solely from a given class prior probability or inferred exclusively from the graph structure, leading their performance significantly lags behind that of fully labeled counterparts. In this paper, we fill this gap by treating unlabeled nodes as samples ambiguously labeled as both positive and negative, and by introducing a learning method called Bootstrap Label Disambiguation (BLD), which progressively resolves label ambiguities during the training of binary classifiers. BLD comprises a node representation learning module via bootstrapping and a novel central region-based label disambiguation strategy. The learning module leverages both previous representations and the derived positive centroid as targets to train positive-aligned representations, eliminating the need for a prior. Consequently,

the disambiguation strategy constructs a central-region to identify ambiguous nodes and steadily transforms them into effective supervision. Extensive experiments on a range of real-world datasets show that our BLD method significantly outperforms existing approaches and in many cases even surpasses fully labeled classification models. The source code is available at <https://github.com/yunyun85/BLD>. © 2025

Graph-based label propagation with dissimilarity regularization

Item Type Conference Paper

Author H. Zheng

Author H.H.S. Ip

Abstract Recent studies have shown promising performance of graphbased semi-supervised learning. But one of major limitations of most graph-based semi-supervised learning approaches is that they did not explore the label dissimilarity knowledge. In this paper, we presented a novel graph-based label propagation framework that effectively incorporates similarity and dissimilarity information into semi-supervised classification. The class mass normalization is utilized to make the label decision rule match class priors. The function induction algorithm is also proposed to predict the labels of test data. In particular, by solving quadratic optimization, our approach can give rise to closed-form solution for classification functions of unlabeled data and out-of-sample data. The proposed framework has been extensively evaluated over three widely used datasets for image classification task. The experimental results in terms of classification accuracy demonstrate that the proposed method can achieve significant performance improvements with respect to the state-of-the-arts. © Springer International Publishing Switzerland 2013.

GRAPH-BASED LIGHT-CURVE FEATURES FOR ROBUST TRANSIENT CLASSIFICATION

Item Type Journal Article

Author J.D. Petro-Ramos

Author D.J. Ruiz-Morales

Author D. Sierra-Porta

Abstract We investigate graph-based representations of astronomical light curves for transient classification on a quality-controlled, class-balanced subset of the MANTRA benchmark (minimum coverage $N_{\min} = 100$ epochs; $N = 1,705$ objects after filtering and Non-Tr. subsampling). Each series is mapped to three visibility-graph views—horizontal (HVG), directed (DHVG), and weighted (W-HVG)—from which we extract compact, length-aware network descriptors (degree/strength moments, clustering and motifs, assortativity, path/efficiency, and spectral summaries). Using object-level stratified five-fold validation and tree-based learners, the best configuration (LightGBM with HVG+DHVG+W-HVG features) attains a macro-F1 of 0.622 ± 0.010 and accuracy of 0.661 ± 0.010 on this subset. For context, the published MANTRA baseline reports $F1_{\text{macro}} = 0.528$ on the full dataset; because class priors differ after quality control, this reference is not a like-for-like comparison. Ablations show that weighted contrasts and directed asymmetry contribute complementary gains to undirected topology. Per-class analysis highlights strong performance for CV, HPM, and Non-Tr., with residual confusions concentrated in the AGN–Blazar–SN block. These results indicate that visibility graphs offer a simple, survey-agnostic bridge between irregular photometric time series and standard classifiers, yielding competitive multiclass performance without bespoke deep architectures. We release code and feature definitions together with the list of object IDs used in the evaluation subset to facilitate reproducibility and future extensions. © 2026, National University of Ireland Maynooth. Graph-based PU learning for binary and multiclass classification without class prior

Item Type Journal Article

Author J. Yoo

Author J. Kim

Author H. Yoon

Author G. Kim

Author C. Jang

Author U. Kang

Abstract How can we classify graph-structured data only with positive labels? Graph-based positive-unlabeled (PU) learning is to train a binary classifier given only the positive labels when the relationship between examples is given as a graph. The problem is of great importance for various tasks such as detecting malicious accounts in a social network, which are difficult to be modeled by supervised learning when the true negative labels are absent. Previous works for graph-based PU learning assume that the prior distribution of positive nodes is known in advance, which is not true in many real-world cases. In this work, we propose GRAB (Graph-based Risk minimization with iterative Belief propagation), a novel end-to-end approach for graph-based PU learning that requires no class prior. GRAB runs marginalization and update steps iteratively. The marginalization step models the given graph as a Markov network and estimates the marginals of latent variables. The update step trains the binary classifier by utilizing the computed marginals in the objective function. We then generalize GRAB to multi-positive unlabeled (MPU) learning, where multiple positive classes exist in a dataset. Extensive experiments on five real-world datasets show that GRAB achieves the state-of-the-art performance, even when the true prior is given only to the competitors. © 2022, The Author(s), under exclusive licence to Springer-Verlag London Ltd., part of Springer Nature.

Graph-based semi-supervised learning as a generative model

Item Type Conference Paper

Author J. He

Author J. Carbonell

Author Y. Liu

Abstract This paper proposes and develops a new graph-based semi-supervised learning method. Different from previous graph-based methods that are based on discriminative models, our method is essentially a generative model in that the class conditional probabilities are estimated by graph propagation and the class priors are estimated by linear regression. Experimental results on various datasets show that the proposed method is superior to existing graph-based semi-supervised learning methods, especially when the labeled subset alone proves insufficient to estimate meaningful class priors.

Graph-in-graph discriminative feature enhancement network for fine-grained visual classification

Item Type Journal Article

Author Y. Wang

Author C. Xu

Author Y. Wang

Author X. Wang

Author W. Ding

Abstract Fine-grained visual classification (FGVC) seeks to identify sub-classes within the same meta-class. Prior efforts mainly mine the features of discriminative parts to enhance classification performance. However, we argue that most of these works ignore the spatial details inside each part and the spatial correlations between parts when extracting local features and fusing global features, inhibiting the further improvement of feature quality, especially for the irregular discriminative parts. To alleviate this issue, we rethink the feature generation route from pixels to parts and to objects, and propose a novel graph-in-graph discriminative feature enhancement network (G2DFE-Net). Specifically, the G2DFE-Net consists of two nested graph convolutional networks, where an internal graph is first developed based on the spatial attention strategy to highlight details of the irregular discriminative regions. Then, a KNN-based external graph is introduced to capture the spatial context correlation among independent discriminative parts. With the collaboration of internal and external graph, G2DFE-Net boosts the class separability and compactness of global feature representation, thereby benefiting the accurate FGVC. We conduct thorough experiments on five benchmark datasets, and both quantitative and qualitative results confirm the superior accuracy of our G2DFE-Net compared to previous state-of-the-art algorithms. The code is available at <https://github.com/WangYuPeng1/G2DFE-Net>. © The Author(s), under exclusive licence to Springer Science+Business Media, LLC, part of Springer Nature 2024.

Graph-Smoothed Bayesian Black-Box Shift Estimator and Its Information Geometry

Item Type Conference Paper

Author M. Kimura

Abstract Label shift adaptation aims to recover target class priors when the labelled source distribution P and the unlabelled target distribution Q share $P(X | Y) = Q(X | Y)$ but $P(Y) \neq Q(Y)$. Classical black-box shift estimators invert an empirical confusion matrix of a frozen classifier, producing a brittle point estimate that ignores sampling noise and similarity among classes. We present Graph-Smoothed Bayesian BBSE (GS-B3SE), a fully probabilistic alternative that places Laplacian-Gaussian priors on both target log-priors and confusion-matrix columns, tying them together on a label-similarity graph. The resulting posterior is tractable with HMC or a fast block Newton-CG scheme. We prove identifiability, $N^{-1/2}$ contraction, variance bounds that shrink with the graph's algebraic connectivity, and robustness to Laplacian misspecification. We also reinterpret GS-B3SE through information geometry, showing that it generalizes existing shift estimators. © 2025 Neural information processing systems

Graphboot: Quantifying uncertainty in node feature learning on large networks

Item Type Journal Article

Author C.G. Akcora

Author Y.R. Gel

Author M. Kantarcioglu

Author V. Lyubchich

Author B. Thuraisingham

Abstract In recent years, as online social networks continue to grow in size, estimating node features, such as sociodemographics, preferences and health status, in a scalable and reliable way has become a primary research direction in social network mining. Although many techniques have been developed for estimating various node features, quantifying uncertainty in such estimations has received little attention. Furthermore, most existing methods study networks parametrically, which limits insights about necessary quantity of queried data, reliable feature estimation, and estimator uncertainty. Uncertainty quantification is critical for answering key questions, such as, given a limited availability of social network data, how much data should be queried from the network?, and which node features can be learned reliably? More importantly, how can we evaluate uncertainty of our estimators? Uncertainty quantification is not equivalent to network sampling but constitutes a key complementary concept to sampling and the associated reliability analysis. To our knowledge, this paper is the first work that sheds light on uncertainty quantification

and uncertainty propagation in social network feature mining. We propose a novel non-parametric bootstrap method for uncertainty analysis of node features in social network mining, derive its asymptotic properties, and demonstrate its effectiveness with extensive experiments. Furthermore, we develop a new metric based on dispersion of estimations, enabling analysts to assess how much more information is needed for increasing prediction reliability based on the estimated uncertainty. We demonstrate the effectiveness of our new uncertainty quantification methodology with extensive experiments on real life social networks, and a case study of mental health on Twitter. © 1989-2012 IEEE.

GraphCast-Qtf: An improved weather prediction model based on uncertainty quantification methods

Item Type Conference Paper

Author L. Zheng

Author R. Xing

Author Y. Wang

Abstract In the field of climate prediction, although the traditional numerical weather forecasting (NWP) method has made significant progress in the processing of historical data and improving the prediction accuracy, it still has significant limitations in using a large amount of historical climate data and improving the credibility of the prediction results. With the rapid development of deep learning technologies, deep learning-based climate prediction models, such as GraphCast, have shown their potential in global mid-term (10-day) climate variable prediction. However, existing methods often ignore the quantification of prediction uncertainty, which is crucial to improving the prediction's reliability and practical application value. This study proposes an improved GraphCast model called GraphCast-Qtf, mainly by introducing uncertainty quantification mechanisms designed to improve the accuracy and credibility of climate predictions. This research is divided into data set construction, model construction, and system development. First, this study constructed a global climate dataset based on the ERA5 reanalysis data set of ECMWF, including historical weather states and associated climate variables from 1979 to the present. This dataset covers the global scope and provides highresolution climate variable data, providing rich input features for the training of deep learning models. Secondly, based on the GraphCast model, this study introduces the Bayesian neural network and Monte Carlo dropout technology to enable the model to output the confidence interval of the prediction value to quantify the uncertainty of the prediction results. These improvements enhance the model's ability to learn from the intrinsic changing laws of climate systems and enable the model to handle better and reflect the uncertainty of prediction outcomes. Finally, we developed a simple climate prediction system based on the GraphCast-Qtf model. The system provides mediumterm climate forecasts and assessments of their uncertainty. The system's front end is developed using JavaScript and the Vue framework. It is user-friendly and easy to operate, enabling users to provide scientific and reasonable decision support according to the prediction results and confidence intervals provided by the model. Through extensive experimental validation, the GraphCast-Qtf model performed better than traditional methods in terms of prediction accuracy and uncertainty quantification of multiple key climate variables. The application examples in the system development section further demonstrate the model's effectiveness and potential in practical climate prediction scenarios. © 2024 IEEE.

GraphGS: Mitigating Pseudo-Label Shift in Imbalanced Node Classification via Balanced Feature Propagation and Minority Node Selection

Item Type Journal Article

Author Z. He

Author C. Zhu

Author C. Xie

Author H. Cai

Author Y. Yang

Abstract Graph-structured data in real-world applications often grapple with class imbalance, where underrepresented minority nodes result in biased predictions and diminished learning performance. Although pseudo-labeling methods offer a promising solution for addressing class imbalance, they remain susceptible to pseudo-label shift. This phenomenon occurs when class biases in pseudo-labels propagate during data augmentation, further compromising model effectiveness. To overcome these challenges, we present GraphGS, an innovative framework designed to alleviate pseudo-label shift in class-imbalanced graph datasets. GraphGS integrates two pivotal components: a feature balancer that curtails excessive information transfer from majority to minority nodes, safeguarding the unique characteristics of minority classes, and a node selector that identifies high-confidence minority nodes through similarity metrics. Together, these components enhance minority class representations without introducing noise, enabling more equitable and reliable training of Graph Neural Networks (GNNs). Comprehensive experiments on diverse real-world datasets underscore the robustness and adaptability of GraphGS. Notably, on the CiteSeer dataset, GraphGS achieves an outstanding 2.60% improvement in accuracy over state-of-the-art methods, marking a significant advance in minority class classification. © 2017 IEEE.

Abstract The task of classifying X-ray data is a problem of both theoretical and clinical interest. Whilst supervised deep learning methods rely upon huge amounts of labelled data, the critical problem of achieving a good classification accuracy when an extremely small amount of labelled data is available has yet to be tackled. In this work, we introduce a novel semi-supervised framework for X-ray classification which is based on a graph-based optimisation model. To the best of our knowledge, this is the first method that exploits graph-based semi-supervised learning for X-ray data classification. Furthermore, we introduce a new multi-class classification functional with carefully selected class priors which allows for a smooth solution that strengthens the synergy between the limited number of labels and the huge amount of unlabelled data. We demonstrate, through a set of numerical and visual experiments, that our method produces highly competitive results on the ChestX-ray14 data set whilst drastically reducing the need for annotated data. © 2019, Springer Nature Switzerland AG.

Abstract Existing visual explanation generating agents learn to fluently justify a class prediction. However, they may mention visual attributes which reflect a strong class prior, although the evidence may not actually be in the image. This is particularly concerning as ultimately such agents fail in building trust with human users. To overcome this limitation, we propose a phrase-critic model to refine generated candidate explanations augmented with flipped phrases which we use as negative examples while training. At inference time, our phrase-critic model takes an image and a candidate explanation as input and outputs a score indicating how well the candidate explanation is grounded in the image. Our explainable AI agent is capable of providing counter arguments for an alternative prediction, i.e. counterfactuals, along with explanations that justify the correct classification decisions. Our model improves the textual explanation quality of fine-grained classification decisions on the CUB dataset by mentioning phrases that are grounded in the image. Moreover, on the FOIL tasks, our agent detects when there is a mistake in the sentence, grounds the incorrect phrase and corrects it significantly better than other models. © 2018, Springer Nature Switzerland AG.

Editor Milazzo A.
Abstract The guided-wave-based damage detection methodology is a well-established branch of Structural Health Monitoring. There are, however, many different approaches to processing and interpretation of signals acquired using guided waves. This paper presents the results of the SYPIN project in which a large database acquired in a diverse set of experiments was assembled. The experiments included static and variable environmental conditions, composite and metallic specimens of simple and complex geometries. The set includes, in particular, results of experiments on real-life aircraft specimens. This dataset was then used to benchmark several damage detection and quantification methodologies, including various classifiers and feature extraction methods. The performance of the methods is evaluated in a series of experiments, including knowledge transfer between different specimens. The paper presents the results of this research and provides a brief description of the dataset, which is made available for the scientific community's use. © 2023, The Author(s), under

Abstract Clinical disease classification naturally follows a hierarchical reasoning process, where clinicians first distinguish coarse diagnostic categories (e.g., benign vs. malignant) before identifying specific subtypes to enhance diagnostic accuracy. While multi-view imaging offers complementary perspectives, most existing machine learning approaches perform flat decision fusion, ignoring this intrinsic hierarchy and handling inter-view conflicts and uncertainty primarily at the decision-fusion level. To address this gap, we propose the Hierarchical Multi-view Evidence Aggregation Network (H-MEAN), an end-to-end architecture that explicitly mimics clinical decision-making process. H-MEAN consists of three key modules: (i) Multi-View Fusion, which jointly encodes heterogeneous imaging views to capture complementary features; (ii) Hierarchical Tree Alignment, which structurally propagates diagnostic cues across granularity levels to enforce clinical consistency; and (iii) Hierarchical Evidential Aggregation, which leverages evidential deep learning to quantify uncertainty throughout the diagnostic hierarchy. Extensive experiments on two multi-view medical datasets demonstrate that H-MEAN consistently outperforms competitive methods, achieving higher classification accuracy, particularly in challenging settings with missing or noisy views. © 2025 IEEE.

Habitat associations of two entomopathogenic nematodes: A quantitative study using real-time quantitative polymerase chain reactions

Item Type Journal Article

Author P. Torr

Author S.E. Spiridonov

Author S. Heritage

Author M.J. Wilson

Abstract Despite nematodes being the most abundant animals on earth, very few animal ecologists study them, probably because of the difficulties of identifying them to species by morphological methods. A group of nematodes that are important both ecologically and economically is the entomopathogenic nematodes, which play a key role in regulating soil food webs and are sold throughout the world as biological insecticides, yet for which very little is known of their population ecology. A novel detection and quantification method was developed for soil nematodes using real-time polymerase chain reaction (PCR), and the technique was used to estimate numbers of two closely related species of entomopathogenic nematodes, *Steinernema kraussei* and *S. affine* in 50 soil samples from 10 sites in Scotland representing two distinct habitats (woodland and grassland). There was a high degree of correlation between our molecular and traditional morphological estimates of population size and our data clearly showed that *Steinernema affine* occurred only in grassland areas, whereas *S. kraussei* was found in grassland and woodland samples to a similar degree. Real-time PCR offers a rapid and accurate method of detecting individual nematode species from soil samples without the need for a specialist taxonomist, and has much potential for use in studies of nematode population ecology. © 2007 The Authors.

HairNet2: deep learning to quantify cotton leaf hairiness, a complex genetic and environmental trait

Abstract Background: Cotton accounts for 80% of the global natural fibre production. Its leaf hairiness affects insect resistance, fibre yield, and economic value. However, this phenotype is still qualitatively assessed by visually attributing a Genotype Hairiness Score (GHS) to a leaf/plant, or by using the HairNet deep-learning model which also outputs a GHS. Here, we introduce HairNet2, a quantitative deep-learning model which detects leaf hairs (trichomes) from images and outputs a segmentation mask and a Leaf Trichome Score (LTS). Results: Trichomes of 1250 images were annotated (AnnCoT) and a combination of six Feature Extractor modules and five Segmentation modules were tested alongside a range of loss functions and data augmentation techniques. HairNet2 was further validated on the dataset used to build HairNet (CotLeaf-1), a similar dataset collected in two subsequent seasons (CotLeaf-2), and a dataset collected on two genetically diverse populations (CotLeaf-X). The main findings of this study are that (1) leaf number, environment and image position did not significantly affect results, (2) although GHS and LTS mostly correlated for individual GHS classes, results at the genotype level revealed a strong LTS heterogeneity within a given GHS class, (3) LTS correlated strongly with expert scoring of individual images. Conclusions: HairNet2 is the first quantitative and scalable deep-learning model able to measure leaf hairiness. Results obtained with HairNet2 concur with the qualitative values used by breeders at both extremes of the scale (GHS 1-2, and 5-5+), but interestingly suggest a reordering of genotypes with intermediate values (GHS 3-4+). Finely ranking mild phenotypes is a difficult task for humans. In addition to providing assistance with this task, HairNet2 opens the door to selecting plants with specific leaf hairiness characteristics which may be associated with other beneficial traits to deliver better varieties. © Crown 2024.

Handling concept drift via ensemble and class distribution estimation technique

Item Type Conference Paper

Author N. Limsetto

Author K. Waiyamai

Abstract In real world settings there is situation where class distribution of data may change after classifier is built resulting in performance degradation of classifier. Attempts to solve this problem from previous Class Distribution Estimation method (CDE method) yield quite interesting performance however we notice there is some flaw since CDE method still have some bias toward train data thus we decide to improve them with ensemble method. Our Class Distribution Estimation-Ensemble (CDE-EM) methods estimate class distribution from many models instead of one resulting in less bias than previous method. All methods are evaluated using accuracy on set of benchmark UCI data sets. Experimental results demonstrate that our methods yield better performance if class distribution of test data is different from train data. © 2011 Springer-Verlag.

Handling New Class in Online Label Shift

Item Type Journal Article**Author** Y.-Y. Qian**Author** Y. Bai**Author** Z.-Y. Zhang**Author** P. Zhao**Author** Z.-H. Zhou

Abstract In many real-world applications, data are continuously accumulated in open environments, and new classes may emerge over time. For instance, in disease diagnosis, the prevalence of a certain disease may vary seasonally, and new diseases can also emerge. This paper investigates the problem of learning from unlabeled data stream where the label distribution evolves over time, and meanwhile, previously unseen new classes may appear. To handle the emerging new classes in online label shift, we first design a novel risk estimator by unbiased risk rewriting and mixture proportion estimation, which enables the identification of new class data. Subsequently, we employ the online ensemble paradigm for model updating to handle unknown distribution shifts. Moreover, we introduce the sketching and ensemble pruning mechanisms to improve the efficiency of the algorithm, making it more lightweight and practical. The proposed approach enjoys a theoretical guarantee of dynamic regret, ensuring its effectiveness in adapting to the unknown distribution shifts and the emergence of new classes in streaming data. Experiments on diverse benchmark datasets and two real-world applications demonstrate the effectiveness of the algorithm. © 1989-2012 IEEE.

Handling uncertainty in optimization enabled the deep Q network for traffic sign and criticality detection

Item Type Journal Article

Author S. Salim

Author J. J. S

Author S. B

Abstract Objective: This research aims to develop an efficient model for Traffic Sign Recognition (TSR) with uncertainty quantification. Methods: The process involves

pre-processing, sign localization, TSR, and criticality detection. After pre-processing with a Gaussian filter, sign localization is carried out using Segmentation U-Net (SegU-Net). Following TSR, a Deep Q Network (DQN) is trained using Gradient Descent-Teamwork Optimization Algorithm-based Deep Q Network (GD-TOA based DQN), which incorporates Gradient Descent model into Teamwork Optimization Algorithm (TOA), is used to classify traffic signs into three categories: mandatory, cautionary, and informatory. After classification, the system revalidates critical signs using Mahalanobis distance to compute confidence levels. A significant drop triggers a flag for human review if it has a high uncertainty. Results: Empirical findings demonstrate that presented methodology achieved an accuracy rate of 97.9%, a precision rate of 98.2%, a recall rate of 98.3%, F-measure of 98.2%, specificity of 97.5%, and balanced accuracy of 97.9%. Conclusions: The results have proven that proposed model is a very promising technique for criticality detection. © 2026 Taylor & Francis Group, LLC.

Author C. Gao

Abstract Coastal wetland ecosystems are pivotal for the sustainable economic development of coastal regions. While prior studies have explored interactions between wetlands and human activities across multiple spatiotemporal scales, current ecosystem service (ES) assessments predominantly rely on existing land cover data products with only ~ 80 % spatial accuracy, insufficient for capturing fine-scale ES spatial variations. This limitation hinders the accurate characterization of complex relationships in wetland environmental science and constrains the reliability of subsequent conservation and management decisions. To address this critical gap, this study aims to improve the accuracy of coastal wetland delineation and ES quantification to ≥ 90 % via an integrated technical method. In this work, the Bohai Economic Rim (BER), a region with intensive interactions between climate change and human activities, was selected as the study case for high-precision coastal wetland mapping and quantification of four key ES types (carbon storage, habitat quality, soil conservation, and water yield). By integrating knowledge-based rules implemented on the Google Earth Engine (GEE) platform with a machine learning algorithm, we identified ES spatial hotspots and cold spots, analyzed trade-off and synergy relationships among the four ESs, and further employed a random forest model to evaluate the relative importance of driving factors (including climate variables and human activity indicators). Results show the total ES index ranges from 0.02 to 0.82 (normalized to 0–1), with all six pairs of ESs exhibiting significant positive correlations, indicating strong synergistic effects. The random forest model reveals that forest proportion and precipitation are the top two influential factors shaping ES spatial variation. This study provides a scalable high-precision ES assessment framework for complex coastal wetland systems with accuracy improved from ~ 80 % to 93.76 %, offering valuable scientific insights and targeted policy recommendations for the conservation and sustainable management of coastal wetland ecosystems in the BER. © 2026 Elsevier B.V.

Abstract Polymerase chain reaction (PCR) is central to methods in molecular ecology. Here, we describe PCR-dependent approaches useful for investigating microbial diversity and its function in various natural, human-associated, and built environment ecosystems. Protocols routinely used for DNA extraction, purification, cloning, and sequencing are included along with various resources for the statistical analysis following gel electrophoresis-based methods (DGGE) and sequencing. We also provide insights into eukaryotic microbiome analysis, sample preservation techniques, PCR troubleshooting, DNA quantification methods, and commonly used ordination techniques. © 2017, Springer Science+Business Media LLC.

Abstract Understanding the flow of traffic on road networks is increasingly important especially with the continued urbanization of the global population. Numerous hardware and software technologies have been applied to measure traffic volumes by Government agencies and/or organizations such as Google, however they are either expensive to deploy; limited in their ability to disambiguate the kinds of vehicles on the road network, or of increasing importance, they infringe on the privacy of individuals, e.g. tracking phones. In this paper we describe work applying deep learning technologies to identify and classify different vehicles on

the road network of Victoria with specific focus on heavy goods vehicles (trucks and trailers). Specifically, we present an approach to automatically detect, classify and count the unique classes of trucks and trailers that are found on the road network and the direction of travel. We apply and compare leading deep learning approaches including You Only Look Once version 3 (YOLOv3) and Single Shot Multi-Box Detector (SSD). This paper builds upon earlier work [1] which focused on data (video) from a single traffic junction in Melbourne. This work is based on a wider range of data (videos) from locations reflecting the diversity of road use including multi-lane motorways, rural roads and city roads. © 2020, Springer Nature Switzerland AG.

HebbR2-Taffic: A novel application of neuro-fuzzy network for visual based traffic monitoring system

Item Type Journal Article**Author** S.-Y. Cho**Author** C. Quek**Author** S.-X. Seah**Author** C.-H. Chong

Abstract This paper presents a robust methodology that automatically counts moving vehicles along an expressway. The domain of interest for this paper is using both neuro-fuzzy network and simple image processing techniques to implement traffic flow monitoring and analysis. As this system is dedicated for outdoor applications, efficient and robust processing methods are introduced to handle both day and night analysis. In our study, a neuro-fuzzy network based on the Hebbian-Mamdani rule reduction architecture is used to classify and count the number of vehicles that passed through a three- or four-lanes expressway. As the quality of the video captured is corrupted under noisy outdoor environment, a series of preprocessing is required before the features are fed into the network. A vector of nine feature values is extracted to represent whether a vehicle is passing through a lane and this vector serves as input patterns would be used to train the neuro-fuzzy network. The vehicle counting and classification would then be performed by the well-trained network. The novel approach is benchmarked against the MLP and RBF networks. The results of using our proposed neuro-fuzzy network are very encouraging with a high degree of accuracy. © 2008 Elsevier Ltd. All rights reserved.

Hellinger distance decision trees for PU learning in imbalanced data sets

Item Type Journal Article

Author C. Ortega Vázquez

Author S. vanden Broucke

Author J. De Weerd

Abstract Learning from positive and unlabeled data, or PU learning, is the setting in which a binary classifier can only train from positive and unlabeled instances, the latter containing both positive as well as negative instances. Many PU applications, e.g., fraud detection, are also characterized by class imbalance, which creates a challenging setting. Not only are fewer minority class examples compared to the case where all labels are known, there is also only a small fraction of unlabeled observations that would actually be positive. Despite the relevance of the topic, only a few studies have considered a class imbalance setting in PU learning. In this paper, we propose a novel technique that can directly handle imbalanced PU data, named the PU Hellinger Decision Tree (PU-HDT). Our technique exploits the class prior to estimate the counts of positives and negatives in every node in the tree. Moreover, the Hellinger distance is used instead of more conventional splitting criteria because it has been shown to be class-imbalance insensitive. This simple yet effective adaptation allows PU-HDT to perform well in highly imbalanced PU data sets. We also introduce PU Stratified Hellinger Random Forest (PU-SHRF), which uses PU-HDT as its base learner and integrates a stratified bootstrap sampling. Our empirical analysis shows that PU-SHRF substantially outperforms state-of-the-art PU learning methods for imbalanced data sets in most experimental settings. © The Author(s), under exclusive licence to Springer Science+Business Media LLC, part of Springer Nature 2023.

Abstract Context Hepatitis E virus (HEV) as a hepatotropic virus is one of the major global health concerns. Autochthonous HEV transmitted by oral fecal-route in poor sanitation conditions as well as vertical and rarely blood transfusion. HEV occurrence is more common in developing countries and recently increased in developed countries too. Middle East (ME) and Eastern Mediterranean region (EMR) of WHO have been an endemic region for HEV infection. In this regard, we aimed to design a systematic review and pooled analysis to determine seroprevalence of anti-HEV antibody in ME and EMR countries. Evidence acquisition By using PRISMA guideline, data were collected from papers identified through PubMed, Web of Science, Science Direct, Scopus and also from some national and regional databases from January 1990 to June 2016. Serum anti-HEV antibody (IgG) used for HEV prevalence estimation. HEV prevalence in the ME, WHO EMR countries, and in total, calculated by each country population size based on 2015 UN report. Results overall, 62 papers with a total sample size of 31,673 were fulfilled our eligibility criteria and included in our project. Considering anti-HEV antibody (IgG), prevalence of HEV infection in the countries of ME, WHO EMR and in total were 12.17% (95% CI: 11.79–12.57), 11.81% (95% CI: 11.43–12.21), and 11.87% (95% CI: 11.52–12.23) respectively. Conclusions HEV seroprevalence in WHO EMR and ME countries has high rate and more considerations are needed for the prevention and control of this infection especially in high-risk groups such as pregnant women. © 2017

Abstract In open-environment applications, data are often collected from heterogeneous modalities with distinct encodings, resulting in feature space heterogeneity. This heterogeneity inherently induces label shift, making cross-modal knowledge transfer particularly challenging when the source and target data exhibit simultaneous heterogeneous feature spaces and shifted label distributions. Existing studies address only partial aspects of this issue, leaving the broader problem unresolved. To bridge this gap, we introduce a new concept of Heterogeneous Label Shift (HLS), targeting this critical but underexplored challenge. We first analyze the impact of heterogeneous feature spaces and label distribution shifts on model generalization and introduce a novel error decomposition theorem. Based on these insights, we propose a bound minimization HLS framework that decouples and tackles feature heterogeneity and label shift accordingly. Extensive experiments on various benchmarks for cross-modal classification validate the effectiveness and practical relevance of the proposed approach. © 2025 by the author(s).

Abstract Given a sequence of observations, classification among two known hidden Markov models (HMMs) can be accomplished with a classifier that minimizes the probability of error (i.e., the probability of misclassification) by enforcing the maximum a posteriori probability (MAP) rule. For this MAP classifier, the a priori probability of error (before any observations are made) can be obtained, as a function of the length of the sequence of observations, by summing up the probability of error over all possible observation sequences of the given length, which is a computationally expensive task. In this paper, we obtain an upper bound on the probability of error of the MAP classifier. Our results are based on a suboptimal decision rule that ignores the order with which observations occur and relies solely on the empirical frequencies with which different symbols appear. We describe necessary and sufficient conditions under which this bound on the probability of error decreases exponentially with the length of the observation sequence. Apart from the usefulness of the suboptimal rule in bounding the probability of misclassification, its numerous advantages (such as low computational complexity, reduced storage requirements, and potential applicability to distributed or decentralized decision schemes) could prove a useful alternative to the MAP rule for HMM classification in many applications. Author F.L.F. Soares

Abstract This study introduces a hierarchical strategy designed to differentiate, classify, and quantify adulterants—namely, sugarcane molasses, inverted sugar, and corn syrup—in commercial honey samples analyzed through TD-NMR. The sample preparation process was simplified to involve only heating, ensuring crystallization was avoided. The DD-SIMCA, a one-class classifier, successfully distinguished between pure and adulterated samples, achieving a specificity of 100.00%. The next step involved

predicting the type of adulterant using PLS-DA analysis, which led to classification accuracy exceeding 97.0% across all three adulterants. Furthermore, the PLS model quantified the adulterant levels in the samples, showing RMSEV values below 0.5 (% w w-1) and an RPD greater than 6.38 for each adulterant. The elliptic joint confidence region (EJCR) test was conducted to assess the method's feasibility and reliability. Consequently, the proposed approach highlights the effectiveness of TD-NMR combined with chemometric methods as a valuable tool for verifying the authenticity of commercial honey and preventing fraudulent adulterations. © The Author(s) 2026.

Abstract Random probabilities are a key component to many nonparametric methods in Statistics and Machine Learning. To quantify comparisons between different laws of random probabilities several works are starting to use the elegant Wasserstein over Wasserstein distance. In this paper we prove that the infinite dimensionality of the space of probabilities drastically deteriorates its sample complexity, which is slower than any polynomial rate in the sample size. We propose a new distance that preserves many desirable properties of the former while achieving a parametric rate of convergence. In particular, our distance 1) metrizes weak convergence; 2) can be estimated numerically through samples with low complexity; 3) can be bounded analytically from above and below. The main ingredient are integral probability metrics, which lead to the name hierarchical IPM. Copyright 2024 by the author(s)

HIFN-Transformer: Learnable Information-Theoretic Parameters for Interpretable Deep Classification

Item Type Journal Article

Author M. Tawfik

Abstract Deep learning models lack intrinsic interpretability and require manual tuning of information-theoretic hyperparameters. This paper presents HIFN-Transformer (HIFN-T), a framework extending the Variational Information Bottleneck through four jointly learnable per-layer parameters: information retention, entropy budget, magnitude scaling, and global information gates. The retention and budget parameters are co-adapted with the network weights via a stop-gradient decoupling that stabilizes training and substantially reduces the manual hyperparameter burden by eliminating per-layer β grid search; the global gates learn per-neuron importance weights, and a Transformer encoder captures complex feature interactions via multi-head self-attention. We prove HIFN generalizes standard VIB as a special case and characterize the role of the entropy budget as an early-training stabilizer that prevents variance explosion before convergence. We evaluate HIFN-T on five benchmarks spanning network intrusion detection (CICIDS-2017, NSL-KDD, GothamDataset2025), image classification (MNIST), and speech emotion recognition (EMO-DB), comparing against XGBoost, TabNet, FT-Transformer, and four additional baselines. HIFN-T delivers consistent improvements across all five. On the official NSL-KDD KDDTrain+ $\rightarrow$ KDDTest+ benchmark, HIFN-T with a 4-method consensus feature-selection front-end achieves 80.22% accuracy and 0.6898 macro F1, lying within the established 78–87% band of published deep models on this cross-distribution split. On the large-scale GothamDataset2025 IoT benchmark, we evaluate HIFN-T on the full 35,126,611-row release under natural class prevalence as a scalability demonstration on this recently published dataset. MNIST is included as a domain-generalization sanity check rather than a competitive benchmark. Gate-derived feature importance correlates strongly with SHAP analysis across all five datasets, validating intrinsic interpretability. We report all results as mean $\pm$ standard deviation over ten independent runs with Friedman and Wilcoxon signed-rank statistical significance tests. © 2013 IEEE.

High dimensional binary classification under label shift: phase transition and regularization

Item Type Journal Article

Author J. Cheng

Author M. Chen

Author H. Liu

Author T. Zhao

Author W. Liao

Abstract Label Shift has been widely believed to be harmful to the generalization performance of machine learning models. Researchers have proposed many approaches to mitigate the impact of the label shift, e.g., balancing the training data. However, these methods often consider the underparametrized regime, where the sample size is much larger than the data dimension. The research under the overparametrized regime is very limited. To bridge this gap, we propose a new asymptotic analysis of the Fisher Linear Discriminant classifier for binary classification with label shift. Specifically, we prove that there exists a phase transition phenomenon: Under certain overparametrized regime, the classifier trained using imbalanced data outperforms the counterpart with reduced balanced data. Moreover, we investigate the impact of regularization to the label shift: The aforementioned phase transition vanishes as the regularization becomes strong. © 2023, The Author(s), under exclusive licence to Springer Nature Switzerland AG.

High Expression of THY1 in Intestinal Gastric Cancer as a Key Factor in Tumor Biology: A Poor Prognosis-Independent Marker Related to the Epithelial–Mesenchymal Transition Profile

Item Type Journal Article

Author P. Rohan

Author E.C. dos Santos

Author E. Abdelhay

Author R. Binato

Abstract Gastric cancer (GC) is an important cancer-related death worldwide. Among its histological subtypes, intestinal gastric cancer (IGC) is the most common. A previous work showed that increased expression of the THY1 gene was associated with poor overall survival in IGC. Furthermore, it was shown that IGC tumor cells with high expression of THY1 have a greater capacity for tumorigenesis and metastasis in vitro. This study aimed to identify molecular differences between IGC with high and low expression of THY1. Using a feature selection method, a group of 35 genes were found to be the most informative gene set for THY1high IGC tumors. Through a classification model, these genes differentiate THY1high from THY1low tumors with 100% of accuracy both in the test subset and the independent test set. Additionally, this group of 35 genes correctly clustered 100% of the samples. An extensive validation of this potential molecular signature in multiple cohorts successfully segregated between THY1high and THY1low IGC tumors (>95%), proving to be independent of the gene expression quantification methodology. These genes are involved in central processes to tumor biology, such as the epithelial–mesenchymal transition (EMT) and remodeling of the tumor tissue composition. Moreover, patients with THY1high IGC demonstrated poor survival and a more advanced

clinicopathological staging. Our findings revealed a molecular signature for IGC with high THY1 expression. This signature showed EMT and remodeling of the tumor tissue composition potentially related to the biology of IGC. Altogether, our results indicate that THY1high IGC tumors are a particular subset of tumors with a specific molecular and prognosis profile. © 2023 by the authors.

High-Accuracy Mangrove Extraction and Degradation Diagnosis Using Time-Series Remote Sensing and Deep Learning: A Case Study of the Largest Delta in the Northern Beibu Gulf, China

Item Type Journal Article

Author X. Xie

Author R. Wang

Author Z. Dai

Author X. Liu

Abstract Mangrove extent has increased in many regions under strengthened conservation policies and large-scale restoration programs. Nevertheless, mangrove ecosystems continue to face multiple pressures, including limited total area, habitat degradation, biodiversity decline, and biological invasion, and localized deterioration in ecosystem structure and function has been increasingly reported. Despite extensive mapping efforts, the spatiotemporal dynamics of mangrove degradation—particularly in tidally influenced environments—remain insufficiently understood. Focusing on the Nanliu River Delta, the largest deltaic mangrove system in the Northern Beibu Gulf of China, this study integrates long-term Landsat time-series imagery (1990–2025) with deep learning to quantify both mangrove extent change and canopy degradation. To mitigate tidal inundation effects, a NDVI Pseudo-P75 compositing strategy was applied using Google Earth Engine (GEE), enabling consistent observation of mangrove canopies across tidal stages. Global Mangrove Watch v4 (GMW-V4) and HGMP2020 mangrove dataset for China were used as reference labels to train a ResNet34–UNet segmentation framework incorporating Digital Elevation Model (DEM) constraints. The model achieved high classification performance, with an IoU of 0.822 for mangroves and 0.981 for background, yielding a mean IoU of 0.902. The resulting maps, following manual verification, provided a robust basis for spatiotemporal and degradation analyses. Canopy condition was further assessed using the Enhanced Vegetation Index (EVI), which is less prone to saturation in high-biomass mangrove stands. Results show that mangrove area in the Nanliu River Delta expanded from 266 ha in 1990 to 1414 ha in 2025, with the annual expansion rate after 2005 being nearly seven times higher than that before 2005. Despite this net gain, a cumulative loss of 347.45 ha was recorded, primarily during 1990–2000, with approximately 70% converted to aquaculture and coastal engineering. Spatial analysis revealed that mangrove expansion occurred predominantly seaward, whereas both mangrove loss and canopy degradation exhibited an inverse J-shaped relationship with seawall proximity. More than 80% of mangrove loss occurred within 200 m of seawalls, indicating concentrated anthropogenic encroachment, while 75.6% of canopy degradation was observed within 350 m, potentially reflecting landward forest senescence. These results indicate a transition in dominant threats from permanent land conversion in the late 20th century to more subtle, internal functional

degradation in recent decades, underscoring the need to complement extent-based assessments with canopy condition monitoring in mangrove conservation and management. © 2026 by the authors.

High-resolution and accelerated multi-parametric mapping with automated characterization of vessel disease using intravascular MRI

Item Type Journal Article

Author G. Wang

Author Y. Zhang

Author S.S. Hegde

Author P.A. Bottomley

Abstract Background: Atherosclerosis is prevalent in cardiovascular disease, but present imaging modalities have limited capabilities for characterizing lesion stage, progression and response to intervention. This study tests whether intravascular magnetic resonance imaging (IVMRI) measures of relaxation times (T1, T2) and proton density (PD) in a clinical 3 Tesla scanner could characterize vessel disease, and evaluates a practical strategy for accelerated quantification. Methods: IVMRI was performed in fresh human artery segments and swine vessels in vivo, using fast multi-parametric sequences, 1-2 mm diameter loopless antennae and 200-300 μm resolution. T1, T2 and PD data were used to train a machine learning classifier (support vector machine, SVM) to automatically classify normal vessel, and early or advanced disease, using histology for validation. Disease identification using the SVM was tested with receiver operating characteristic curves. To expedite acquisition of T1, T2 and PD data for vessel characterization, the linear algebraic method ('SLAM') was modified to accommodate the antenna's highly-nonuniform sensitivity, and used to provide average T1, T2 and PD measurements from compartments of normal and pathological tissue segmented from high-resolution images at acceleration factors of $R \leq 18$ -fold. The results were validated using compartment-average measures derived from the high-resolution scans. Results: The SVM accurately classified $\sim 80\%$ of samples into the three disease classes. The 'area-under-the-curve' was 0.96 for detecting disease in 248 samples, with T1 providing the best discrimination. SLAM T1, T2 and PD measures for $R \leq 10$ were indistinguishable from the true means of segmented tissue compartments. Conclusion: High-resolution IVMRI measures of T1, T2 and PD with a trained SVM can automatically classify normal, early and advanced atherosclerosis with high sensitivity and specificity. Replacing relaxometric MRI with SLAM yields good estimates of T1, T2 and PD an order-of-magnitude faster to facilitate IVMRI-based characterization of vessel disease. © 2017 The Author(s).

High-Resolution Burned-Area Mapping and Vegetation Resilience in Heterogeneous Landscapes Using Sentinel-2 and Explainable Machine Learning

Item Type Journal Article

Author S. Lu

Author J. Shang

Author Z. Ouyang

Author C. Wei

Author F. Liu

Abstract Accurate wildfire impact assessment and understanding post-disturbance recovery are essential for land management in fire-prone regions. This study develops a Sentinel-2–based burned-area extraction framework and integrates NDVI time-series analysis with explainable machine learning to quantify vegetation resilience across

five fire-affected regions in China. The burned-area map achieves an overall accuracy of 99.8%, substantially outperforming MODIS products (77.9% and 92.7%) by better detecting fragmented patches in complex terrain. NDVI trajectories reveal three resilience pathways: compensatory recovery, stable recovery without compensation, and persistent degradation. Recovery times ranged from approximately 2 months to over 6 months, with some high-altitude areas showing no effective recovery. An XGBoost–SHAP model explains spatial recovery variability ($R^2 = 0.50\text{--}0.88$) and identifies a consistent shift from early climate control to later topographic regulation. Landscape heterogeneity promotes recolonization only within intermediate thresholds, temperature exhibits optimal windows, and precipitation shows diminishing returns. Topography acts primarily by redistributing hydrothermal conditions rather than as an independent driver. The results demonstrate strong spatial variability in ecosystem stability and highlight nonlinear interactions among climate, terrain, and landscape structure as key determinants of resilience. The proposed framework improves burned-area monitoring and supports targeted ecological restoration and adaptive land-use planning in heterogeneous landscapes. © 2026 by the authors.

High-THC Cannabis Smoke Impairs Incidental Memory Capacity in Spontaneous Tests of Novelty Preference for Objects and Odors in Male Rats

Item Type Journal Article**Author** I.L. Barnard**Author** T.J. Onofrychuk**Author** A.D. Toderash**Author** V.N. Patel**Author** A.E. Glass**Author** J.C. Adrian**Author** R.B. Laprairie**Author** J.G. Howland

Abstract Working memory is an executive function that orchestrates the use of limited amounts of information, referred to as working memory capacity, in cognitive functions. Cannabis exposure impairs working memory in humans; however, it is unclear whether Cannabis facilitates or impairs rodent working memory and working memory capacity. The conflicting literature in rodent models may be at least partly because of the use of drug exposure paradigms that do not closely mirror patterns of human Cannabis use. Here, we used an incidental memory capacity paradigm where a novelty preference is assessed after a short delay in spontaneous recognition-based tests. Either object or odorbased stimuli were used in test variations with sets of identical [identical stimuli test (IST)] and different [different stimuli test (DST)] stimuli (three or six) for low-memory and high-memory loads, respectively. Additionally, we developed a human-machine hybrid behavioral quantification approach which supplements stopwatch-based scoring with supervised machine learning-based classification. After validating the spontaneous IST and DST in male rats, 6-item test versions with the hybrid quantification method were used to evaluate the impact of acute exposure to high- Δ^9 -tetrahydrocannabinol (THC) or high-CBD Cannabis smoke on novelty preference. Under control conditions, male rats showed novelty preference in all test variations. We found that high-THC, but not high-CBD, Cannabis smoke exposure impaired novelty preference for objects under a high-memory load. Odor-based recognition deficits were seen under both low-memory and high-memory loads only following high-THC smoke exposure. Ultimately, these data show that Cannabis smoke exposure impacts incidental memory capacity of male rats in a memory load-dependent, and stimuli-specific manner. © 2023 Barnard et al.

Abstract Kidney-related diseases have incrementally become one major cause of death. Glomeruli are the physiological units in the kidney responsible for the blood filtration. Therefore, their statistics including number and volume, directly describe the efficiency and health state of the kidney. Stereology is the current quantification method relying on histological sectioning, sampling and further 2D analysis, being laborious and sample destructive. New micro-Computed Tomography (μ CT) imaging protocols resolute structures down to capillary level. However large-scale glomeruli analysis remains challenging due to object identifiability, allotted memory resources and computational time. We present a methodology for high-throughput glomeruli analysis that incorporates physiological apriori information relating the kidney vasculature with estimates of glomeruli counts. We propose an effective sampling strategy that exploits scalable sparse segmentation of kidney regions for refined estimates of both glomeruli count and volume. We evaluated the proposed approach on a database

of μ CT datasets yielding a comparable segmentation accuracy as an exhaustive supervised learning method. Furthermore we show the ability of the proposed sampling strategy to result in improved estimates of glomeruli counts and volume without requiring a exhaustive segmentation of the μ CT image. This approach can potentially be applied to analogous organizations, such as for example the quantification of alveoli in lungs. © Springer International Publishing AG 2016.

Abstract Urban areas are associated with higher depression risks than rural areas. However, less is known about how different types of urban environments relate to depression risk. Here, we use satellite imagery and machine learning to quantify three-dimensional (3D) urban form (i.e., building density and height) over time. Combining satellite-derived urban form data and individual-level residential addresses, health, and socioeconomic registers, we conduct a case-control study (n = 75,650 cases and 756,500 controls) to examine the association between 3D urban form and depression in the Danish population. We find that living in dense inner-city areas did not carry the highest depression risks. Rather, after adjusting for socioeconomic factors, the highest risk was among sprawling suburbs, and the lowest was among multistory buildings with open space in the vicinity. The finding suggests that spatial land-use planning should prioritize securing access to open space in densely built areas to mitigate depression risks. © 2023 The Authors.

Abstract Purpose: To develop and validate a vendor-agnostic, motion-insensitive proton-density fat-fraction (PDFF) quantification method. Methods: Flip-angle-modulated (FAM) 2D chemical-shift-encoded (CSE) MRI for PDFF quantification was implemented in both the vendor-agnostic platform Pulseseq (“Pulseseq-FAM”) and one vendor-specific platform (“GE-specific FAM”). These implementations were distributed to four sites with twelve MR systems of three vendors (Siemens/GE/Philips) and field strengths (0.55T/1.5T/3T). A sequentially-shipped 16-vial phantom (PDFF = 0%–30%/T1water = 200–1400 ms) underwent confounder-corrected PDFF mapping with commercial 3D-CSE methods and GE-specific FAM as available on each system, and Pulseseq-FAM on every system. To assess bias, phantom PDFF measurements were compared to reference. Between-system variance was evaluated with linear mixed-effects modeling. Different volunteers were also imaged at each site to assess free-breathing PDFF mapping feasibility. A prospective single-site volunteer study was also conducted. Adult patients and children were imaged with breath-held 3D-CSE and free-breathing GE-specific and Pulseseq-FAM. Radiologists evaluated images for overall quality and motion artifacts. To assess bias, Pulseseq-FAM

PDF measurements were compared to 3D-CSE and GE-specific FAM. Test–retest repeatability was assessed by re-imaging after repositioning. Between-field-strength reproducibility was assessed at 1.5T and 3.0T. Results: In the multi-center study, Pulseq-FAM showed reduced T1-bias and between-system variability versus 3D-CSE in phantom PDF measurements, and free-breathing feasibility in volunteers. In the single-site volunteer study (N = 57), Pulseq-FAM improved image quality and motion artifacts versus 3D-CSE ($p < 0.01$). Pulseq-FAM showed excellent agreement with 3D-CSE (95% limits-of-agreement (LoA) = 3.4% PDF) and GE-specific FAM (LoA = 2.0%). Pulseq-FAM showed excellent repeatability (repeatability coefficient (RC) = 1.6% PDF) and between-field-strength reproducibility (reproducibility coefficient (RDC) = 2.4%) versus 3D-CSE (RC = 2.7%/RDC = 3.4%; differences $p < 0.05$). Conclusion: Pulseq-FAM enables accurate, reproducible, vendor-agnostic, and motion-insensitive PDF quantification in adults and children. © 2025 The Author(s). Highly sensitive automated method for DNA damage assessment: Gamma-H2AX foci counting and cell cycle sorting

Item Type Journal Article

Author L. Hernández

Abstract Phosphorylation of the H2AX protein is an early step in the double strand break (DSB) repair pathway; therefore, phosphorylated histone (γ H2AX) foci scoring is widely used as a measure for DSBs. Foci scoring is performed either manually or semi-automatically using hand-operated capturing and image analysis software. In general, both techniques are laborious and prone to artifacts associated with manual scoring. While a few fully automated methods have been described in the literature, none of them have been used to quantify γ H2AX foci in combination with a cell cycle phase analysis. Adding this feature to a rapid automated γ H2AX foci quantification method would reduce the scoring uncertainty that arises from the variations in the background level of the γ H2AX signal throughout the cell cycle. The method was set up to measure DNA damage induced in human mammary epithelial cells by irradiation under a mammogram device. We adapted a FISH (fluorescent in situ hybridization) Spot-counting system, which has a slide loader with automatic scanning and cell capture system throughout the thickness of each cell (z-stack), to meet our assay requirements. While scanning the sample, the system classifies the selected nuclei according to the signal patterns previously described by the user. For our purposes, a double staining immunofluorescence was carried out with antibodies to detect γ H2AX and pericentrin, an integral component of the centrosome. We could thus distinguish both the number of γ H2AX foci per cell and the cell cycle phase. Furthermore, restrictive settings of the program classifier reduced the "touching nuclei" problem described in other image analysis software. The automated scoring was faster than and as sensitive as its manually performed counterpart. This system is a reliable tool for γ H2AX radio-induced foci counting and provides essential information about the cell cycle stage. It thus offers a more complete and rapid assessment of DNA damage. © 2013 by the authors; licensee MDPI, Basel, Switzerland.

Abstract Anti-angiogenic (AA) therapy is a cornerstone of metastatic clear cell renal cell carcinoma (ccRCC) treatment, but not everyone responds, and predictive biomarkers are lacking. CD31, a marker of vasculature, is insufficient, and the Angioscore, an RNA-based angiogenesis quantification method, is costly, associated with delays, difficult to standardize, and does not account for tumor heterogeneity. Here, we developed an interpretable deep learning (DL) model that predicts the Angioscore directly from ubiquitous histopathology slides yielding a visual vascular network (H&E DL Angio). H&E DL Angio achieves a strong correlation with the Angioscore across multiple cohorts (spearman correlations of 0.77 and 0.73). Using this approach, we found that angiogenesis inversely correlates with grade and stage and is associated with driver mutation status. Importantly, DL Angio expediently predicts AA response in both a real-world and IMmotion150 trial cohorts, out-performing CD31, and closely approximating the Angioscore (c-index 0.66 vs 0.67) at a fraction of the cost. © The Author(s) 2025.

Abstract We propose a learning problem involving adapting a pre-trained source model to the target domain for classifying all classes that appeared in the source data, using target data that covers only a partial label space. This problem is practical, as it is unrealistic for the target end-users to collect data for all classes prior to adaptation. However, it has received limited attention in the literature. To shed light on this issue, we construct benchmark datasets and conduct extensive experiments to uncover the inherent challenges. We found a dilemma - on the one hand, adapting to the new target domain is important to claim better performance; on the other hand, we observe that preserving the classification accuracy of classes missing in the target adaptation data is highly challenging, let alone improving them. To tackle this, we identify two key directions: 1) disentangling domain gradients from classification gradients, and 2) preserving class relationships. We present several effective solutions that maintain the accuracy of the missing classes and enhance the overall performance, establishing solid baselines for holistic transfer of pre-trained models with partial target data. © 2023 Neural information processing systems foundation. Homeolog expression quantification methods for allopolyploids

Item Type Journal Article

Author T.C.Y. Kuo

Author T. Tameshige

Author K.K. Shimizu

Author J. Sese

Abstract Genome duplication with hybridization, or allopolyploidization, occurs in animals, fungi and plants, and is especially common in crop plants. There is an increasing interest in the study of allopolyploids because of advances in polyploid genome assembly; however, the high level of sequence similarity in duplicated gene copies (homeologs) poses many challenges. Here we compared standard RNA-seq expression quantification approaches used currently for diploid species against subgenome-classification approaches which maps reads to each subgenome separately. We examined mapping error using our previous and new RNA-seq data in which a subgenome is experimentally added (synthetic allotetraploid *Arabidopsis kamchatica*) or reduced (allohexaploid wheat *Triticum aestivum* versus extracted allotetraploid) as ground truth. The error rates in the two species were very similar. The standard approaches showed higher error rates (>10% using pseudo-alignment with Kallisto) while subgenome-classification approaches showed much lower error rates (<1% using EAGLE-RC, <2% using HomeoRoq). Although downstream analysis may partly mitigate mapping errors, the difference in methods was substantial in hexaploid wheat, where Kallisto appeared to have systematic differences relative to other methods. Only approximately half of the differentially expressed homeologs detected using Kallisto overlapped with those by any other method in wheat. In general, disagreement in low-expression genes was responsible for most of the discordance between methods, which is consistent with known biases in Kallisto. We also observed that there exist uncertainties in genome sequences and annotation which can affect each method differently. Overall, subgenome-classification approaches tend to perform better than standard approaches with EAGLE-RC having the highest precision. © 2018 The Author(s) 2018. How large a training set is needed to develop a classifier for microarray data?

Item Type Journal Article

Author K.K. Dobbin

Author Y. Zhao

Author R.M. Simon

Abstract Purpose: A common goal of gene expression microarray studies is the development of a classifier that can be used to divide patients into groups with different prognoses, or with different expected responses to a therapy. These types of classifiers are developed on a training set, which is the set of samples used to train a classifier. The question of how many samples are needed in the training set to produce a good classifier from high-dimensional microarray data is challenging. Experimental Design: We present a model-based approach to determining the sample size required to adequately train a classifier. Results: It is shown that sample size can be determined from three quantities: standardized fold change, class prevalence, and number of genes or features on the arrays. Numerous examples and important experimental design issues are discussed. The method is adapted to address ex post facto determination of whether the size of a training set used to develop a classifier was adequate. An interactive web site for performing the sample size calculations is provided. Conclusion: We showed that sample size calculations for classifier development from high dimensional microarray data are feasible, discussed numerous important considerations, and presented examples. © 2008 American Association for Cancer Research.

How Painful are Lumbar Hernias? A Comprehensive Review of Intervention Strategies

Item Type Journal Article

Author R. Moreno-Gómez-Toledano

Author I. Méndez-Mesón

Author S. Aguado-Henche

Author A. Sebastián-Martín

Author M. Grande-Alonso

Abstract Purpose of Review: Low back pain (LBP) is considered an important issue of public health, with annual prevalence estimations almost achieving 60% of the worldwide population. Available treatments have a limited impact on this condition, although they allow to alleviate pain and recover the patient's quality of life. This review aims to go deeper on the understanding of this condition, providing an updated, brief, and concise whole picture of this common musculoskeletal problem. Recent Findings: Scientific literature, current clinical practice and clinical guidelines are summarized, focusing on three key aspects: classification of LBP, diagnosis of symptomatic lumbar hernia, and intervention strategies (conservative, surgical, and pharmacological). Benefits and drawbacks of each approach are tackled. Summary: The most appropriate intervention for LBP suffers is hitherto a conservative treatment based on therapeutic exercise, manual therapy and therapeutic education on the neurophysiological mechanisms of pain. Whether patient's condition is severe, does not improve with conservative treatment, or presents neurological symptoms, then surgical intervention is recommended. The efficiency of pharmaceutical approaches

for LBP lacks high-quality evidence-based studies, and still needs to be in-depth explored. Current treatments help to improve symptoms and patient's perspectives. However, further research in the field of herniated discs is essential in order to seek a therapy that could definitely cure or eliminate this condition. © The Author(s) 2025.

How to evaluate uncertainty estimates in machine learning for regression?

Item Type Journal Article

Author L. Sluijterman

Author E. Cator

Author T. Heskes

Abstract As neural networks become more popular, the need for accompanying uncertainty estimates increases. There are currently two main approaches to test the quality of these estimates. Most methods output a density. They can be compared by evaluating their loglikelihood on a test set. Other methods output a prediction interval directly. These methods are often tested by examining the fraction of test points that fall inside the corresponding prediction intervals. Intuitively, both approaches seem logical. However, we demonstrate through both theoretical arguments and simulations that both ways of evaluating the quality of uncertainty estimates have serious flaws. Firstly, both approaches cannot disentangle the separate components that jointly create the predictive uncertainty, making it difficult to evaluate the quality of the estimates of these components. Specifically, the quality of a confidence interval cannot reliably be tested by estimating the performance of a prediction interval. Secondly, the loglikelihood does not allow a comparison between methods that output a prediction interval directly and methods that output a density. A better loglikelihood also does not necessarily guarantee better prediction intervals, which is what the methods are often used for in practice. Moreover, the current approach to test prediction intervals directly has additional flaws. We show why testing a prediction or confidence interval on a single test set is fundamentally flawed. At best, marginal coverage is measured, implicitly averaging out overconfident and underconfident predictions. A much more desirable property is pointwise coverage, requiring the correct coverage for each prediction. We demonstrate through practical examples that these effects can result in favouring a method, based on the predictive uncertainty, that has undesirable behaviour of the confidence or prediction intervals. Finally, we propose a simulation-based testing approach that addresses these problems while still allowing easy comparison between different methods. This approach can be used for the development of new uncertainty quantification methods. © 2024 The Authors

How to optimize blue-green space to enhance urban diurnal cooling effects?

Item Type Journal Article

Author X. Li

Author W. Qian

Author Y. Chen

Abstract Rapid urbanization has intensified the urban heat island effect, exacerbating heatwaves and threatening public health and energy security. Most previous studies have focused on blue or green spaces separately, whereas the combined cooling effects of Blue-Green Spaces (BGSs) have not yet been fully researched. The role of their morphological structure and landscape configuration in regulating diurnal land surface temperature variations remains largely unexplored. Moreover, traditional studies have generally relied on linear models, whereas the relationship between BGS and land surface temperature is inherently nonlinear. Machine learning methods can efficiently capture these complex, nonlinear mechanisms, enabling more precise quantification. Therefore, this study employs machine learning to quantify the cooling effects of BGS in high-density urban areas of Nanjing. Results reveal significant differences between daytime and nighttime cooling. Large Core areas provide strong daytime cooling but may release heat at night, while high landscape connectivity enhances cooling potential across both periods. Interaction analyses show that, for a fixed patch size, increasing the Core area strengthens daytime cooling, and for a fixed core area, highly connected patches further amplify cooling effects. This study highlights the complex role of BGS in urban thermal regulation and its diurnal variations, revealing the synergistic cooling effects of BGS morphology and landscape configuration, and providing scientific guidance for urban planning and climate-adaptive city development. © 2025 Elsevier B.V.

Human action recognition based on Adaptive Distance Generalization of Isometric Mapping

Item Type Conference Paper

Author H. Qu

Author J. Cheng

Abstract Manifold learning could effectively represent human action which has Non-linear characteristics. Isometric Mapping (ISOMAP) is a classic unsupervised algorithm of manifold learning. However, ISOMAP couldn't work well for the data with the class priori information. Moreover, the computational complexity of dimension reduction to the new data point is too high to be used in real time. Considering two shortages of ISOMAP, the Adaptive Distance Generalization of Isometric Mapping (ADGI) is proposed, using human action silhouette sequences as the features, in which the adaptive distance factor is introduced to combine with generalization of ISOMAP. Finally the nearest neighbor classifier is used for recognition. For the dimension reduction of human action features, ADGI is effective. Experiments in Weizmann database show the presented algorithm is better both in recognition ratio and in real time for human action recognition. © 2012 IEEE.

HVAC Equipment Monitoring

Item Type Journal Article

Author Z. Zhao

Author X. Han

Author S. Yang

Author B. Yang

Abstract This chapter comprehensively examines non-contact monitoring technologies for heating, ventilation, and air conditioning (HVAC) systems, focusing on infrared thermography and computer vision (CV) applications. Infrared thermography (IRT) enables precise fault detection in mechanical, electrical, and HVAC equipment by capturing temperature anomalies, with advancements in image enhancement algorithms improving visualization and diagnostic accuracy. CV techniques automate frost/dew observation and enhance defrost control, utilizing machine learning to quantify frost thickness, coverage, and fractal dimension for optimized defrost timing. In condensation heat transfer measurement, CV technology integrates droplet dynamics with deep learning to predict heat transfer performance, reducing experimental errors via multi-angle imaging and extended video analysis. Applications span energy infrastructure monitoring and equipment operation performance assessment. Future directions emphasize multi-technology integration (IRT and CV and artificial intelligence), dynamic droplet feature extraction, and universal condensation models to minimize energy consumption and enhance system reliability. These innovations collectively advance intelligent HVAC management, supporting energy efficiency and sustainability across built environmental domains. © 2026 selection and editorial matter, Bin Yang, Zhihan Lyu, Xiaogang Cheng, and Yihang Liu; individual chapters, the contributors.

Hybrid Bayesian classifier for improved classification accuracy

Item Type Journal Article

Author U. Kumar

Author S.K. Raja

Author C. Mukhopadhyay

Author T.V. Ramachandra

Abstract The widely used Bayesian classifier is based on the assumption of equal prior probabilities for all the classes. However, inclusion of equal prior probabilities may not guarantee high classification accuracy for the individual classes. Here, we propose a novel technique Hybrid Bayesian Classifier (HBC) where the class prior probabilities are determined by unmixing a supplemental low spatial high spectral resolution multispectral (MS) data that are assigned to every pixel in a high spatial low spectral resolution MS data in Bayesian classification. This is demonstrated with two separate experiments first, class abundances are estimated per pixel by unmixing Moderate Resolution Imaging Spectroradiometer data to be used as prior probabilities, while posterior probabilities are determined from the training

data obtained from ground. These have been used for classifying the Indian Remote Sensing Satellite LISS-III MS data through Bayesian classifier. In the second experiment, abundances obtained by unmixing Landsat Enhanced Thematic Mapper Plus are used as priors, and posterior probabilities are determined from the ground data to classify IKONOS MS images through Bayesian classifier. The results indicated that HBC systematically exploited the information from two image sources, improving the overall accuracy of LISS-III MS classification by 6% and IKONOS MS classification by 9%. Inclusion of prior probabilities increased the average producer's and user's accuracies by 5.5% and 6.5% in case of LISS-III MS with six classes and 12.5% and 5.4% in IKONOS MS for five classes considered. © 2010 IEEE.

Hybrid Deep Learning with Uncertainty Quantification for Robust Detection of Acute Lymphoblastic Leukemia in Blood Smear Images

Item Type Conference Paper

Author S.J. Mitu
Author M.F. Jaman
Author S.S. Shouma
Author M. Parvin

Abstract The diagnosis of acute lymphoblastic leukemia (ALL) is extremely difficult because of the very aggressive course wreaking severe havoc on the economy. A very rapid recognition is important in order to lower the mortality. In this work we present a complete deep learning pipeline with the aim of detecting leukemia from the blood smear microscopy as images. Different CNN architectures using pretrained convolutional networks are provided in this work, MobileNetV2, InceptionV3 and EfficientNetB3 are provided. Gated recurrent units (GRU) are also incorporated to extract not only spatial aspects, but temporal characteristics as well. A very important difficulty in this area is the great imbalance of the classes in open public data sets. We employ strategic data augmentation and leverage deep ensemble methods with uncertainty quantification to increase model confidence and improve interpretability. The preprocessing pipeline incorporates standard techniques such as resizing and normalization and different geometric transformations to improve robustness. We evaluate our methodology on the ALL-IDB1 and ALL-IDB2 datasets, each separately and in combination, to show consistent improvement over baseline applications. The EfficientNetB3-GRU variant having ensemble uncertainty estimation achieves 99.67% accuracy and 99.45% F1 quality measures on the combined dataset, outperforming competitive hybrid methods and published results. Our framework offers both high diagnostic quality and reliable confidence scores as a potential clinical aid. Our main contributions are the hybrid CNN-GRU design, methods to overcome data imbalance, and the introduction of uncertainty quantification methods to enhance automation of ALL diagnosis. © 2025 IEEE.

Hybrid Modelling of Austempering in the Automotive Industry

Item Type Conference Paper

Author J. Wörner

Author T. Waldenmaier

Author L. Hagymási

Author V. Schulze

Abstract Austempering is a heat treatment process used in the automotive industry. In contrast to case hardening, austempering results in a bainitic microstructure with only slightly lower hardness and significantly higher fatigue strength. For economic reasons, the heat treatment is carried out in batch processes, usually with several components being quality tested. Extensive sensor data is available for each batch, but the variance is low due to the stability of the series process. At the same time, quality control using Vickers hardness testing is subject to measurement uncertainty, especially when only a few indentations are measured, as is common in production. Deviations within a batch further limit the prediction accuracy for an individual part. The prediction quality of a machine learning (ML) model is limited by the quality of the data. One way to better model the process, is to use simulation data in a hybrid model. Another approach is Uncertainty Quantification, which provides an indication of how confident the model is that the prediction is accurate. Many of these models are also more robust and have higher prediction accuracy. The aim of this work is the implementation of several Uncertainty Quantification methods for a hybrid model as well as the comparison of these models and a recommended action for hybrid models in production. The ML models with Uncertainty Quantification are better suited for data with a higher uncertainty (e.g. measurement uncertainty). These models learn next to the labels how reliable the predictions are. This is particularly important in production and can be used as an additional criterion in quality control. The developed model will be evaluated with production data to assess its performance. © 2023 28th IFHTSE 2023 Congress. All rights reserved.

Hybrid statistical-machine learning approach for analyzing legacy and new phosphorus losses from subsurface drainage systems

Item Type Journal Article

Author E. Aniekwensi

Author E. Ghane

Abstract Phosphorus (P) is essential for crop growth but leaches through subsurface drainage discharge, impacting water quality. This study's objectives are to (1) apply hybrid statistical-machine learning to quantify the contributions of incidental (new) and legacy (old) P in drainage discharge from organic site and inorganic site and (2) evaluate the effect of manure application timing on P loss. We collected data from two on-farm sites in southeast Michigan, USA. A linear regression equation was used to analyze P load based on drainage discharge and fertilizer application timing. The data were split into calibration and validation sets, and machine learning was used for training. The results showed strong model prediction performance. Organic fertilizers contributed approximately twice the observed total phosphorus (TP) loss (7.54 kg ha⁻¹ vs. 3.73 kg ha⁻¹) and nearly four times the dissolved reactive phosphorus (DRP) loss (4.90 kg ha⁻¹ vs. 1.05 kg ha⁻¹) compared to inorganic P loss, mainly due

to the greater P application rate and higher soil test P. When applied during winter months (December–January), organic fertilizer contributed to greater new P loss, whereas early fall applications (October–November) resulted in lower new P loss, showing the importance of application timing. At the organic site, legacy P was the dominant contributor to TP and DRP losses, accounting for 84% and 79% of losses, respectively. At the inorganic site, legacy P was responsible for 97% of TP loss and the entirety (100%) of DRP loss. In conclusion, legacy P was the dominant source of P loss through drainage discharge, and winter organic fertilizer application significantly increased new P loss. © 2026 The Author(s). Abstract Deep neural networks (DNNs) have been shown to perform well on exclusive, multi-class classification tasks. However, when different classes have similar visual features, it becomes challenging for human annotators to differentiate them. This scenario necessitates the use of composite class labels. In this paper, we propose a novel framework called Hyper-Evidential Neural Network (HENN) that explicitly models predictive uncertainty due to composite class labels in training data in the context of the belief theory called Subjective Logic (SL). By placing a grouped Dirichlet distribution on the class probabilities, we treat predictions of a neural network as parameters of hyper-subjective opinions and learn the network that collects both single and composite evidence leading to these hyper-opinions by a deterministic DNN from data. We introduce a new uncertainty type called vagueness originally designed for hyper-opinions in SL to quantify composite classification uncertainty for DNNs. Our results demonstrate that HENN outperforms its state-of-the-art counterparts based on four image datasets. The code and datasets are available at: <https://github.com/Hugo101/HyperEvidentialNN>. © 2024 12th International Conference on Learning Representations, ICLR 2024. All rights reserved.

Hyperdimensional Uncertainty Quantification for Multimodal Uncertainty Fusion in Autonomous Vehicles Perception

Item Type Conference Paper

Author L. Chen

Author J. Wang

Author T. Mortlock

Author P. Khargonekar

Author M.A. Al Faruque

Abstract Uncertainty Quantification (UQ) is crucial for ensuring the reliability of machine learning models deployed in real-world autonomous systems. However, existing approaches typically quantify task-level output prediction uncertainty without considering epistemic uncertainty at the multimodal feature fusion level, leading to sub-optimal outcomes. Additionally, popular uncertainty quantification methods, e.g., Bayesian approximations, remain challenging to deploy in practice due to high computational costs in training and inference. In this paper, we propose HyperDUM, a novel deterministic uncertainty method (DUM) that efficiently quantifies feature-level epistemic uncertainty by leveraging hyper-dimensional computing. Our method captures the channel and spatial uncertainties through channel and patch -wise projection and bundling techniques respectively. Multimodal sensor features are then adaptively weighted to mitigate uncertainty propagation and improve feature fusion. Our evaluations show that HyperDUM on average outperforms the state-of-the-art (SOTA) algorithms by up to 2.01%/1.27% in 3D Object Detection and up to 1.29% improvement over baselines in semantic segmentation tasks under various types of uncertainties. Notably, HyperDUM requires $2.36\times$ less Floating Point Operations and up to $38.30\times$ less parameters than SOTA methods, providing an efficient solution for real-world autonomous systems. © 2025 IEEE.

Hyperspectral image classification and development of fluorescence index for single corn kernels infected with *Aspergillus flavus*

Item Type Journal Article

Author H. Yao

Author Z. Hruska

Author R. Kincaid

Author R.L. Brown

Author D. Bhatnagar

Author T.E. Cleveland

Abstract Aflatoxins are toxic secondary metabolites predominantly produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*. Aflatoxin-contaminated corn is toxic to domestic animals when ingested in feed and is a known carcinogen associated with liver and lung cancer in humans. Consequently, aflatoxin levels in food and feed are regulated by the U.S. Food and Drug Administration (FDA), which allows 20 ppb (parts per billion) limits in food and 100 ppb in feed for interstate commerce. Currently, aflatoxin detection and quantification methods are based on analytical tests, including thin-layer chromatography (TCL) and high-performance liquid chromatography (HPLC). These analytical tests require the destruction of samples and are costly and time consuming. Thus, the ability to detect aflatoxin in a rapid, nondestructive way is crucial to the grain industry, particularly the corn industry. Hyperspectral imaging technology offers a non-invasive approach to screening for

food safety inspection and quality control based on spectral signatures. The focus of this study was to classify aflatoxin-contaminated single corn kernels using fluorescence hyperspectral imagery. Field-inoculated corn kernels were used in the study. Contaminated and control kernels under long-wavelength ultraviolet excitation were imaged using a visible near-infrared (VNIR) hyperspectral camera. The imaged kernels were chemically analyzed to provide reference information for image analysis. This article describes a procedure for processing corn kernels located in different images for statistical training and classification. Two classification algorithms (maximum likelihood and binary encoding) were used to classify each corn kernel as "control" or "contaminated" through pixel classification. The binary encoding approach had a slightly better performance, with accuracy equal to 87% or 88% when 20 ppb or 100 ppb, respectively, was used as the classification threshold. In addition, three narrow-band fluorescence indices were developed and tested in this study. It was found that the highest correlation was -0.81 with the normalized difference fluorescence index (NDFI). The two bands used for the NDFI were 437 and 537 nm. The use of key wavelengths for contamination detection would be helpful for developing rapid and non-invasive inspection systems. This study demonstrated the potential of using fluorescence hyperspectral imagery for aflatoxin contamination detection in corn kernels infected with *A. flavus*.

Hyperspectral imagery classification based on sparse feature and markov random field

Item Type Journal Article

Author J. Yang

Author L. Wang

Author J. Qian

Abstract Aiming at the deficiencies that some implicit information is not well reflected in the traditional hyperspectral image classification methods, this paper presents a new hyperspectral image classification method based on Sparse Feature and Markov Random Field (SFMRF). The core idea of the SFMRF is firstly to express the hyperspectral image with the sparse feature, and then to apply the Support Vector Machine (SVM) to estimate the class conditional probability density functions, also, the MRF method is used to estimate the context-based class priors. Finally, the final class labels are determined by the Maximum a Posteriori (MAP) method. Theory analysis and simulation results on the Indian Pines hyperspectral data show that the proposed SFMRF method can greatly improve the classification accuracy. Abstract Background: Hypophosphatemic rickets is a rare, genetic syndrome with multisystem involvement. It causes skeletal abnormalities, painful enthesopathies, increased risk of fracture, and short stature; leading to a substantial burden of disease, disability, and worsening of quality of life. To improve health conditions of people living with this disease, it is essential to know its prevalence which is currently unknown in Colombia. This study aimed to estimate the prevalence of hypophosphatemic rickets in Colombia by using a mathematical model and national statistic records. Methods: We executed a model to estimate probabilities of transitions between health, disease, and death states (Markov chains). The model was fed with international prevalences taken from original studies (systematic review) and administrative records' data from SISPRO (a national health information system) using the International Classification of Diseases (ICD-10) E833 code, vital statistics, and census data. World Health Organization's (WHO) DISMOD II software was used to develop the model. Findings: The estimated overall prevalence of hypophosphatemic rickets in Colombia in 2018 was 2.03 cases per 100 000 people (981 affected people), with a sensitive range of 1.97 to 2.09. The estimated prevalence by sex was 2.61 (645 people) and 1.43 (336 people) cases per 100 000 women and men, respectively. Interpretation: Our overall estimated prevalence shows consistency with original international data. This is the first prevalence estimation of hypophosphatemic rickets in Colombia and will be relevant to support public health decisions for rare diseases and to provide a pre-test probability framework in clinical practice. DISMOD II and the model are useful tools to estimate the prevalence of rare and orphan diseases, when probabilistic studies cannot be carried out. There are limited bibliographic resources worldwide reporting prevalence values supported by original studies. Our study can be used as a cost-effective methodology reference in this regard, especially for Latin America.

Abstract Assessing the hypoxic status within the tumor microenvironment (TME) is crucial for its significant clinical relevance in evaluating drug resistance and tailoring individualized strategies. In this study, we proposed a robust pan-cancer hypoxic quantification method utilizing multiple public databases, diverse bioinformatics, and statistical methods. All tumor samples were classified into four subtypes: non-

hypoxic/TMEhigh (C1), hypoxic/TMEhigh (C2), non-hypoxic/TMElow (C3), and hypoxic/TMElow (C4). We systematically analyzed multi-omics data and single-cell RNA-sequencing (scRNA-seq) data to reveal distinct immune landscape patterns and genomic characteristics among the four subtypes across pan-cancer. Furthermore, we employed multiple machine learning approaches to construct a hypoxic-TME model to enhance the predictive accuracy of immunotherapy response. Additionally, drug repositioning was implemented for cancer patients predicted as non-responders to immunotherapy. A pan-cancer analysis identified PDK1 as a hub gene linking tumor hypoxia, glycolysis, and immunotherapy resistance. In vivo experimental validation further confirmed that targeting PDK1 could improve the response to immunotherapy. Overall, our study may offer valuable insights for integrating hypoxic-TME classification into tumor staging and providing personalized strategies for cancer patients. © The Author(s) 2024.

Identification and classification of trucks and trailers on the road network through deep learning

Item Type Conference Paper

Author L. Chen

Author P.-Y. Sun

Author Y. Jia

Author R.O. Sinnott

Abstract Understanding the flow of traffic on road networks is a primary focus of road transport authorities. A range of technologies has been applied to measure throughput and potential congestion on the roads. However, such technologies are currently limited in disambiguating the kinds of vehicles on the road network. Certain vehicles types are especially important to distinguish from other traffic, e.g. trucks and trailers. These are larger vehicles that can have a major impact on the roads and surrounding areas, e.g. due to pollution or the excess noise that they can give rise to. In this paper, we present an approach to automatically detect, classify and count the unique classes of trucks and trailers that are found on the road network of Victoria using approaches based on deep learning. In particular, we consider two leading object detection systems: You Only Look Once version 3 (YOLOv3) and Single Shot Multi-Box Detector (SSD). We compare the models and the performance achieved for truck and trailer classification, including dealing with more common and less common truck and trailer types. We measure the efficiency and accuracy of the approaches based on the mean average precision achieved. © 2019 Association for Computing Machinery.

Identification and counting of mature apple fruit based on BP feed forward neural network

Item Type Conference Paper

Author S. Lal

Author S.K. Behera

Author P.K. Sethy

Author A.K. Rath

Abstract Classification of fruits is an onerous and tedious task because of countless number of fruits. The traditional approach for detection and classification of fruit and its maturity level is based on the naked eye observation by the experts, which is both time consuming and causes eye fatigue. Advance techniques in image processing and machine learning helps to automatic classify and count the fruits, accurately, quickly and non-destructively. A method to automatic detect and classify apple fruit maturity level, whether it is mature or immature based on its color features has been proposed. Images of the apple are resized and Image Processing Techniques are applied for the extraction of apple color components (R, G, B). Artificial Neural Network is used as a classifier to identify and count the mature and immature apples using color components. The proposed model has an accuracy of 98.1%, when all the three attributes are used as an input. © 2017 IEEE.

Identification and Estimation of Causal Effects Defined by Shift Interventions

Item Type Conference Paper

Author N. Sani

Author J.J.R. Lee

Author I. Shpitser

Editor Peters J.

Editor Sontag D.

Abstract Causal inference quantifies cause effect relationships by means of counterfactual responses had some variable been artificially set to a constant. A more refined notion of manipulation, where a variable is artificially set to a fixed function of its natural value is also of interest in particular domains. Examples include increases in financial aid, changes in drug dosing, and modifying length of stay in a hospital. We define counterfactual responses to manipulations of this type, which we call shift interventions. We show that in the presence of multiple variables being manipulated, two types of shift interventions are possible. Shift interventions on the treated (SITs) are defined with respect to natural values, and are connected to effects of treatment on the treated. Shift interventions as policies (SIPs) are defined recursively with respect to values of responses to prior shift interventions, and are connected to dynamic treatment regimes. We give sound and complete identification algorithms for both types of shift interventions, and derive efficient semi-parametric estimators for the mean response to a shift intervention in a special case motivated by a healthcare problem. Finally, we demonstrate the utility of our method by using an electronic health record dataset to estimate the effect of extending the length of stay in the intensive care unit (ICU) in a hospital by an extra day on patient ICU readmission probability. © 2020 Proceedings of Machine Learning Research. Identification and quantification of feathers, down, and hair of avian and mammalian origin using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry

Item Type Journal Article**Author** K. Hollemeyer**Author** W. Altmeyer**Author** E. Heinzle

Abstract We describe a fast method for the identification of the origin of native and chemically processed feathers, down, and hair and for distinguishing closely related species using enzyme digestion and MALDI-TOF mass spectrometry. Additionally we present two methods for the quantification of different identified bird and mammalian samples, respectively, in binary species mixtures. Without any prior cleaning or isolation of single proteins, enzymatical digests of feathers, down, and hair are performed. Fragments generated are analyzed by MALDI-TOF mass spectrometry, and peak groups of different selectivity are established for every animal species. For the identification of individual animal species, only unique species-specific peaks are accepted while for species classification of tinted or bleached hair, the group of semispecific peaks (SEMPs) is used. Samples from native animal species show a higher coincidence of digest peak masses of SEMPs than far-related species, indicating a phylogenetical relationship of the investigated structure proteins. Quantification of mixed binary avian samples is performed by identification of preweighed single feathers and down, followed by calculation of the gravimetric mass fractions. The composition of mixed binary mammalian samples is calculated

from correlation of the quotient of the relative peak intensities or areas of these species and the quotient of corresponding gravimetric mass fractions. High accuracy is achieved by both quantification methods. The fast methods are well suited for industrial quality control for example.

Identification and quantification of individual volatile organic compounds in a binary mixture by SAW multisensor array and pattern recognition analysis

Item Type Journal Article

Author M. Penza

Author G. Cassano

Author F. Tortorella

Abstract We have developed a surface acoustic wave (SAW) multisensor array with five acoustic sensing elements configured as two-port resonator 433.92 MHz oscillators and a reference SAW element to recognize different individual components and determine their concentrations in a binary mixture of volatile organic compounds (VOCs) such as methanol and acetone, in the ranges 15-130 and 50-250 ppm, respectively. The SAW sensors have been specifically coated by various sensing thin films such as arachidic acid, carbowax, behenic acid, triethanolamine or acrylated polysiloxane, operating at room temperature. By using the relative frequency change as the output signal of the SAW multisensor array with an artificial neural network (ANN), a recognition system has been realized for the identification and quantification of tested VOCs. The features of the SAW multisensor array exposed to a binary component organic mixture of methanol and acetone have been extracted from the output signals of five SAW sensors by pattern recognition (PARC) techniques, such as principal component analysis (PCA). An organic vapour pattern classifier has been implemented by using a multilayer neural network with a backpropagation learning algorithm. The normalized responses of a reduced set of SAW sensors or selected principal components scores have been used as inputs for a feed-forward multilayer perceptron (MLP), resulting in a 70% correct recognition rate with the normalized responses of the four SAW sensors and in an enhanced 80% correct recognition rate with the first two principal components of the original data consisting of the normalized responses of the four SAW sensors. The prediction of the individual vapour concentrations has been tackled with PCA for features extraction and by using the first two principal components scores as inputs to a feed-forward MLP consisting of a gating network, which decides which of three specific subnets should be used to determine the output concentration: the first subnet for methanol only, the second subnet for acetone only and the third subnet for methanol and acetone in the binary mixture. Good 0.941 and 0.932 correlation coefficients for the predicted versus real concentrations of methanol and acetone, respectively, as individual components in a binary mixture have been obtained. The experimental results demonstrated that the proposed binary organic vapour mixture classifier is effective in the identification of the tested VOCs of methanol and acetone. Also, the combination of PCA and ANN techniques provides a rapid and accurate quantification method for the individual components' concentration in the tested binary mixture of methanol and acetone.

Identification and quantification of the traditional chinese medicinal plant *Gentiana macrophylla* using taqman real-time PCR

Item Type Journal Article

Author C.-Y. Xue

Author D.-Z. Li

Author Q.-Z. Wang

Abstract *Gentiana macrophylla* Pall. is a commonly used antirheumatic herb. There are four species of *Gentiana* recorded as herbal drugs in the Chinese Pharmacopoeia. The other species are often marketed as *G. macrophylla*, and thus the therapeutic effects of *G. macrophylla* are not achieved. A novel one-step methodology based on real-time polymerase chain reaction (PCR) technology has been developed for the identification of *G. macrophylla*. This relative quantification methodology does not require a known amount of standard, allowing the analysis of many more samples together. The utilization of real-time PCR does not require sample handling, preventing contamination and resulting in much faster and higher throughput results. © Georg Thieme Verlag KG Stuttgart.

Identification of attacks against wireless sensor networks based on behaviour analysis

Item Type Journal Article

Author V. Korzhuk

Author A. Groznykh

Author A. Menshikov

Author M. Strecker

Abstract The paper describes the problem of identification of network layer attacks on wireless sensor networks for subsequent development of intrusion detection systems. 15 types of behaviour (including 14 states under attack and the normal state) and identification features are briefly specified. A technique for attacks identifying based on a combination of Random Forest algorithm and probability classifier is proposed. A study of the dependence of the accuracy of the probability classifier and the average number of used features on a confidence level and a priori probability of the normal state, which allows reducing the feature space to one feature, is described. For most attacks, there is a relative constancy of the dependence values in the range from 0 to 0.7 ± 0.15 , after which a decrease occurs, corresponding to the quality of identification. Recommendations to the algorithm parameters are formed and its evaluation is carried out. © 2019, Innovative Information Science and Technology Research Group. All rights reserved.

Author C. Liu

Author J. Zhao

Abstract Diatom test is one of the commonly used diagnostic methods for drowning in forensic pathology, which provides supportive evidence for drowning. However, in forensic practice, it is time-consuming and laborious for forensic experts to classify and count diatoms, whereas artificial intelligence (AI) is superior to human experts in processing data and carrying out classification tasks. Some AI techniques have focused on searching diatoms and classifying diatoms. But, they either could not classify diatoms correctly or were time-consuming. Conventional detection deep network has been used to overcome these problems but failed to detect the occluded diatoms and the diatoms similar to the background heavily, which could lead to false positives or false negatives. In order to figure out the problems above, an improved

region-based full convolutional network (R-FCN) with online hard example mining and the shape prior of diatoms was proposed. The online hard example mining (OHEM) was coupled with the R-FCN to boost the capacity of detecting the occluded diatoms and the diatoms similar to the background heavily and the priors of the shape of the common diatoms were explored and introduced to the anchor generation strategy of the region proposal network in the R-FCN to locate the diatoms precisely. The results showed that the proposed approach significantly outperforms several state-of-the-art methods and could detect the diatom precisely without missing the occluded diatoms and the diatoms similar to the background heavily. From the study, we could conclude that (1) the proposed model can locate the position and identify the genera of common diatoms more accurately; (2) this method can reduce the false positives or false negatives in forensic practice; and (3) it is a time-saving method and can be introduced. © 2021, The Author(s), under exclusive licence to Springer-Verlag GmbH Germany, part of Springer Nature.

Abstract Differentiation between Emmental cheese produced in diverse regions is of major interest to verify product authenticity and avoid product imitation. The objective of this study was to identify parameters that allow a differentiation between Southern German Emmental cheese and Emmental cheese produced in other regions based on physical properties and volatile and non-volatile compounds. Emmental cheese samples were collected from seven German dairies located in Bavaria and Baden-Wuerttemberg (regional Emmental cheese). Additionally, generic Emmental cheeses produced in Northern Germany, the Netherlands and Poland (European Emmental cheese) were added to the data set as well as Swiss Emmental and Allgäu Emmental cheeses. A large variety of characteristics was previously analysed by application of thermo-rheological methods and targeted quantification methods (e.g. GC-MS and dynamic oscillatory shear measurement). Stepwise discriminant analysis was used to identify parameters with high discriminant power. These were brightness L*, loss modulus G'' at 20 °C, loss factor tan δmax, 3-methylbutyric acid, acetic acid, propionic acid, γ-Glu-Leu, γ-Glu-Val and the peptide Ile-Val-Pro-Asn. The data set resulting from the nine parameters was subjected to linear discriminant analysis followed by a cross validation step. Regional Emmental cheese was classified correctly at 95%, whereas 75% of European Emmental cheese and 100% of Swiss and Allgäu Emmental cheeses were correctly classified. The results are preliminary but may provide, upon further verification, a useful tool for cheese makers to identify

Emmental cheese produced in different regions based on a small number of characteristic parameters and prevent product imitation. © 2015, INRA and Springer-Verlag France.

Identifying depressive subtypes in a large cohort study: Results from the Netherlands Study of Depression and Anxiety (NESDA)

Item Type Journal Article

Author F. Lamers

Author B.W.J.H. Penninx

Abstract Objective: The heterogeneity of depression in the current classification system remains a point of discussion in the psychiatric field, despite previous efforts to

subclassify depressive disorders. Data-driven techniques may help to come to a more empirically based classification. This study aimed to identify depressive subtypes within a large cohort of subjects with depression. Method: Baseline data from 818 persons with a DSM-IV diagnosis of current major depressive disorder or minor depression who participated in the Netherlands Study of Depression and Anxiety were used. Respondents were recruited in the community, in primary care, and in specialized mental health care from September 2004 through February 2007. Latent classes were derived from latent class analysis using 16 depressive symptoms from the Composite International Diagnostic Interview and the Inventory of Depressive Symptomatology. Classes were characterized using demographic, clinical psychiatric, psychosocial, and physical health descriptors. Results: Three classes were identified: a severe melancholic class (prevalence, 46.3%), a severe atypical class (prevalence, 24.6%), and a class of moderate severity (prevalence, 29.1%). Both severe classes were characterized by more neuroticism (melancholic OR = 1.05 [95% CI, 1.01-1.10]; atypical OR = 1.07 [95% CI, 1.03-1.12]), more disability (melancholic OR = 1.07 [95% CI, 1.05-1.09]; atypical OR = 1.06 [95% CI, 1.04-1.07]), and less extraversion (melancholic OR = 0.95 [95% CI, 0.92-0.99]; atypical OR = 0.95 [95% CI, 0.92-0.99]) than the moderate class. Comparing the melancholic class with the atypical class revealed that the melancholic class had more smokers (atypical OR = 0.57 [95% CI, 0.39-0.84]) and more childhood trauma (atypical OR = 0.86 [95% CI, 0.74-1.00]), whereas the atypical class had more women (atypical OR = 1.52 [95% CI, 0.99-2.32]), a higher body mass index (atypical OR = 1.13 [95% CI, 1.09-1.17]), and more metabolic syndrome (atypical OR = 2.17 [95% CI, 1.38-3.42]). Conclusions: Both depression severity (moderate vs severe) and the nature of depressive symptoms (melancholic vs atypical) were found to be important differentiators between subtypes. Higher endorsement rates of somatic symptoms and more metabolic syndrome in the atypical class suggest the involvement of a metabolic component. © Copyright 2010 Physicians Postgraduate Press, Inc.

Identifying spatiotemporal patterns and driving factors of nitrogen leaching in Henan Province by integrating a process-based model with machine learning

Item Type Journal Article

Author K. Hu

Abstract Understanding the spatiotemporal patterns and driving factors of nitrogen (N) leaching is crucial to mitigating groundwater nitrate contamination. This study integrated a process-based model with machine learning to quantify the spatiotemporal distribution of N leaching and identify its dominant drivers in Henan Province, a major wheat-maize rotation region in China. Thirty-year (1992–2022) simulations revealed a south-to-north decreasing gradient in annual N leaching, from 215 kg N ha⁻¹ in southern areas to 85 kg N ha⁻¹ in the north. Mean N leaching was substantially higher during the maize season (36–123 kg N ha⁻¹) than during the wheat season (42–100 kg N ha⁻¹), with the maize season contributing about 70% of annual N leaching in parts of Henan. Interannual variability was mainly driven by precipitation, with significantly greater maize-season leaching occurring in wet years. Water and N management were the dominant drivers across all temporal scales. Soil factors exerted stronger influence than meteorological conditions during the wheat season, but weaker influences during the maize season. Nitrogen application, precipitation, irrigation, relative humidity and field capacity (FC) collectively explained over 70% of leaching variability. Nitrogen application exhibited a softplus-type relationship with N leaching, whereas water-related variables displayed sigmoidal response patterns. Field capacity regulated the seasonal redistribution of N leaching. Relatively high FC promoted N accumulation during dry years, resulting in

higher N leaching during wet years. These findings provide a scientific basis for developing targeted water and N management and soil amendment to mitigate N leaching risks. © 2026 The Authors.

Identifying Undiagnosed High-Risk Suicidality Cases by Matching Patients With a Similar Comorbidity Burden: Retrospective Observational Study

Item Type Journal Article

Author L. Bode

Author R. Xu

Author M. Garber

Author K.D. Mandl

Author A.J. McMurry

Abstract Background: Suicide is the second leading cause of death for children and adolescents aged 6 to 18 years. Pediatric suicidality is underreported, which poses significant challenges for effective intervention and prevention strategies. Identifying populations at risk of suicidality can provide critical benefits in terms of study cohort selection, prevalence estimation, and clinical resource allocation. Objective: This study sought to (1) measure the prevalence of mental health comorbidities in pediatric suicidality and (2) identify undiagnosed high-risk suicidality cases by matching them with patients with a similar mental health comorbidity burden. Methods: Electronic health record data from a large academic pediatric hospital in Boston, Massachusetts, were analyzed for patients aged 6 to 18 years presenting to the emergency department between June 1, 2016, and June 1, 2022. Suicidality cases were defined using International Classification of Diseases, 10th Revision (ICD-10) codes for 3 suicidality subtypes: suicidal ideation, self-harm, and suicide attempt. Comorbidities of suicidality were calculated as the conditional probability of ICD-10 code pairs. After multiple hypothesis corrections, statistically significant comorbidities and patient encounter demographics were input as covariates into a propensity score matching (PSM) model. The accuracy of the PSM model was validated against chart review by 2 independent subject matter experts. Results: In total, 2.9% (2638/90,980) of emergency department encounters met an ICD-10–based case definition of suicidality during the study period. The prevalence of suicidality by subtype was 2.5% (2275/90,980) for ideation, 1.1% (1030/90,980) for self-harm, and 0.2% (177/90,980) for suicide attempt. Suicidality prevalence was more common for the female sex (1825/43,929, 4.2%) than for the male sex (813/47,045, 1.7%). Comorbidities of suicidality were statistically significant for 55 frequently co-occurring ICD-10 codes. Nearly half of these comorbidities (26/55, 47.3%) were not present in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, and nearly a quarter (12/55, 21.8%) consisted of ICD-10 codes for accidental rather than intentional self-harm. Increased probability of suicidality was observed for patients with personality disorder (84/190, 44.2%), gender dysphoria (143/333, 42.9%), bipolar disorder (162/448, 36.2%), depression (1791/5426, 33%), and schizophrenia spectrum disorders (133/411, 32.4%). On the basis of gold-standard chart review, 53.4% of propensity-matched noncases were unrecognized cases of suicidality. Conclusions: PSM using comorbidity profiles is an effective approach for identifying suicidality cases that lack ICD-10 codes for suicidality. © Louisa Bode, Rena Xu, Matthew Garber, Kenneth D Mandl, Andrew J Mcmurry.

Abstract The aim of this experiment was to quantify the stained areas of coffee seeds submitted to the LERCAFE test using image analysis. The seeds used were of the Catuaí Vermelho IAC 99 and Paradise cultivars. The physiological quality of the lots was assessed using germination tests, moisture content and a germination speed index. The LERCAFE test was conducted using seeds without parchment immersed in a solution of 3% sodium hypochlorite for 3 hours. Color photographs (RGB) with a resolution of 5 MPx were taken of each seed. The seeds were visually evaluated, and the functions generated from the analyses of the stained and non-stained regions were quantified by the Matlab R2009b program. Classification models were developed based on the Fisher Linear Discriminant Function and the evaluation of the adequacy of the models confusion matrix between the visual references and the classification generated by the linear functions. The image analysis for the creation of Fisher's linear discriminant function in the development of classifiers for the coffee seeds submitted to the LERCAFE test is potentially efficient; however, it remains necessary to test other discriminant functions and quantification methodologies. © 2016, Eduem - Editora da Universidade Estadual de Maringá. Editor Casas J.-R.

Editor Frangopol D.M.

Editor Turmo J.

Abstract Traditional inspections are typically performed manually. They require specialized equipment, which usually is expensive, time-consuming and can often be a source of risk. Unmanned Aerial Vehicles (UAV) provide an alternative to overcome the challenges of traditional manual inspections. This has been studied as well as the use of machine learning and image analysis algorithms for detection and quantification of damages, in particular cracks. This paper presents a framework for inspections that combines data acquisition, crack detection, and the quantification of essential parameters of concrete cracks. From this method, the width and length of cracks are determined and compared with control measurements to estimate the accuracy of the method. The results show that using the pre-trained network to detect cracks, only a few to no false negatives are obtained. From the images classified as containing cracks, the quantification methodology is performed obtaining measurements of crack width down to 0.13 mm. © 2022 the Author(s).

Abstract	Over the past decades, rice crops are crucially admitted as one of the powerful energy streams for the production of resources. Rice plant diseases are considered as a raising factor behind the agricultural, economic and communal loss in the upcoming development of the agricultural field. Since last 10 years diagnosis of plant disease in approach to image processing techniques have remained keen are

of interest among the researcher. A number of disease detection, identification and quantification methods have been developed and applied in a wide variety of crops. This paper reviews related research papers from the period between 2007 and 2018 with a focus on the development of state of the art. The related studies are compared based image segmentation, feature extraction, feature selection and classification. This paper also outlines the current achievements, limitations, and suggestions for future research associated with the diagnosis of rice plant diseases. © 2020 The Authors. Image-Based Quantitation of Host Cell–Toxoplasma gondii Interplay Using HRMAN: A Host Response to Microbe Analysis Pipeline

Item Type Journal Article

Author D. Fisch

Author A. Yakimovich

Author B. Clough**Author** J. Mercer**Author** E.-M. Frickel

Abstract Research on *Toxoplasma gondii* and its interplay with the host is often performed using fluorescence microscopy-based imaging experiments combined with manual quantification of acquired images. We present here an accurate and unbiased quantification method for host–pathogen interactions. We describe how to plan experiments and prepare, stain and image infected specimens and analyze them with the program HRMAN (Host Response to Microbe Analysis). HRMAN is a high-content image analysis method based on KNIME Analytics Platform. Users of this guide will be able to perform infection studies in high-throughput volume and to a greater level of detail. Relying on cutting edge machine learning algorithms, HRMAN can be trained and tailored to many experimental settings and questions. © Springer Science+Business Media, LLC, part of Springer Nature 2020.

Imaging Amyloid and Tau in the Retina: Current Research and Future Directions

Item Type Journal Article

Author M.Y. Tang

Author M.S. Blazes

Author C.S. Lee

Author F. Costello

Author S. Prasad

Abstract Background:The retina is a key focus in the search for biomarkers of Alzheimer's disease (AD) because of its accessibility and shared development with the brain. The pathological hallmarks of AD, amyloid beta (A β), and hyperphosphorylated tau (pTau) have been identified in the retina, although histopathologic findings have been mixed. Several imaging-based approaches have been developed to detect retinal AD pathology in vivo. Here, we review the research related to imaging AD-related pathology in the retina and implications for future biomarker research.Evidence Acquisition:Electronic searches of published literature were conducted using PubMed and Google Scholar.Results:Curcumin fluorescence and hyperspectral imaging are both promising methods for detecting retinal A β , although both require validation in larger cohorts. Challenges remain in distinguishing curcumin-labeled A β from background fluorescence and standardization of dosing and quantification methods. Hyperspectral imaging is limited by confounding signals from other retinal features and variability in reflectance spectra between individuals. To date, evidence of tau aggregation in the retina is limited to histopathologic studies. New avenues of research are on the horizon, including near-infrared fluorescence imaging, novel A β labeling techniques, and small molecule retinal tau tracers. Artificial intelligence (AI) approaches, including machine learning models and deep learning-based image analysis, are active areas of investigation.Conclusions:Although the histopathological evidence seems promising, methods for imaging retinal A β require further validation, and in vivo imaging of retinal tau remains elusive. AI approaches may hold the greatest promise for the discovery of a characteristic retinal imaging profile of AD. Elucidating the role of A β and pTau in the retina will provide key insights into the complex processes involved in aging and in neurodegenerative disease. © 2023 Lippincott Williams and Wilkins. Author G. Mosser

Author M.-C. Schanne-Klein

Abstract The recent booming of multiphoton imaging of collagen fibrils by means of second harmonic generation microscopy generates the need for the development and automation of quantitative methods for image analysis. Standard approaches sequentially analyse two-dimensional (2D) slices to gain knowledge on the spatial arrangement and dimension of the fibrils, whereas the reconstructed three-dimensional (3D) image yields better information about these characteristics. In this work, a 3D analysis method is proposed for second harmonic generation images of collagen fibrils, based on a recently developed 3D fibre quantification method. This analysis uses operators from mathematical morphology. The fibril structure is scanned with a directional distance transform. Inertia moments of the directional distances yield the main fibre orientation, corresponding to the main inertia axis. The collaboration of directional distances and fibre orientation delivers a geometrical estimate of the fibre radius. The results include local maps as well as global distribution of orientation and radius of the fibrils over the 3D image. They also bring a segmentation of the image into foreground and background, as well as a

classification of the foreground pixels into the preferred orientations. This accurate determination of the spatial arrangement of the fibrils within a 3D data set will be most relevant in biomedical applications. It brings the possibility to monitor remodelling of collagen tissues upon a variety of injuries and to guide tissues engineering because biomimetic 3D organizations and density are requested for better integration of implants. © 2012 Royal Microscopical Society.

Imbalanced domain adaptation Net for multi-class Electrocardiography signals classification

Item Type Journal Article

Author R. An

Author J. Ren
Author Z. Zhao

Abstract Arrhythmia detection using Electrocardiogram (ECG) signals plays a crucial role in cardiovascular disease diagnosis. Deep learning has shown great promise in developing diagnostic models for ECG classification. However, maintaining the performance of these models remains challenging in cross-domain scenarios, where ECG data might be collected from different devices, patient populations, or environments. Although existing unsupervised domain adaptation (UDA) methods have been utilized to improve the generalization of the model, many consider the discrepancies in feature distributions across domains but overlook variations in label distributions, also known as label shift. To tackle this problem, an imbalanced domain adaptation network (IDANet) is proposed for multi-class ECG diagnosis, accounting for both changes in feature distributions and variations in label distributions. Specifically, to address label shift, a class-sensitive re-weighting method with label-distribution-aware re-margining regularization is utilized which effectively enables the extraction of class-invariant features and facilitates the establishment of differentiated classification boundaries. Meanwhile, semantic alignment is applied to reduce the category-wise feature distribution discrepancies. Experiments on four ECG datasets show a considerable improvement (up to ~ 16 % in accuracy and ~ 17 % in F1 score) over other state-of-the-art UDA methods. These results highlight the promising potential of the proposed approach for future medical diagnostic applications. © 2025 Elsevier Ltd

ImbSAM: A Closer Look at Sharpness-Aware Minimization in Class-Imbalanced Recognition

Item Type Conference Paper

Author Y. Zhou

Author Y. Qu

Author X. Xu

Author H. Shen

Abstract Class imbalance is a common challenge in real-world recognition tasks, where the majority of classes have few samples, also known as tail classes. We address this challenge with the perspective of generalization and empirically find that the promising Sharpness-Aware Minimization (SAM) fails to address generalization issues under the class-imbalanced setting. Through investigating this specific type of task, we identify that its generalization bottleneck primarily lies in the severe overfitting for tail classes with limited training data. To overcome this bottleneck, we leverage class priors to restrict the generalization scope of the class-agnostic SAM and propose a class-aware smoothness optimization algorithm named Imbalanced-SAM (ImbSAM). With the guidance of class priors, our ImbSAM specifically improves generalization targeting tail classes. We also verify the efficacy of ImbSAM on two prototypical applications of class-imbalanced recognition: long-tailed classification and semi-supervised anomaly detection, where our ImbSAM demonstrates remarkable performance improvements for tail classes and anomaly. Our code implementation is available at <https://github.com/cool-xuan/Imbalanced-SAM>. © 2023 IEEE.

Abstract Background: For patients with thoracic aortic aneurysms (TAA), aortic size on imaging is widely used to guide clinical decision making. This study examined the impact of methodological variance on aortic quantification. Methods: We studied enrollees in the National Registry of Genetically Triggered Thoracic Aortic Aneurysms and Cardiovascular Conditions. Aortic size on computed tomography was quantified by 2 linear methods; cross-sectional dimensions in axial (AX) and double oblique (DO) plane. Calculated area was compared to planimetry. Established cutoffs (area/height >10 cm²/m, diameter < 5cm) for prophylactic TAA repair were used to compare surgical eligibility by each method. Results: Fifty subjects were studied. Aortic size differed between AX and DO at all locations ($p \leq 0.001$), with magnitude greatest at the sinotubular junction (4.8 ± 1.1 vs 4.0 ± 1.0 cm, $p < 0.001$). The difference between AX and DO correlated with aortic angular displacement ($r = 0.37$, $p < 0.01$), which was threefold larger at the sinotubular junction (37 ± 12 degrees)

than the ascending aorta (12 ± 5 degrees; $p < 0.001$). At all locations, aortic area calculated using DO yielded smaller differences with planimetry than AX ($p < 0.05$). DO and planimetry yielded equal prevalence (24%) of subjects eligible for prophylactic TAA repair based on area-height cutoff, whereas AX prevalence was higher (44%; $p = 0.006$). Using a linear cutoff, AX yielded over a twofold greater prevalence of surgically eligible subjects (56%) than did DO (24%; $p < 0.001$). Conclusions: Established linear methods for aortic measurement yield different results that impact surgical eligibility. DO yielded improved agreement with planimetry and differed with AX in proportion to aortic geometric obliquity. Findings support DO measurements for imaging evaluation of subjects with TAA. © 2011 The Society of Thoracic Surgeons.

Impact of low class prevalence on the performance evaluation of neural network based classifiers: Experimental study in the context of computer-assisted medical diagnosis

Item Type Conference Paper

Author M.A. Mazurowski

Author P.A. Habas

Author J.M. Zurada

Author G.D. Tourassi

Abstract This paper presents an experimental study on the impact of low class prevalence on the neural network based classifier performance as measured using Receiver Operator Characteristic (ROC) analysis. Two methods of dealing with the problem are investigated: oversampling and undersampling in the context of varying the class prevalence and the size of training datasets with uncorrelated and correlated features. The results show that the class imbalance can significantly decrease the classifier performance especially in the case of small training datasets. Furthermore, the oversampling method is shown to be more effective than the undersampling method in compensating the class imbalance. Statistically significant differences, however, are observed only in the cases with large total number of samples and very low prevalence. ©2007 IEEE.

Abstract **OBJECTIVE.** The objective of our study was to assess whether there is an association between native thoracic aortic curvature and the development of endoleaks after thoracic endovascular aortic repair. **MATERIALS AND METHODS.** Quantitative analysis of the native aortic lumen was performed on preprocedural CT angiograms of 40 patients with thoracic aortic aneurysm treated by thoracic endovascular aortic repair. The curvature of the median centerline was measured. Tortuosity indexes were calculated on the basis of the sum of the curvature values within the diseased segment and in the proximal and distal fixation zones. The association between the tortuosity index and endoleak was analyzed. **RESULTS.** Compared with patients without endoleaks, the tortuosity index of the proximal fixation zone was higher in patients with type Ia endoleak (9.5 vs 1.5 cm⁻¹, $p < 0.01$); the tortuosity index of the distal fixation zone was higher in type Ib endoleak patients (6.6 vs 0.5 cm⁻¹, $p < 0.05$); and the tortuosity indexes of the proximal fixation zone and of the diseased segment were higher in type III endoleak patients (11.0 vs 1.5 cm⁻¹, $p < 0.01$; and 15.8 vs 7.2 cm⁻¹, $p < 0.01$, respectively). Patients with a type III endoleak had longer diseased segments and larger mean diameters of the aneurysm than patients without endoleaks (148.6 vs 87.1 mm, $p < 0.01$; and 75.4 vs 63.2 mm, $p < 0.05$, respectively). Logistic regression analysis revealed that the risk of a type I or type III endoleak increased as the tortuosity index increased, with a 90% risk of endoleak at a tortuosity index of 10 cm⁻¹ in the proximal fixation zone. **CONCLUSION.** Quantification of aortic tortuosity using CT angiograms may help to predict whether an endoleak will develop after thoracic endovascular aortic repair, and this quantification method may become an important tool for risk stratification before thoracic endovascular aortic repair. © American Roentgen Ray Society.

Impact of the preprocessing stage on the performance of offline automatic vehicle counting using YOLO

Item Type Journal Article

Author D. Valencia

Author E. Munoz Espana

Author M. Munoz Anasco

Abstract Vehicle counting systems detect, classify, and count vehicles with sensors or image processing, providing valuable information for road management. Image processing systems provide detailed information on vehicle flow with adequate lighting conditions and a higher computational cost compared to sensor systems. The image processing systems with higher accuracy require higher computational cost. This feature limits the number of application cases in cities with low technology level. This research analyzes urban vehicle counting using an automatic image processing system using YOLOv5 in the vehicle detection-classification stage and the SORT algorithm in the tracking stage. The study used videos recorded from a pedestrian bridge in Popayan, Colombia, for an exploratory study of the influence of preprocessing operations on the performance of a low-tech vehicle counting system. The study performed a comparative statistical analysis to determine the impact of different settings on system performance. An ANOVA analysis evaluates the incidence of frame cut and reshape on YOLO processing. The results indicate that a 30% cut of the image area prior to YOLO processing produces the lowest weighted average error. In addition, the frame reshape only increases the processing time. The study proposes improvements in the performance of an offline automatic vehicle counting system from the video preprocessing stage. © 2003-2012 IEEE.

Author Y. Lu

Author Y. Zhao

Author J. Xie

Author X. Zhang

Author H. Zhu

Abstract This study aimed to evaluate the impact of updated pediatric hypertension (HTN) criteria (the 2017 AAP Guidelines) on prevalence estimates of HTN and prehypertension among Chinese children compared to the 2004 Fourth Report. A total of 2093 children aged 7–15 years from five schools in Tianjin, China were selected using a multistage random cluster sampling method. The prevalence of HTN per the 2017 AAP Guidelines (10.1%) was significantly higher than that per the

Fourth Report (6.6%), whereas the prevalence of prehypertension per the 2017 AAP Guidelines (6.3%) was significantly lower than that per the Fourth Report (8.8%). From the 2004 Fourth Report to the 2017 AAP Guidelines, a total of 117 (5.6%) children were reclassified to have higher blood pressure. The two criteria had better consistency in the diagnosis of systolic abnormalities than in the diagnosis of diastolic abnormalities. The updated definitions for pediatric HTN have a substantive impact on the prevalence estimation among Chinese children, especially among boys, overweight children, and older children. © 2020, The Author(s), under exclusive licence to Springer Nature Limited.

Impact of Urban Expansion and in Situ Greenery on Community-Wide Carbon Emissions: Method Development and Insights from 11 US Cities

Item Type Journal Article

Author M. Milnar

Author A. Ramaswami

Abstract Biogenic CO₂ emissions in cities are shaped by urban land cover change which can release carbon stocks, and, carbon sequestration by in situ vegetation. To date, these two processes have not been studied together and compared with transboundary fossil fuel-based CO₂ emissions of urban energy use. We leverage remote sensing and machine learning to quantify biogenic CO₂ emissions between 2006 and 2012, across 11 U.S cities, including central and suburban cities, in different climate zones. Results indicate that in situ carbon sequestration by greenery varied moderately across cities (-2.1 to -0.87 Mg CO₂ ha⁻¹ yr⁻¹), while emissions from the carbon stock change due to land conversion varied much more (-3.4 to 9.8 Mg CO₂ ha⁻¹ yr⁻¹), indicating that the latter dominates biogenic CO₂ emissions. Net biogenic CO₂ emissions were negative (carbon sink) in four cities, while large net positive emissions were present in rapidly growing suburbs. As a ratio of community-wide energy use for travel and buildings, biogenic CO₂ emissions were a small proportion in the core cities Denver (0.17%) and Minneapolis (0.33%) and as high as 38.2% in growing exurban communities. These results show that land cover change and greenery will be important policy levers in zero-carbon city planning. © 2020 American Chemical Society.

Impacts of climate, cryosphere and vegetation changes on blue and green water in the Qinghai-Tibetan Plateau

Item Type Journal Article**Author** W. Kang**Author** G. Wang**Author** K. Li**Author** X. Sun**Author** B. Yong**Author** J. Sun**Author** L. Guo**Author** P. Huang**Author** J. Ma**Author** Z. Deng**Author** H. Wang**Author** S. Sun

Abstract The Qinghai-Tibetan Plateau is experiencing pronounced warming and wetting, which are reshaping regional hydrological regimes. However, the systemic impacts on blue and green water resources remain insufficiently understood. This study integrates hydrological modeling and machine learning to quantify how warming and wetting, vegetation greening, and cryosphere degradation drive changes in blue and green water in the source region of the Yangtze River. Results show that blue and green water resources increased by 37% and 10%, respectively, in the basin from 1982 to 1998 to 1999-2022. Precipitation increase dominates the blue water increase, contributing 85.2%; the green water increase is jointly driven by precipitation increase and temperature rise, with contributions of 57.2% and 30.8%, respectively. Vegetation greening decreases blue water and increases green water by enhancing evapotranspiration. Cryosphere degradation, including snowmelt increase and thickening of the active layer, contributes positively to both blue and green water. Notably, despite upward trends in blue and green water, the green water coefficient declines, indicating a shift in the regional water resource structure. This transition may enhance basin water conservation capacity and temporarily increase downstream water supply, yet it could raise downstream flood risk and promote swamping of alpine meadows over longer horizons. The findings clarify mechanisms governing water cycle evolution on the Tibetan Plateau under concurrent environmental changes and provide a scientific basis for regional water resource management. © 2026 Elsevier Ltd

Implementation of automatic crack evaluation using Crack Fundamental Element

Item Type Conference Paper
Author Y.J. Tsai
Author C. Jiang
Author Z. Wang

Abstract Crack evaluation is a vital component in the pavement condition survey. However, researchers have had difficulty automatically mimicking the in-field evaluation practice to achieve a fully automated pavement crack evaluation due to the diversity of real-world crack patterns and the complexity of crack definitions in an agency's survey protocol. The multi-scale crack analysis model based on a Crack Fundamental Element is developed to topologically represent complex crack patterns and provide systematic crack properties to support crack classification. Utilizing this model, this study implements an automatic crack classification and quantification method for use on the state highways in Georgia, United States. Both image-based validation and field validation are conducted with the pavement experts from the Georgia Department of Transportation (GDOT) on State Route 236 in Atlanta, and the proposed method achieves a classification accuracy of 92.2% for load cracking and 98.1% for B/T cracking. © 2014 IEEE.

Implementing Real-Time Retail Shelf Monitoring via YOLOv8 on a ROS-Based Mobile Robot

Item Type Conference Paper

Author D.J. Hoong

Author Z.H. Azizul

Author J.H. Chia

Abstract Maintaining optimal shelf inventory and product availability is critical in the contemporary retail landscape to maximise sales and customer satisfaction. The demand for service robots is increasing, but few existing works have explored retail product detection, classification, and counting on a robotic platform. This paper presents an automated, real-time system for monitoring retail products. The primary goal is to detect, classify, and count retail products on shelves to streamline inventory management and minimise stockouts. This work utilised the YOLOv8 object detection model, selected for its superior balance of speed and accuracy, and trained it on the Freiburg Groceries Dataset. The system was implemented on a robot based on ROS. The model achieved a mean Average Precision (mAP50) of 88.3%, and completed detection within 3 seconds, showcasing a robust and scalable solution for automated retail product management. © 2025 IEEE.

Importance Weight Estimation and Generalization in Domain Adaptation under Label Shift

Item Type Journal Article

Author K. Azizzadenesheli

Abstract We study generalization under labeled shift for categorical and general normed label spaces. We propose a series of methods to estimate the importance weights from labeled source to unlabeled target domain and provide confidence bounds for these estimators. We deploy these estimators and provide generalization bounds in the unlabeled target domain. © 1979-2012 IEEE.

Improved approach to robust speech recognition using minimum error classification

Item Type Journal Article

Author M.-T. Lin

Author A. Spanias

Author P. Loizou

Abstract An effective way of applying minimum error classification (MEC) to improve robustness in speech recognition is presented in this paper. In contrast to the traditional maximum likelihood (ML) training procedure that attempts to maximize the a priori probability of generating the training data set, MEC training attempts to minimize a function of the recognition error on the given training data set. In the MEC training procedure, the N-best algorithm is used to maximize the separation between the correct and competing models over confusable training tokens. The main focus of this paper is to investigate the effectiveness of MEC training when combined with four existing speech recognition algorithms under noisy and telephone mismatched environments. These algorithms are the weighted projection measure (WPM), the minimax approach (MA), the cepstral mean subtraction (CMS) method and the stochastic matching algorithms (SMAs). Experiments were performed using the Texas Instruments isolated digits database and the E-set words from the OGI Spelled and Spoken Telephone Corpus. The average word error rate reduction due to MEC training was 22.5% for isolated digit recognition and 8% for E-set word recognition.

Improved Balanced Classification with Theoretically Grounded Loss Functions

Item Type	Conference Paper
Author	C. Cortes
Author	M. Mohri
Author	Y. Zhong
Abstract	The balanced loss is a widely adopted objective for multi-class classification under class imbalance. By assigning equal importance to all classes, regardless of their frequency, it promotes fairness and ensures that minority classes are not overlooked. However, directly minimizing the balanced classification loss is typically intractable, which makes the design of effective surrogate losses a central question. This paper introduces and studies two advanced surrogate loss families: Generalized Logit-Adjusted (GLA) loss functions and Generalized Class-Aware weighted (GCA) losses. GLA losses generalize Logit-Adjusted losses, which shift logits based on class priors, to the broader general cross-entropy loss family. GCA loss functions extend the standard class-weighted losses, which scale losses inversely by class frequency, by incorporating class-dependent confidence margins and extending them to the general cross-entropy family. We present a comprehensive theoretical analysis of consistency for both loss families. We show that GLA losses are Bayes-consistent, but only H-consistent for complete (i.e., unbounded) hypothesis sets. Moreover, their H-consistency bounds depend inversely on the minimum class probability, scaling at least as $1/p_{\min}$. In contrast, GCA losses are H-consistent for any hypothesis set that is bounded or complete, with H-consistency bounds that scale more favorably as $1/\sqrt{p_{\min}}$, offering significantly stronger theoretical guarantees in imbalanced settings. We report the results of experiments demonstrating that, empirically, both the GCA losses with calibrated class-dependent confidence margins and GLA losses can greatly outperform straightforward class-weighted losses as well as the LA losses. GLA generally performs slightly better in common benchmarks, whereas GCA exhibits a slight edge in highly imbalanced settings. Thus, we advocate for both GLA and GCA losses as principled, theoretically sound, and state-of-the-art surrogates for balanced classification under class imbalance. © 2025 Neural information processing systems foundation. Improved classification of Landsat Thematic Mapper data using modified prior probabilities in large and complex landscapes

Item Type Journal Article

Author L. Pedroni

Abstract The use of modified prior probabilities to exploit ancillary data and increase classification accuracy has been proposed before. However, this method has not been widely applied because it has heavy computing requirements and because obtaining prior probability estimates has presented practical problems. This article presents a procedure that generates large sets of prior probability estimates from class frequencies modelled with ancillary data and a Mahalanobis Distance selection of previously classified pixels. The method produces a pixel sample size that is large enough to estimate class frequencies in numerous strata, which is particularly desirable for the study of large and complex landscapes. A case study is presented in which the procedure made it possible to estimate 537 sets of prior probabilities for an entire Landsat Thematic Mapper (TM) scene of central Costa Rica. After modifying the class prior probabilities, the overall classification consistency of the training sites improved from 74.6% to 91.9%, while the overall classification accuracy of sites controlled in the field by independent studies improved from 68.7% to 89.0%. The classification accuracy was most improved for spectrally similar classes. The method improves classification accuracy in large and complex landscapes with spectrally mixed land-cover categories.

Improved modulation classification using a factor-graph-based iterative receiver

Item Type Conference Paper**Author** D. Jakubisin**Author** R.M. Buehrer

Abstract We bring together two research topics which have been the focus of significant research individually: modulation classification and iterative receiver design. In this work, these topics are joined within the framework of factor graphs which provide a unified approach to representing a variety of algorithms, especially iterative algorithms. Specifically, in this paper we present a factor graph which incorporates modulation classification into the iterative receiver structure. The proposed iterative receiver applies message passing on the factor graph to approximate the optimal solution to joint modulation classification, demodulation, and decoding. This results in a classifier which treats feedback from the decoder as a priori probabilities for the coded bits. We show that the proposed receiver is able to achieve significant performance gains over a receiver which performs maximum likelihood classification separately from demodulation and decoding. © 2012 IEEE.

Improved nearest centroid classifier with shrunken distance measure for null LDA method on cancer classification problem

Item Type Journal Article

Author A. Sharma

Author K.K. Paliwal

Abstract Null linear discriminant analysis (LDA) is a well-known dimensionality reduction technique for the small sample size problem. When the null LDA technique projects the samples to a lower dimensional space, the covariance matrices of individual classes become zero, i.e. all the projected vectors of a given class merge into a single vector. In this case, only the nearest centroid classifier (NCC) can be applied for classification. To improve the classification performance of NCC in the reduced-dimensional space, a shrunken distance based NCC technique is proposed that uses class-conditional a priori probabilities for distance computation. Experiments on several DNA microarray gene expression datasets using the proposed technique show very encouraging results for cancer classification. © 2010 The Institution of Engineering and Technology.

Abstract Purpose: The analysis of the [11C]PiB-PET amyloid images of a unique Asian cohort of 186 participants featuring overlapping vascular diseases raised the question about the validity of current standards for amyloid quantification under abnormal conditions. In this work, we implemented a novel pipeline for improved amyloid PET quantification of this atypical cohort. Methods: The investigated data correction and amyloid quantification methods included motion correction, standardized uptake value ratio (SUVR) quantification using the parcellated MRI (standard method) and SUVR quantification without MRI. We introduced a novel amyloid analysis method yielding 2 biomarkers: A β L which quantifies the global A β burden and ns that characterizes the non-specific uptake. Cut-off points were first determined using visual assessment as ground truth and then using unsupervised classification techniques. Results: Subject's motion impacts the accuracy of the measurement outcome but has however a limited effect on the visual rating and cut-off point determination. SUVR computation can be reliably performed for all the subjects without MRI parcellation while, when required, the parcellation failed or was of mediocre quality in 10% of the cases. The novel biomarker A β L showed an association increase of 29.5% with the cognitive tests and increased effect size between positive and negative scans compared with SUVR. ns was found sensitive to cerebral microbleeds, white matter hyperintensity, volume, and age. The cut-off points for SUVR using parcellated MRI, SUVR without parcellation, and A β L were 1.56, 1.39, and 25.5. Finally, k-means produced valid cut-off points without the requirement of visual assessment. Conclusion: The optimal processing for the amyloid quantification of this atypical cohort allows the quantification of all the subjects, producing SUVR values and two novel biomarkers: A β L, showing important increased in their association with various cognitive tests, and ns, a parameter sensitive to non-specific retention variations caused by age and cerebrovascular diseases. © 2019, Springer-Verlag GmbH Germany, part of Springer Nature.

Improved white blood cells classification based on pre-trained deep learning models

Item Type Journal Article

Author E.H. Mohamed

Author W.H. El-Behaidy

Author G. Khoriba

Author J. Li

Abstract Leukocytes, or white blood cells (WBCs), are microscopic organisms that fight against infectious disease, bacteria, viruses and others. The manual method to classify and count WBCs is tedious, time-consuming and may have inaccurate results, whereas the automated methods are costly. This research aims to automatically identify and classify WBCs in a microscopic image into four types with higher accuracy. BCCD is the used dataset in this study, which is a scaled-down blood cell detection dataset. BCCD is firstly preprocessed by passing through various processes such as segmentation and augmentation; then, it is passed to the proposed model. Our model combines the advantage of deep models in automatically extracting features with the higher classification accuracy of traditional machine learning classifiers. The proposed model consists of two main stages: a shallow tuning pre-trained model and

a traditional machine learning classifier on top of it. In this study, ten different pre-trained models with six types of machine learning are used. Moreover, the fully connected network (FCN) of pre-trained models is used as a baseline classifier for comparison. The evaluation process shows that the hybrid of MobileNet-224 as a feature extractor and logistic regression as classifier has a higher rank-1 accuracy of 97.03%. Besides, the proposed hybrid model outperformed the baseline FCN by 25.78% on average. © 2020 CCIS

Author L. Zhang

Author Z. Zhang

Author Z. Leng

Author Y. Su

Abstract With the explosive development of the Internet of things technology, IOT technology is used in agricultural production. Wireless sensor network(WSN) is a universal form of agricultural Internet of Things. It realizes fixed-point acquisition of data and storage of data. However, when it is applied to soil moisture monitoring, its sensor is easily damaged, resulting in incomplete data collection. In the presence of these problems, this paper put forward a kind solution of mobile sensing platform combined with cloud platform. The sensor, smart car, GPRS module, and cloud platform constitute a vegetable greenhouse environmental information cloud platform system. The system can realize environmental information monitoring in vegetable greenhouses. The sensor and smart car are used to build up mobile sensing platform. The GPRS module is responsible for transmitting the soil data to the cloud service platform through network transmission. The cloud service platform can receive data and store, classify, and count data. © 2018 IEEE.

Improving 18F-FDG PET Quantification Through a Spatial Normalization Method

Item Type Journal Article

Author D. Kim

Author S.K. Kang

Author S.A. Shin

Author H. Choi

Author J.S. Lee

Abstract Quantification of 18F-FDG PET images is useful for accurate diagnosis and evaluation of various brain diseases, including brain tumors, epilepsy, dementia, and Parkinson disease. However, accurate quantification of 18F-FDG PET images requires matched 3-dimensional T1 MRI scans of the same individuals to provide detailed information on brain anatomy. In this paper, we propose a transfer learning approach to adapt a pretrained deep neural network model from amyloid PET to spatially normalize 18F-FDG PET images without the need for 3-dimensional MRI. **Methods:** The proposed method is based on a deep learning model for automatic spatial normalization of 18F-FDG brain PET images, which was developed by fine-tuning a pretrained model for amyloid PET using only 103 18F-FDG PET and MR images. After training, the algorithm was tested on 65 internal and 78 external test sets. All T1 MR images with a 1-mm isotropic voxel size were processed with FreeSurfer software to provide cortical segmentation maps used to extract a ground-truth regional SUV ratio using cerebellar gray matter as a reference region. These values were compared with those from spatial normalization-based quantification methods using the proposed method and statistical parametric mapping software. **Results:** The proposed method showed superior spatial normalization compared with statistical parametric mapping, as evidenced by increased normalized mutual information and better size and shape matching in PET images. Quantitative evaluation revealed a consistently higher SUV ratio correlation and intraclass correlation coefficients for the proposed method across various brain regions in both internal and external datasets. The remarkably good correlation and intraclass correlation coefficient values of the proposed method for the external dataset are noteworthy, considering the dataset's different ethnic distribution and the use of different PET scanners and image reconstruction algorithms. **Conclusion:** This study successfully applied transfer learning to a deep neural network for 18F-FDG PET spatial normalization, demonstrating its resource efficiency and improved performance. This highlights the efficacy of transfer learning, which requires a smaller number of datasets than does the original network training, thus increasing the potential for broader use of deep learning-based brain PET spatial normalization techniques for various clinical and research radiotracers. Improving classification under changes in class and within-class distributions

Item Type Conference Paper

Author R. Alaiz-Rodríguez

Author A. Guerrero-Curieses

Author J. Cid-Sueiro

Abstract The fundamental assumption that training and operational data come from the same probability distribution, which is the basis of most learning algorithms, is often not satisfied in practice. Several algorithms have been proposed to cope with classification problems where the class priors may change after training, but they can show a poor performance when the class conditional data densities also change. In this paper, we propose a re-estimation algorithm that makes use of unlabeled operational data to adapt the classifier behavior to changing scenarios.

We assume that (a) the classes may be decomposed in several (unknown) subclasses, and (b) the prior subclass probabilities may change after training. Experimental results with practical applications show an improvement over an adaptive method based on class priors, while preserving a similar performance when there are no subclass changes. © 2009 Springer Berlin Heidelberg.

Improving CNN classifiers by estimating test-time priors

Item Type Conference Paper

Author M. Sulc

Author J. Matas

Abstract The problem of different training and test set class priors is addressed in the context of CNN classifiers. We compare two approaches to the estimation of the unknown test priors: an existing Maximum Likelihood Estimation (MLE) method

and a proposed Maximum a Posteriori (MAP) approach introducing a Dirichlet hyper-prior on the class prior probabilities. Experimental results show a significant improvement in the fine-grained classification tasks using known evaluation-time priors, increasing top-1 accuracy by 4.0% on the FGVC iNaturalist 2018 validation set and by 3.9% on the FGVCx Fungi 2018 validation set. Estimation of the unknown test set priors noticeably increases the accuracy on the PlantCLEF dataset, allowing a single CNN model to achieve state-of-the-art results and to outperform the competition-winning ensemble of 12 CNNs. The proposed MAP estimation increases the prediction accuracy by 2.8% on PlantCLEF 2017 and by 1.8% on FGVCx Fungi, where the MLE method decreases accuracy. © 2019 IEEE.

Improving imbalance classification via ensemble learning based on two-stage learning

Item Type Journal Article

Author N. Liu

Author J. Wang

Author Y. Zhu

Author L. Wan

Author Q. Li

Abstract The excellent performance of deep neural networks on image classification tasks depends on a large-scale high-quality dataset. However, the datasets collected from the real world are typically biased in their distribution, which will lead to a sharp decline in model performance, mainly because an imbalanced distribution results in the prior shift and covariate shift. Recent studies have typically used a two-stage learning method consisting of two rebalancing strategies to solve these problems, but the combination of partial rebalancing strategies will damage the representational ability of the networks. In addition, the two-stage learning method is of little help in addressing the problem of covariate shift. To solve the above two issues, we first propose a sample logit-aware reweighting method called (SLA), which can not only repair the weights of majority class hard samples and minority class samples but will also integrate with logit adjustment to form a stable two-stage learning strategy. Second, to solve the covariate shift problem, inspired by ensemble learning, we propose a multi-domain expert specialization model, which can achieve a more comprehensive decision by averaging expert classification results from multiple different domains. Finally, we combine SLA and logit adjustment into a two-stage learning method and apply our model to the CIFAR-LT and ImageNet-LT datasets. Compared with the most advanced methods, our experimental results show excellent performance. Copyright © 2024 Liu, Wang, Zhu, Wan and Li.

Improving Reliability of Seismic Stratigraphy Prediction: Integration of Uncertainty Quantification in Attention Mechanism Neural Network

Item Type Conference Paper

Author C.T. Ang

Author A.H. Elsheikh

Abstract Despite technological advancement, subsurface studies continue to encounter uncertainties caused by structural complexities and data noise, which can result in inaccurate seismic interpretation and drilling locations. Although machine learning holds great potential by enabling the simultaneous analysis of large datasets, its effectiveness is often compromised by data noise and ambiguity, which can degrade the accuracy of the algorithms. Hence, this research incorporates uncertainty quantification into attention mechanism neural network to produce more reliable outcomes in seismic interpretation and stratigraphic mapping. The methodology is also benchmarked against other uncertainty quantification methods such as dropout and randomized ensemble techniques, followed by an evaluation using the Brier score. Improving System Utilization on Wireless HPC Systems with Torus Interconnects

Item Type Conference Paper**Author** K. Li**Author** Y. Qiu**Author** C. Jiang**Author** M. Malawski**Author** J. Nabrzyski

Abstract Recent advances in wireless technologies promote the concept of wireless HPC systems, in which the wired cable interconnect in a conventional HPC system is augmented with wireless links to configure the system for desired interconnection topology. In this paper, we study the problem of improving system utilization and job scheduling efficiency on HPC systems with torus interconnects. First, we design and analyze a novel wireless HPC system to improve system utilization, avoid inter-job communication interference, and achieve efficient job scheduling. Second, we present a topology-Aware job scheduling algorithm, which is applicable to both of our proposed wireless HPC system and a conventional 3D torus HPC system. Third, the simulation results validate the efficiency of our proposed wireless HPC system in improving system utilization. At last, we apply machine learning to quantify the impact of job arrival rate and the number of backfilling jobs on the system utilization of HPC systems with torus interconnects. © 2020 IEEE.

Improving the Output Quality of Official Statistics Based on Machine Learning Algorithms

Item Type Journal Article

Author Q.A. Meertens

Author C.G.H. Diks

Author H.J. Van Den Herik

Author F.W. Takes

Abstract National statistical institutes currently investigate how to improve the output quality of official statistics based on machine learning algorithms. A key issue is concept drift, that is, when the joint distribution of independent variables and a dependent (categorical) variable changes over time. Under concept drift, a statistical model requires regular updating to prevent it from becoming biased. However, updating a model asks for additional data, which are not always available. An alternative is to reduce the bias by means of bias correction methods. In the article, we focus on estimating the proportion (base rate) of a category of interest and we compare two popular bias correction methods: the misclassification estimator and the calibration estimator. For prior probability shift (a specific type of concept drift), we investigate the two methods analytically as well as numerically. Our analytical results are expressions for the bias and variance of both methods. As numerical result, we present a decision boundary for the relative performance of the two methods. Our results provide a better understanding of the effect of prior probability shift on output quality. Consequently, we may recommend a novel approach on how to use machine

learning algorithms in the context of official statistics. © 2022 Q.A. Meertens et al., published by Sciendo.

Improving the performance of association classifiers by class prioritization

Item Type Journal Article

Author C. Chen

Author D. Chiang

Author C. Chen

Abstract Although different associative classification algorithms have been proposed, as pointed out by [8], none of the available associative algorithm considers the rule dependence problem that will directly influence the classification accuracy of the associative classifier. Since finding the optimal execution order of class association rules (CARs) is a combinational problem, in this paper, instead of finding the optimal execution order of CARs, we propose a polynomial time algorithm to re-rank the execution order of CARs by class priority to reduce the influence of the rule dependency problem. Consequently, the performance (the classification accuracy and recall rate) of the associative classification algorithm can be improved. The experimental results show that the association classifier with our method can get better classification result than that of the association classifier without considering the rule dependence problem. © 2011 by Binary Information Press.

Improving the Performance of the Feature Drift Detector by Lasso Observation of Sample Feature Fluctuations

Item Type Journal Article

Author P. Porwik

Author T. Orczyk

Author N. Japkowicz

Abstract Feature drift is a subtype of data distribution drift that occurs when the statistical significance of input features changes over time, despite the overall decision boundary remaining stable. This phenomenon can cause a subtle degradation in model accuracy in streaming environments. In this paper, we propose a new model-aware method called feature importance-driven drift detection (FIDD). Rather than relying on classification error signals, FIDD tracks changes in feature importance rankings obtained from LASSO regression across neighbouring data fragments. As it observes the dynamics of feature importance instead of global label shifts, this method is particularly suited to detecting subtle shifts in data distribution. Experimental evaluation on both synthetic and real-world data (including different types of drift, such as abrupt, gradual, incremental and recurrent) shows that FIDD achieves higher accuracy consistently and produces significantly fewer false alarms than standard drift detectors (e.g., DDM, EDDM and ADWIN). Furthermore, FIDD

is robust to labelling noise and computationally efficient, which makes it a practical and interpretable solution for adaptive learning in real-time applications. © 2025 Piotr Porwik et al., published by University of Zielona Góra.

Editor Holzinger A.

Editor Calma A.

Abstract Domain adaptation is a technique that tackles the dataset shift scenario, where the training (source) data and the test (target) data can come from different distributions. Current research works mainly focus on either the covariate shift or the label shift settings, each making a different assumption on how the source and target data are related. Nevertheless, we observe that neither of the settings can perfectly match the needs of a real-world bio-chemistry application. We carefully study the difficulties encountered by those settings on the application and propose a novel method that takes both settings into account to improve the performance on the application. The key idea of our proposed method is to select examples from the source data that are similar to the target distribution of interest. We further explore two selection schemes, the hard-selection scheme that plugs similarity into a nearest-neighbor style approach, and the soft-selection scheme that enforces similarity by soft constraints. Experiments demonstrate that our proposed method not only achieves better accuracy for the bio-chemistry application but also shows promising performance on other domain adaptation tasks when the similarity can be concretely defined. © 2020 for this paper by its authors. In Situ Sequencing: A High-Throughput, Multi-Targeted Gene Expression Profiling Technique for Cell Typing in Tissue Sections

Item Type Journal Article

Author M.M. Hilscher

Author D. Gyllborg

Author C. Yokota

Author M. Nilsson

Abstract Recent advances of image-based in situ mRNA quantification methods allow to visualize where in a tissue section a set of genes is expressed. It enables to map large numbers of genes in parallel and by capturing cellular boundaries allows to assign genes to cells. Here, we present a high-throughput, multi-targeted gene expression profiling technique called in situ sequencing that is capable of localizing hundreds of genes simultaneously and supports cell type classifications that follow transcriptome-based taxonomy. In situ sequencing is a targeted, amplified, and barcoded approach using padlock probes (PLPs) and rolling circle amplification (RCA). The current protocol relies on mRNA fixation, mRNA reverse transcription, residual mRNA degradation, and PLP hybridization. PLPs are amplified by RCA and labeled with fluorophore-conjugated probes, allowing their detection under conventional fluorescence microscopes. © 2020, Springer Science+Business Media, LLC, part of Springer Nature.

In vitro cell migration quantification method for scratch assays

Item Type Journal Article**Author** A.V.P. Bobadilla**Author** J. Arévalo**Author** E. Sarró**Author** H.M. Byrne**Author** P.K. Maini**Author** T. Carraro**Author** S. Balocco**Author** A. Meseguer**Author** T. Alarcón

Abstract The scratch assay is an in vitro technique used to assess the contribution of molecular and cellular mechanisms to cell migration. The assay can also be used to evaluate therapeutic compounds before clinical use. Current quantification methods of scratch assays deal poorly with irregular cell-free areas and crooked leading edges which are features typically present in the experimental data. We introduce a new migration quantification method, called 'monolayer edge velocimetry', that permits analysis of low-quality experimental data and better statistical classification of migration rates than standard quantification methods. The new method relies on quantifying the horizontal component of the cell monolayer velocity across the leading edge. By performing a classification test on in silico data, we show that the method exhibits significantly lower statistical errors than standard methods. When applied to in vitro data, our method outperforms standard methods by detecting differences in the migration rates between different cell groups that the other methods could not detect. Application of this new method will enable quantification of migration rates from in vitro scratch assay data that cannot be analysed using existing methods. © 2019 The Author(s) Published by the Royal Society. Abstract The proposed study is based on the hybrid framework, which is a convergence between machine learning algorithms and fuzzy decision-making techniques to determine and rank the most important factors regarding the Green Supply Chain Management (GSCM) within the offshore industry under the influence of climate change. The research follows a three-phase methodology: (1) systematic literature review and expert consultation to establish the dimensions of relevancy in GSCM (2) hybrid fuzzy Delphi machine learning to quantify uncertainty and elicit expert opinion (3) an Analytic Network Process to establish interdependency and global priorities. The framework was applied to Saudi Arabia's Arabian Gulf offshore sector, where four primary GSCM dimensions and twelve operational indicators were validated with expert consensus levels between 0.82 and 0.93. Results show that climate change adaptation mechanisms represent the most influential dimension (global weight = 0.334), while Climate Risk Assessment Protocols rank as the top indicator (0.127). The hybrid model got an accuracy of 0.863 which was 34.4 percent higher than the traditional methods in predicting disruption and 44.3 percent in risk assessment accuracy. Three offshore validation indicated performance improvement

of 11 to 25. These results have shown that the process of combining machine learning and fuzzy logic makes GSCM decision-making much more effective, providing a pragmatic and climate-adaptive architecture to make offshore operations more sustainable and resilient. © 2026 University of Novi Sad. Incomplete Multi-View Learning Under Label Shift

Item Type Journal Article

Author R. Fan

Author X. Ouyang

Author T. Luo

Author D. Hu

Author C. Hou

Abstract In image processing, images are usually composed of partial views due to the uncertainty of collection and how to efficiently process these images, which is called incomplete multi-view learning, has attracted widespread attention. The incompleteness and diversity of multi-view data enlarges the difficulty of annotation, resulting in the divergence of label distribution between the training and testing data, named as label shift. However, existing incomplete multi-view methods generally

assume that the label distribution is consistent and rarely consider the label shift scenario. To address this new but important challenge, we propose a novel framework termed as Incomplete Multi-view Learning under Label Shift (IMLLS). In this framework, we first give the formal definitions of IMLLS and the bidirectional complete representation which describes the intrinsic and common structure. Then, a multilayer perceptron which combines the reconstruction and classification loss is employed to learn the latent representation, whose existence, consistency and universality are proved with the theoretical satisfaction of label shift assumption. After that, to align the label distribution, the learned representation and trained source classifier are used to estimate the importance weight by designing a new estimation scheme which balances the error generated by finite samples in theory. Finally, the trained classifier reweighted by the estimated weight is fine-tuned to reduce the gap between the source and target representations. Extensive experimental results validate the effectiveness of our algorithm over existing state-of-the-arts methods in various aspects, together with its effectiveness in discriminating schizophrenic patients from healthy controls. © 1992-2012 IEEE.

Increased chloroplast occupancy in bundle sheath cells of rice hap3H mutants revealed by Chloro-Count: a new deep learning-based tool

Abstract There is an increasing demand to boost photosynthesis in rice to increase yield potential. Chloroplasts are the site of photosynthesis, and increasing their number and size is a potential route to elevate photosynthetic activity. Notably, bundle sheath cells do not make a significant contribution to overall carbon fixation in rice, and thus, various attempts are being made to increase chloroplast content specifically in this cell type. In this study, we developed and applied a deep learning tool, Chloro-Count, and used it to quantify chloroplast dimensions in bundle sheath cells of OsHAP3H gain- and loss-of-function mutants in rice. Loss of OsHAP3H increased chloroplast occupancy in bundle sheath cells by 50%. When grown in the field, mutants exhibited increased numbers of tillers and panicles. The implementation of Chloro-Count enabled precise quantification of chloroplasts in loss- and gain-of-function OsHAP3H mutants and facilitated a comparison between 2D and 3D quantification methods. Collectively, our observations revealed that a mechanism operates in bundle sheath cells to restrict chloroplast occupancy as cell dimensions increase. That mechanism is unperturbed in Oshap3H mutants but loss of OsHAP3H function leads to an increase in chloroplast numbers. The use of Chloro-Count also revealed that 2D quantification is compromised by the positioning of chloroplasts within the cell. © 2024 The Author(s). Inductive Conformal Prediction for Harvest-Readiness Classification of Cauliflower Plants: A Comparative Study of Uncertainty Quantification Methods

Item Type Conference Paper

Author M. Farag

Author J. Kierdorf

Author R. Roscher

Abstract Quantifying the uncertainty of machine learning models is a promising way to make better-informed decisions in digital agriculture. Efforts have been made to address this, ranging from understanding and segregating sources of uncertainty to utilizing diverse approaches for quantifying the cumulative amount. However, in order to fully realize the potential of uncertainty quantification in digital agriculture, more research is needed to compare and contrast different methods and determine which are most effective in different contexts. In this paper, we investigate inductive conformal prediction as another family of machine learning methods besides the commonly used softmax outputs and Monte Carlo dropout. Inductive conformal prediction constructs valid prediction sets by selecting a pre-defined level of predictive confidence in the system. In our experiments, we

analyze this method for an image-based harvest-readiness classification task of cauliflower plants, and compare the results to softmax outputs and uncertainties derived from Monte Carlo dropout. Inductive conformal prediction turns out as a complementary tool offering distinct advantages and providing another level of information for decision support. © 2023 IEEE.

Inductive transfer learning for unlabeled target-domain via hybrid regularization

Item Type Journal Article

Author F. Zhuang

Author P. Luo

Author Q. He

Author Z. Shi

Abstract Recent years have witnessed an increasing interest in transfer learning. This paper deals with the classification problem that the target-domain with a different distribution from the source-domain is totally unlabeled, and aims to build an inductive model for unseen data. Firstly, we analyze the problem of class ratio drift in the previous work of transductive transfer learning, and propose to use a normalization method to move towards the desired class ratio. Furthermore, we develop a hybrid regularization framework for inductive transfer learning. It considers three factors, including the distribution geometry of the target-domain by manifold regularization, the entropy value of prediction probability by entropy regularization, and the class prior by expectation regularization. This framework is used to adapt the inductive model learnt from the source-domain to the target-domain. Finally, the experiments on the real-world text data show the effectiveness of our inductive method of transfer learning. Meanwhile, it can handle unseen test points. © 2009 Science in China Press and Springer-Verlag GmbH.

Abstract Objective: To develop a novel algorithm for tracking acute mental stress which can infer acute mental stress state from multi-modal digital signatures of physiological parameters compatible with wearable-enabled sensing. Methods: We derived prominent digital signatures of physiological responses to mental stress using cross-integration of multi-modal physiological signals including the electrocardiogram (ECG), photoplethysmogram (PPG), seismocardiogram (SCG), ballistocardiogram (BCG), electrodermal activity (EDA), and respiratory effort. Then, we developed an algorithm for tracking acute mental stress that can continuously classify stress vs no stress states by computing an aggregated likelihood computed with respect to a priori probability density distributions associated with the digital signatures of mental stress under stress and no stress states. Results: Our algorithm could adequately infer mental stress state (average classification accuracy: 0.85, sensitivity: 0.85, specificity: 0.86) using a small number of prominent digital signatures derived from cross-integration of multi-modal physiological signals. The digital signatures in our work significantly outperformed the digital signatures employed in the state-of-the-art in tracking acute mental stress. Its exploitation of collective inference allowed for improved inference of mental stress state relative to naïve data mining techniques. Conclusion: Our algorithm for tracking acute mental stress has the potential to make a leap in continuous, high-accuracy, and high-confidence inference of mental stress via convenient wearable-enabled physiological sensing. Significance: The ability to continuously monitor and track mental stress can collectively improve human wellbeing. © 2024 Nalecz Institute of Biocybernetics and Biomedical Engineering of the Polish Academy of Sciences

Abstract We propose selective debiasing - an inference-time safety mechanism designed to enhance the overall model quality in terms of prediction performance and fairness, especially in scenarios where retraining the model is impractical. The method draws inspiration from selective classification, where at inference time, predictions with low quality, as indicated by their uncertainty scores, are discarded. In our approach, we identify the potentially biased model predictions and, instead of discarding them, we remove bias from these predictions using LEACE - a post-processing debiasing method. To select problematic predictions, we propose a bias quantification approach based on KL divergence, which achieves better results than standard uncertainty quantification methods. Experiments on text classification datasets with encoder-based classification models demonstrate that selective debiasing helps to reduce the performance gap between post-processing methods and debiasing techniques from the at-training and pre-processing categories.¹ © 2025 Association for Computational Linguistics

Inferring insect feeding patterns from sugar profiles: a comparison of statistical methods

Abstract Investigations in nutritional ecology often require the identification of animal feeding patterns in natural conditions (what, where, and when do animals eat). Thus, methods are needed to trace not only individual resource uptake but also the relative use of different resources in a population or community. Recent biochemical developments allow predicting the use of sugar-rich resources from insects in the field. Individual feeding status (feeding history, food sources) is inferred by comparing insect sugar profiles with those of individuals fed on controlled diets. Individual assignments are then used to predict the relative consumption of different resources at the population or community level. As both steps may generate error, accurate prediction rules are needed. However, research from other domains (e.g., protein-marking studies) suggests that classical decision rules used for such tasks may sometimes induce bias. This study evaluated the performance of these rules and compared them to alternative methods on simulated, realistic datasets. It tested different methods for individual classification but also introduced methods for prevalence estimation, whose specific purpose is to estimate the relative frequency of different classes. Alternative methods substantially outperformed the traditional algorithms to predict insect individual feeding status and population class distribution (relative frequency of insects with different feeding status). This study provided a simple decision tool to choose a method according to dataset size, variance, and biochemical method used. Alternative methods should increase prediction confidence in future studies. Such approaches should easily be generalized to a wider range of systems. © 2020 The Royal Entomological Society

Abstract Reliable out-of-distribution (OOD) detection is important for safe deployment of deep learning models in fetal ultrasound amidst heterogeneous image characteristics and clinical settings. OOD detection relies on estimating a classification model's uncertainty, which should increase for OOD samples. While existing research has largely focused on uncertainty quantification methods, this work investigates the impact of the classification task itself. Through experiments with eight uncertainty quantification methods across four classification tasks on the same image dataset, we demonstrate that OOD detection performance significantly varies with the task, and that the best task depends on the defined ID-OOD criteria; specifically, whether the OOD sample is due to: i) an image characteristic shift or ii) an anatomical feature shift. Furthermore, we reveal that superior OOD detection does not guarantee optimal abstained prediction, underscoring the necessity to align task selection and uncertainty strategies with the specific downstream application in medical image analysis. Author J. Kamphues

Abstract The aim of the present study was to examine possible effects of a different protein supply on the presence of *Campylobacter* in excreta and caecal content of broiler chickens. Therefore, 220 one-day-old chickens were fed five different diets in the experimental period (day 8 onwards). In the control group (CON; n = 3 boxes), a soya bean-based industrially produced complete diet containing 5–10% whole wheat

and coccidiostats was fed, whereas in the remaining groups, four own-made complete diets with four protein sources and combinations (4×2 boxes; soya bean meal-based diet = SBM; rapeseed meal-containing diet = RSM; haemoglobin meal-containing diet = HGP; algae-containing diet = ALG) were offered. During the 6-week trial period, data concerning performance parameters, excreta and litter characteristics and microbiological analysis of excreta and caecal content at dissection were collected. The qualitative bacteriological investigation was based on the EN ISO 10272-1:2006, taken from the official collection of analysis methods in accordance with § 64 LFBG. For quantitative bacteriological tests, a 10-fold dilution series was made followed by culture-based quantification methods on approved selective media in duplicate. Comparing the results of the final dissection (day 44/45), nearly all samples of animals receiving the own-made complete diet were *Campylobacter* positive in the caecal content, whereas only seven of fifteen samples were positive in the CON group. With regard to the CFU in the caecal content, the counts of *Campylobacter* were significantly lower for animals fed the commercial diet (2.47 ± 3.06 vs. $7.36 \pm 0.66 \log_{10}$ CFU/g). When only the positive animals were evaluated, significant differences were also found between the CON group and the total of the other groups (5.30 ± 2.08 vs. $7.54 \pm 1.70 \log_{10}$ CFU/g). Although significant differences were seen in the results, no final recommendation can be given how to create a diet to reduce an infection with *Campylobacter*. Influence of iris color on corneal densitometry

Item Type Journal Article

Author A.R. Arizcuren

Author A. Consejo

Abstract Purpose: To determine whether iris pigmentation introduces a measurable bias in corneal densitometry (CD) values obtained via Scheimpflug imaging, and to develop an objective metric for iris color quantification. Methods: This observational study included 91 eyes from 47 healthy adults. CD was assessed as mean pixel intensity (MPI) from 25 Scheimpflug images per eye. Brightness artefacts from the iris were quantified using automated image processing. Iris color was objectively characterized from slit-lamp photographs using an objective single-value metric (IrisColor) derived from normalized CIELAB components. Associations among CD, iris brightness, and iris pigmentation were evaluated using Pearson correlation and linear mixed-effects models (LMMs). Results: CD correlated positively with iris brightness artefacts ($r = 0.47$, $\beta = 1.49$, $p < 0.001$), which in turn showed a strong negative correlation with IrisColor ($r = -0.83$, $\beta = -1.11$, $p < 0.001$). Lighter-colored irises (lower IrisColor values) exhibited statistically significantly higher CD values equivalent to a 6.6% relative overestimation. Groupwise comparisons confirmed that iris pigmentation significantly influences both CD and overall image brightness. Conclusion: Iris pigmentation induces a measurable bias in Scheimpflug-based CD estimates, primarily through increased brightness artefacts in light-colored eyes. The proposed IrisColor metric enables objective, continuous classification of iris color and could support future corrections for pigmentation-induced bias in CD-based diagnostics. © 2026 The Authors

Influence of missing values on artificial neural network performance

Item Type Conference Paper

Author C.M. Ennett

Author M. Frize

Author C.R. Walker

Abstract The problem of databases containing missing values is a common one in the medical environment. Researchers must find a way to incorporate the incomplete data into the data set to use those cases in their experiments. Artificial neural networks (ANNs) cannot interpret missing values, and when a database is highly skewed, ANNs have difficulty identifying the factors leading to a rare outcome. This study investigates the impact on ANN performance when predicting neonatal mortality of increasing the number of cases with missing values in the data sets. Although previous work using the Canadian Neonatal Intensive Care Unit (NICU) Network's database showed that the ANN could not correctly classify any patients who died when the missing values were replaced with normal or mean values, this problem did not arise as expected in this study. Instead, the ANN consistently performed better than the constant predictor (which classifies all cases as belonging to the outcome with the highest training set a priori probability) with a 0.6-1.3% improvement over the constant predictor. The sensitivity of the models ranged from 14.5-20.3% and the specificity ranged from 99.2-99.7%. These results indicate that nearly 1 in 5 babies who will eventually die are correctly classified by the ANN, and very few babies were incorrectly identified as patients who will die. These findings are important for patient care, counselling of parents and resource allocation. © 2001 IMIA. All right reserved.

INFLUENCE OF PRE-PROCESSING METHODS ON THE AUTOMATIC PRIORITY PREDICTION OF NATIVE-LANGUAGE END-USERS' MAINTENANCE REQUESTS THROUGH MACHINE LEARNING METHODS

Item Type Journal Article

Author M. D'Orazio

Author G. Bernardini

Author E. Di Giuseppe

Abstract Feedback and requests by occupants are relevant sources of data to improve building management, and building maintenance. Indeed, most predictable faults can be directly identified by occupants and communicated to facility managers through communications written in the end-users' native language. In this sense, natural language processing methods can support the request identification and attribution process if they are robust enough to extract useful information from these unstructured textual sources. Machine learning (ML) can support assessing and managing these data, especially in the case of many simultaneous communications. In this field, the application of pre-processing and ML methods to English-written databases has been widely provided, while efforts in other native languages are still

limited, impacting the real applicability. Moreover, the performance of combinations of methods for pre-processing, ML and classification classes attribution, has been limitedly investigated while comparing different languages. To fill this gap, this work hence explores the performance of automatic priority assignment of maintenance end-users' requests depending on the combined influence of: (a) different natural language pre-processing methods, (b) several supervised ML algorithms, (c) two priority classification rules (2-class versus 4-class), (d) the database language (i.e. the original database written in Italian, the native end-users' language; a translated database version in English, as standard reference). Analyses are performed on a database of about 12000 maintenance requests written in Italian concerning a stock of 23 buildings open to the public. A random sample of the sentences is supervised and labelled by 20 expert annotators following the best-worst method to attribute a priority score. Labelled sentences are then pre-processed using four different approaches to progressively reduce the number of unique words (potential predictors). Five different consolidated ML methods are applied, and comparisons involve accuracy, precision, recall and F1-score for each combination of pre-processing action, ML method and the number of priority classes. Results show that, within each ML algorithm, different pre-processing methods limitedly impact the final accuracy and average F1-score. In both Italian and English conditions, the best performance is obtained by NN, LR, SVM methods, while NB generally fails, and by considering the 2-class priority classification scale. In this sense, results confirm that facility managers can be effectively supported by ML methods for preliminary priority assessments in building maintenance processes, even when the requests database is written in end-users' native language. © 2024 The author(s).

Abstract Within contemporary tourism contexts, classical-garden spatial narratives have become decoupled from visitor behaviours, underscoring the need to elucidate mechanisms for engagement. This study investigates the Du Fu Thatched Cottage in Xishu Gardens as a case study, integrating panoramic imaging, semantic segmentation and machine learning to quantify five visual-spatial metrics: naturalness, commemorativeness, complexity, scale and colour. Visitor dwell time and visit frequency were recorded via a panoramic roaming platform. The results reveal that the spatiotemporal distributions of visual attributes and visitor dwell and movement behaviours synergistically align along the central axis. These distributions exhibit positive correlations, with commemorative element visibility and water-body coverage showing the strongest associations and manifesting multidimensional threshold effects within the commemorative dimension. By examining both dwell and movement behaviours, this study uncovers synergistic mechanisms underlying heritage-space interactions and offers actionable recommendations for the sustainable conservation and management of classical gardens. © The Author(s) 2025.

Information fusion strategy for aircraft engine health management

Item Type	Conference Paper
Author	L. Yu
Author	D. Cleary
Author	M. Osborn
Author	V. Rajiv
Abstract	Modern aircraft engines are equipped with sophisticated sensing instruments to enable proactive condition monitoring and effective health management capability. Development of intelligent systems that efficiently process sensor and operational data both onboard and off-board, to provide maintenance personnel with timely decision support, is the key to minimize flight service disruption and reduce engine ownership cost. The goal of this research is to develop a practical approach and strategy to leverage various available information sources and modeling techniques to streamline the engine health management process and maximize system accuracy and efficiency. This paper demonstrates a flexible fusion architecture that encapsulates the key elements of the engine monitoring and diagnostic process, i.e., sensor trend analysis module for anomaly detection, feature selection and fault isolation module for root cause identification, a decision module for diagnostic model fusion and action determination, and finally, a feedback module for knowledge validation and continuous learning. At the core of this engine health management system is a diagnostic fusion model designed around a common fault hierarchy which captures both a priori probabilities and interactions among various engine faults isolated by different classification models. The fusion model will resolve conflicting assessments from individual diagnostic models and provide a more accurate and comprehensive engine state estimate. Copyright © 2007 by ASME.

Information value of property description: A Machine learning approach

Item Type Journal Article

Author L. Shen

Author S. Ross

Abstract This paper employs machine learning to quantify the value of “soft” information contained in real estate property descriptions. Textual descriptions contain information that traditional hedonic attributes cannot capture. A one standard deviation increase in the uniqueness of a property based on this “soft” information leads to a 15% increase in property sale price in a hedonic price model and a 10% increase in a repeat sales price model. The effects in the hedonic model appear to arise through two channels: the unobserved quality of the housing unit, and the market power of the housing unit relative to competing properties. The effects in the repeat sales model appear to be driven entirely by the market power of the unit. Further, an annual hedonic price index ignoring our measure of unobserved quality overstates real estate prices by between 10% to 23% and mistimes the stabilization of housing prices following the Great Recession. Similar, but smaller effects, are observed for the repeat sales price index. © 2020 Elsevier Inc.

Information-theoretic representation learning for positive-unlabeled classification

Item Type Journal Article

Author T. Sakai

Author G. Niu

Author M. Sugiyama

Abstract Recent advances in weakly supervised classification allow us to train a classifier from only positive and unlabeled (PU) data. However, existing PU classification methods typically require an accurate estimate of the class-prior probability, a critical bottleneck particularly for high-dimensional data. This problem has been commonly addressed by applying principal component analysis in advance, but such unsupervised dimension reduction can collapse the underlying class structure. In this letter, we propose a novel representation learning method from PU data based on the information-maximization principle. Our method does not require class-prior estimation and thus can be used as a preprocessing method for PU classification. Through experiments, we demonstrate that our method, combined with deep neural networks, highly improves the accuracy of PU class-prior estimation, leading to state-of-the-art PU classification performance. © 2020 Massachusetts Institute of Technology.

Initial interpretation and evaluation of a profile-based classification system for the anxiety and mood disorders: Incremental validity compared to DSM-IV categories

Item Type Journal Article

Author A.J. Rosellini

Author T.A. Brown

Abstract Limitations in anxiety and mood disorder diagnostic reliability and validity due to the categorical approach to classification used by the Diagnostic and Statistical Manual of Mental Disorders (DSM) have been long recognized. Although these limitations have led researchers to forward alternative classification schemes, few have been empirically evaluated. In a sample of 1,218 outpatients with anxiety and mood disorders, the present study examined the validity of Brown and Barlow's (2009) proposal to classify the anxiety and mood disorders using an integrated dimensional-categorical approach based on transdiagnostic emotional disorder vulnerabilities and phenotypes. Latent class analyses of 7 transdiagnostic dimensional indicators suggested that a 6-class (i.e., profile) solution provided the best model fit and was the most conceptually interpretable. Interpretation of the classes was further supported when compared with DSM diagnoses (i.e., within-class prevalence of diagnoses, using diagnoses to predict class membership). In addition, hierarchical multiple regression models were used to demonstrate the incremental validity of the profiles; class probabilities consistently accounted for unique variance in anxiety and mood disorder outcomes above and beyond DSM diagnoses. These results provide support for the potential development and utility of a hybrid dimensional-categorical profile approach to anxiety and mood disorder classification. In particular, the availability of dimensional indicators and corresponding profiles may serve as a useful complement to DSM diagnoses for both researchers and clinicians. © 2014 American Psychological Association.

Insomnia-LCA classifier: an open web application for insomnia subtype classification using latent class analysis

Item Type Journal Article
Author M. Carpi
Author D.R. Marques
Abstract The heterogeneity of insomnia presentations has long challenged research and clinical practice, motivating efforts to identify reliable disorder phenotypes. Person-centered, data-driven approaches such as latent class analysis (LCA) have provided new insights, suggesting that insomnia subtypes may differ not only in nocturnal symptoms but also in perceived impact and daytime distress. Despite this progress, LCA solutions often remain confined to the original datasets, limiting replication and applied use. To address this gap, we developed the insomnia-LCA classifier , an

open-source web application that assigns new Insomnia Severity Index (ISI) response profiles to one of four subtypes identified in a previously published LCA of Italian university students: no insomnia (NI), subthreshold insomnia (SI), high insomnia risk (HI), and predominant daytime symptoms (DS). Using the original model's class priors and item-level conditional response probabilities, the app computes posterior class probabilities from user-entered ISI responses, individually or in batch mode. Outputs include class probabilities and modal assignment, ISI total and subscale scores, and a visual comparison between the individual profile and subtype mean patterns. Reclassification of the original dataset showed near-perfect agreement with the latent class model (accuracy = 0.999; Cohen's kappa = 0.999), and synthetic profiles behaved as expected. The insomnia-LCA classifier provides a practical, reproducible tool for deploying and testing LCA-derived phenotypes in clinical research. © 2026 The Authors.

InteBOMB: Integrating generic object tracking and segmentation with pose estimation for animal behavior analysis

Item Type Journal Article**Author** H. Zhai**Author** H.-Y. Yan**Author** J.-Y. Zhou**Author** J. Liu**Author** Q.-W. Xie**Author** L.-J. Shen**Author** X. Chen**Author** H. Han

Abstract Advancements in animal behavior quantification methods have driven the development of computational ethology, enabling fully automated behavior analysis. Existing multi-animal pose estimation workflows rely on tracking-by-detection frameworks for either bottom-up or top-down approaches, requiring retraining to accommodate diverse animal appearances. This study introduces InteBOMB, an integrated workflow that enhances top-down approaches by incorporating generic object tracking, eliminating the need for prior knowledge of target animals while maintaining broad generalizability. InteBOMB includes two key strategies for tracking and segmentation in laboratory environments and two techniques for pose estimation in natural settings. The “background enhancement” strategy optimizes foreground-background contrastive loss, generating more discriminative correlation maps. The “online proofreading” strategy stores human-in-the-loop long-term memory and dynamic short-term memory, enabling adaptive updates to object visual features. The “automated labeling suggestion” technique reuses the visual features saved during tracking to identify representative frames for training set labeling. Additionally, the “joint behavior analysis” technique integrates these features with multimodal data, expanding the latent space for behavior classification and clustering. To evaluate the framework, six datasets of mice and six datasets of nonhuman primates were compiled, covering laboratory and natural scenes. Benchmarking results demonstrated a 24% improvement in zero-shot generic tracking and a 21% enhancement in joint latent space performance across datasets, highlighting the effectiveness of this approach in robust, generalizable behavior analysis. Integrated machine learning approaches for flow cytometric quantification of myeloid-derived suppressor cells in acute sepsis

Item Type Journal Article

Author A.S. Bonavia

Author A. Samuelsen

Author J. Luthy

Author E.S. Halstead

Abstract Highly heterogeneous cell populations require multiple flow cytometric markers for appropriate phenotypic characterization. This exponentially increases the complexity of 2D scatter plot analyses and exacerbates human errors due to variations in manual gating of flow data. We describe a semi-automated workflow, based entirely on the Flowjo Graphical User Interface (GUI), that involves the stepwise integration of several, newly available machine learning tools for the analysis of myeloid-derived suppressor cells (MDSCs) in septic and non-septic critical illness. Supervised clustering of flow cytometric data showed correlation with, but significantly different numbers of, MDSCs as compared with the cell numbers obtained by manual gating. Neither quantification method predicted 30-day clinical outcomes in a cohort of 16 critically ill and septic patients and 5 critically ill and non-septic patients. Machine learning identified a significant decrease in the proportion of PMN-MDSC in critically ill and septic patients as compared with healthy controls. There was no difference between the proportion of these MDSCs in septic and non-septic critical illness. Copyright © 2022 Bonavia, Samuelsen, Luthy and Halstead.

Integrated Networks for Viscoelastic FWI: Mapping from Q to Relaxation Variables and Quantifying Modeling Error

Item Type Journal Article

Author T. Zhang

Author D. Trad

Author K. Innanen

Abstract In the conventional approach to viscoelastic full waveform inversion (FWI) utilizing the generalized standard linear solid (GSLs) model, the quality factor (Q) is usually not directly inverted. Instead, this method converts Q into a suite of relaxation variables before inversion. Consequently, viscoelastic FWI entails the inversion of both elastic and relaxation models, with a subsequent conversion of relaxation variables back to the Q model to obtain final results. This method is partially due to the accurate intricate relationship between Q values and relaxation variables, where the mapping functions between these two sets are not simple inverses of each other. We introduce an approach that incorporates a multilayer perceptron (MLP) that is pretrained to learn complex mapping from Q values to relaxation variables. This MLP is then seamlessly integrated into a recurrent neural network (RNN)-based

GSLS viscoelastic FWI framework, establishing a computational graph, linking Q models and elastic models to data discrepancies, facilitating the direct inversion of both Q and elastic models. To address the inherent uncertainty in the MLP's mapping process, we apply Monte Carlo (MC) dropout within the neural network, quantifying the uncertainty of converting Q values into relaxation variables. Assuming a constant Q model, this uncertainty quantification method highlights the limited ability of relaxation variables to represent a constant Q model precisely. The feasibility of adapting our method for frequency-variant Q values appears straightforward. We also explore how this limitation, essentially a modeling error, influences the accuracy of forward modeling data. Our numerical results reveal that this modeling error has apparent impacts on the inversion outcomes for both elastic and attenuation models, underscoring the critical nature of this error in the viscoelastic FWI processes. © 1980-2012 IEEE.

Integrating artificial intelligence into radiological practice for automated pneumonia assessment

Item Type Journal Article

Author S. Benlakhdar

Author M. Rziza

Author R. Oulad Haj Thami

Abstract Background: Accurate assessment of lung involvement in coronavirus disease 2019 (COVID-19) patients is crucial for clinical decision-making. Traditional semi-quantitative and manual methods, while commonly used, may lack objectivity and reproducibility. This study aims to evaluate the clinical utility of artificial intelligence (AI)-based automated quantification of lung lesions and compare its performance with conventional semi-quantitative and manual approaches. Methods: This retrospective cross-sectional study was conducted at CHU Ibn Sina in Rabat from March 17 to May 11, 2020, and included 106 patients diagnosed with COVID-19 pneumonia. All patients underwent chest computed tomography (CT) using Siemens Somatom Definition AS+ equipment. Lung involvement was assessed using three methods: semi-quantitative scoring (Q20 and Q24), manual visual estimation by radiologists, and AI-based automated quantification. Concordance between the methods was evaluated using Lin's concordance correlation coefficient. Analysis time for each method was compared using the Kruskal-Wallis test. Results: AI-based quantification showed strong agreement with the semi-quantitative method, with a Lin's concordance correlation coefficient of 0.9271 [95% confidence interval (CI): 0.8975-0.9484]. The average analysis time was 65±8 s for AI and 28±5 s for the semi-quantitative method (P<0.001). The agreement in lesion classification between radiologists and AI reached 88%, indicating the potential reliability of AI in supporting clinical interpretation. Conclusions: AI-based automated quantification methods demonstrate high concordance with conventional techniques and provide consistent, objective, and reproducible assessments of COVID-19-related lung damage. Although AI requires more time than semi-quantitative approaches, its accuracy and reliability suggest it could complement or even replace traditional methods in certain clinical settings. Further large-scale studies are recommended to confirm these findings and assess the long-term clinical utility of AI in radiological evaluation. © AME Publishing Company, Taiwan Society for Therapeutic Radiology and Oncology.

Integrating causal inference and machine learning to quantify climate-malaria relationships: Evidence of temperature and rainfall thresholds from Colombian municipalities

Item Type Journal Article

Author J.D. Gutiérrez

Abstract Rainfall and temperature are key climate determinants of malaria incidence; yet their causal exposure-response curves on malaria incidence across the entire Colombian territory remain unquantified. We estimated the effects of rainfall and temperature on malaria incidence at the municipal scale from 2007 to 2023. We conducted an ecological observational study in 969 Colombian municipalities located below 1,600 meters. The monthly Standardized Incidence Ratio (SIR) of malaria was calculated for each municipality. Directed acyclic graphs guided the identification of the appropriate adjustments needed to emulate the corresponding experimental design and avoid inducing bias, and the effect was estimated using a modified approach of the Targeted Maximum Likelihood Estimation (TMLE). Exposure-response curves were estimated for two outcomes: the current month and the moving average for the current and previous month. A total of 1,075,112 cases of malaria were reported. The results suggest a non-linear relationship between rainfall and temperature concerning the SIR of malaria, indicating an optimal temperature of 25 °C and approximately 37 mm of rainfall for the highest incidence. The negative control test revealed the presence of residual confounding bias ($p < 0.05$) in all estimates. Meanwhile, the estimations of the E-value indicated low to moderate tolerance (E-value = 1.14 - 1.48) to an unmeasured confounder. These findings support the integration of rainfall and temperature thresholds into early-warning systems for targeted malaria control. © 2026 Juan David Gutiérrez. Integrating InSAR and Channel Steepness for AI-Based Coseismic Landslide Modeling in the Nepal Himalaya

Item Type Journal Article

Author R. Silwal

Author G. Wang

Author S. KC

Author R. Rimal

Author S. Rawal

Abstract Earthquake-induced landslides in active orogens such as the Nepal Himalaya pose severe threats to lives, infrastructure, and post-disaster recovery. While machine learning (ML) and deep learning (DL) approaches to coseismic landslide susceptibility mapping have advanced considerably, spaceborne interferometric synthetic aperture radar (InSAR) products, particularly line-of-sight (LOS) displacement and coherence-based damage proxy maps (DPMs), remain underutilized in event-based frameworks. This study develops and evaluates a multi-factor coseismic landslide probability model that integrates InSAR-derived deformation metrics with geomorphic and hydrologic predictors to support rapid post-earthquake hazard assessment. Using the 25 April 2015 Mw 7.8 Gorkha earthquake as a case study, LOS displacement was derived from ALOS-2 PALSAR-2 ScanSAR interferometry, and the normalized channel steepness index (K_{sn}) was computed from a digital elevation model. Fourteen conditioning factors were used to train five architectures: Random Forest (RF), XGBoost, CNN, U-Net, and

DeepLabV3. Spatial autocorrelation was mitigated using a leave-one-basin-out three-fold spatial cross-validation strategy, with models evaluated on a patch-based domain comprising 655,360 pixels at a positive-class prevalence of 6.35%, establishing a no-skill AUC-PR baseline of 0.0635. InSAR integration consistently improved model performance under high class imbalance, increasing AUC-PR across all models by 7.8% to 17.3%. Random Forest achieved the highest AUC-PR (0.7940, nearly 12.5 times the baseline) and CSI (0.3027), providing the best balance between landslide recall (88.09%) and non-landslide specificity (88.68%) with the lowest false alarm rate (11.32%). XGBoost attained the highest AUC-ROC (0.9501) but exhibited lower recall (83.73%) and poorer calibration (Brier = 0.1397). Among DL models, DeepLabV3 produced the best-calibrated probabilities (Brier = 0.0693) and the highest CSI (0.2307), while U-Net offered the most balanced DL performance and CNN achieved the highest recall (92.40%) at the expense of elevated false alarms. Permutation feature importance identified Ksn as the dominant predictor, highlighting the strong tectono-geomorphic control on coseismic landslide occurrence. These results demonstrate that integrating InSAR-derived products substantially enhances landslide hazard assessment and supports more reliable rapid response in the Nepal Himalaya. © 2026 by the authors.

Abstract Purpose: Low-light stress poses a significant threat to global food security by impairing crop yield and grain quality. Therefore, investigating the impact of low-light stress on staple crops is imperative. Methods: In this study, we integrated meta-analysis (239 studies, 8019 observations) and machine learning to quantify the effects of low-light stress on crop yield and grain components across diverse environmental contexts. Results and conclusions: Our results demonstrated that low-light stress significantly reduced crop yield (CY: 54.13 %), thousand-grain weight (TGW: 11.38 %), grain number (GN: 29.70 %), and harvest index (HI: 26.70 %), while altering grain composition, including reduced starch content (SC: 7.40 %), starch yield (SY: 67.10 %), amylose content (AC: 6.53 %), amylopectin content (APC: 4.81 %), and protein yield (PY: 32.25 %), despite increasing protein content (PC: 11.72 %). Machine learning models identified crop type, low-light stage, degree, duration, climatic and soil conditions as key factors driving these responses. Under low-light stress, maize (cereal crops) exhibited the most severe reductions in CY, GN, and HI, while legume crops showed the greatest declines in PC and PY, and root and tuber crops experienced the largest decreases in SC and SY. The stage of low-light stress was the most critical factor influencing CY, TGW, GN, and HI, with the reproductive growth stage being the period when crops are most sensitive to low-light stress. Furthermore, the detrimental effects of low-light stress on crops aggravated with either increased degree or prolonged duration. With mean annual temperature (MAT) of 10–15°C or mean annual precipitation (MAP) of 400–800 mm, low-light stress caused the most pronounced reductions in CY, GN, and HI. When MAT > 15°C, the greatest reductions in SC, SY, AC, and PY were observed under low-light stress, with the highest increase in PC. Additionally, in sandy or neutral soils (pH 6.5–7.5), low-light stress exerted the most significant impacts on CY, GN, SC, and AC. Conversely, soils with high organic matter content (> 20 kg–1) help mitigate the negative effects of low-light stress on crops. Significance: These findings provide a scientific basis for designing targeted strategies to alleviate low-light stress and promoting sustainable agricultural production under changing climatic conditions. © 2025 Elsevier B.V.

Integrating mineral elements and metabolite features to distinguish Lotus seeds from different geographic origins

Item Type Journal Article**Author** H. Su**Author** Z. Li**Author** W. Yu**Author** T. Liu**Author** L. Luo

Abstract The characteristics of lotus seeds (LS) are influenced by variety and environment. However, it remains unknown the difference of metabolites and elements of LS from different origins. In this study, an accurate quantification method (97–107 %) for 20 mineral elements in LS was developed, and a metabolomic method was established to identify a total of 323 metabolites in LS. Mineral composition analysis revealed significant variations in the mineral element contents among LS samples from seven geographical regions. LS were rich in potassium (14,710 mg/kg), manganese (67.19 mg/kg), with a low level of sodium (210 mg/kg). A total of 10 mineral elements and 117 metabolites ($p < 0.05$ and $VIP > 1$) were identified as the potential geographical markers of LS by integration analysis. The linear discriminant analysis model showed high prediction accuracy. This study provides strong experimental evidence to maintain the authenticity and quality of LS in the food industry. © 2024 Elsevier Ltd

Abstract In this work, an adaptive-learning model predictive control (AL-MPC) framework that integrates disturbance forecasting, uncertainty quantification, learning, and recursive subspace identification is developed. The proposed technique can be used for continuous systems affected by repetitive disturbances with unknown periods. The AL-MPC integrates online learning from historical data to anticipate impending disturbances and proactively counteract their effects to an adaptive MPC. This is done by using machine learning to quantify the significant disturbances from historical data and forecast their future evolution time series. Behavior patterns of the system can be identified from historical data, and the set-point, objective function weights, and constraints of the controller can be modified in advance for the anticipated time periods of the disturbance effects. AL-MPC is used to regulate glucose concentration (GC) in people with diabetes by automated insulin delivery. Simulation results indicate that the AL-MPC can regulate the BGC 75.4% of the simulation time in the target range (70-180) mg/dL without causing any hypoglycemia and hyperglycemia events. © 2020 Elsevier B.V.. Author A. Ouallali

Abstract Land surface temperature (LST) is a key parameter for understanding thermal conditions in urban environments, where surface characteristics and anthropogenic activities strongly influence the intensity of the Urban Heat Island (UHI) phenomenon. Analysing the spatial and temporal variability of LST enables the assessment of how land-use and land-cover changes affect the local temperature distribution. This study proposes a machine-learning (ML) based framework for assessing the Surface Urban Heat Island (SUHI) effect in a medium-to-large city in Romania. Spectral indices derived from Landsat 8 imagery, including the Normalised Difference Vegetation Index (NDVI), Normalised Difference Built-up Index (NDBI), Normalised Difference Water Index (NDWI), Urban Index (UI), and Albedo, were integrated as explanatory variables. Non-parametric correlation analyses were applied to evaluate the relationships between these indices and LST. ML-derived LST estimates were validated against independent LST data from the Moderate Resolution Imaging Spectroradiometer (MODIS) instrument on the Terra satellite to assess model accuracy and robustness. The results indicate a significant increase in LST between 2013 and 2024, with an average warming of approximately 1.6 °C across the study area, largely driven by urban expansion and structural land-use changes. Among the evaluated models, the Random Forest algorithm achieved the highest predictive accuracy (RMSE $\approx$ 2.70 °C, MAPE $\approx$ 6.47%, $R^2 \approx$ 0.49), followed by Extreme Gradient Boosting (XGBoost) (RMSE $\approx$ 2.73 °C, MAPE $\approx$ 6.55%, $R^2 \approx$ 0.48) and the Support Vector Machine (SVM) (RMSE $\approx$ 2.79 °C, MAPE $\approx$ 6.78%, $R^2 \approx$ 0.45). Although all models successfully delineated the spatial patterns of SUHI, their ability to reproduce absolute LST values was limited, and some biases were observed in the estimation of thermal extremes. Overall, the findings demonstrate that integrating multi-source remote sensing data with ML techniques provides a reliable and effective approach for monitoring SUHI dynamics. © 2026 The Author(s)

Integrating uncertainty quantification and ML for network robustness study: From metrics to surfaces

Item Type Journal Article

Author F.A. Lucay

Author W. Palma

Abstract Network robustness, defined as a system's capacity to retain functionality under failures or attacks, is conventionally studied using synthetic models such as Erdős-Rényi (ER), Barabási-Albert (BA), and Holme-Kim (HK). However, model parameters are often chosen arbitrarily, neglecting their influence on robustness metrics. This study integrates forward uncertainty quantification and machine learning to quantify parameter impact on measures —natural connectivity (NC), global efficiency (GE), algebraic connectivity (AC), spectral radius (SR), average path length (APL), and effective graph conductance (C). We analyse how these metrics vary across model configurations by constructing response surfaces based on influential parameters. Some key findings reveal distinct parameter dominance: in ER models, the number of nodes (n) and edge probability (p) govern NC, AC, and SR, while p predominantly shapes GE, APL, and C. For BA models, n and attachment edges variably influence all metrics. In KH models, n and random edge additions drive all robustness metrics with minimal impact from triangle-formation probability. The derived robustness surfaces offer practical tools for network design: identifying critical vulnerability thresholds, optimising topologies and benchmarking architectures for resilience. Integrating weight with ensemble to handle changes in class distribution

Item Type Conference Paper

Author N. Limsetto

Author K. Waiyamai

Abstract Concept drift can be considered as a distribution mismatch problem where class distribution changes as a time passes. This problem is commonly found in classification task of data mining. Among the proposed solutions, the cost-based Class Distribution Estimation (CDE) shows the best performance in coping with difference in class distribution between train and test datasets. However there is still some problem, as CDE lost its performance when there is too much change in class distribution. In this paper, CDE-weight is proposed to reduce the impact of high change in class distribution. The idea is to use many models suitable with many class distributions along with dynamic weighting method that adjusts weight of each model according to its class distribution. Experimented results indicate that CDE-Weight methods are able to reduce the impact of misestimating and improve the classifier performance when train and test data are different. © 2014 Springer International Publishing Switzerland.

Intelligent Assistant Diagnosis System of Osteosarcoma MRI Image Based on Transformer and Convolution in Developing Countries

Item Type Journal Article**Author** Z. Ling**Author** S. Yang**Author** F. Gou**Author** Z. Dai**Author** J. Wu

Abstract Osteosarcoma is a malignant bone tumor commonly found in adolescents or children, with high incidence and poor prognosis. Magnetic resonance imaging (MRI), which is the more common diagnostic method for osteosarcoma, has a very large number of output images with sparse valid data and may not be easily observed due to brightness and contrast problems, which in turn makes manual diagnosis of osteosarcoma MRI images difficult and increases the rate of misdiagnosis. Current image segmentation models for osteosarcoma mostly focus on convolution, whose segmentation performance is limited due to the neglect of global features. In this paper, we propose an intelligent assisted diagnosis system for osteosarcoma, which can reduce the burden of doctors in diagnosing osteosarcoma from three aspects. First, we construct a classification-image enhancement module consisting of resnet18 and DeepUPE to remove redundant images and improve image clarity, which can facilitate doctors' observation. Then, we experimentally compare the performance of serial, parallel, and hybrid fusion transformer and convolution, and propose a Double U-shaped visual transformer with convolution (DUconViT) for automatic

segmentation of osteosarcoma to assist doctors' diagnosis. This experiment utilizes more than 80,000 osteosarcoma MRI images from three hospitals in China. The results show that DUconViT can better segment osteosarcoma with DSC 2.6% and 1.8% higher than Unet and Unet++, respectively. Finally, we propose the pixel point quantification method to calculate the area of osteosarcoma, which provides more reference basis for doctors' diagnosis. © 2013 IEEE.

Intelligent data analysis techniques—machine learning and data mining

Item Type Journal Article

Author D. Simovici

Abstract This introductory chapter presents some of the main paradigms of intelligent data analysis provided by machine learning and data mining. After discussing several types of learning (supervised, unsupervised, semi-supervised, active and reinforcement learning) we examine several classes of learning algorithms (naive Bayes classifiers, decision trees, support vector machines, and neural networks) and the modalities to evaluate their performance. Examples of specific applications of algorithms are given using System R. © Springer International Publishing Switzerland 2015.

Intelligent Quantification Method of Pipeline Flow Based on 'YOLO v5-FCN-AdaBoost'

Item Type Conference Paper

Author H. Yu

Author D. Di

Author J. Shi

Abstract The quantification of underground drainage pipeline flow is an important component of urban flood warning. In response to the high error rate and instability of current flow measurement devices, poor measurement accuracy, and the inability to accurately measure in complex drainage pipeline environments with confined spaces, strong corrosion, and low visibility, we have proposed, for the first time, an improved YOLO v5 algorithm, an Fully Convolutional Networks(FCN) algorithm based on dynamic pixel weighting strategy, and an AdaBoost regression algorithm combined with neural networks and machine learning to develop an intelligent quantification method of drainage pipeline flow. Based on this, the 'object recognition + image segmentation + flow regression analysis' steps are taken. Generative Adversarial Networks (GAN) are used to provide more samples for target detection. Through data collection, image enhancement, iterative expansion of the dataset, and continuous updating of the parameters of the neural network and machine learning models, intelligent quantification of drainage pipeline flow is ultimately achieved, ensuring real-time, high-precision, and intelligentization. © 2024 IEEE.

Interpret the Predictions of Deep Networks Via Re-Label Distillation

Item Type Conference Paper

Author Y. Hua

Author S. Ge

Author D. Zhang

Abstract Interpreting the predictions of a black-box deep network can facilitate the reliability of its deployment. In this work, we propose a re-label distillation approach to learn a direct map from the input to the prediction in a self-supervision manner. The image is projected into a VAE subspace to generate some synthetic images by randomly perturbing its latent vector. Then, these synthetic images can be annotated into one of two classes by identifying whether their labels shift. After that, using the labels annotated by the deep network as teacher, a linear student model is trained to approximate the annotations by mapping these synthetic images to the classes. In this manner, these re-labeled synthetic images can well describe the local classification mechanism of the deep network, and the learned student can provide a more intuitive explanation towards the predictions. Extensive experiments verify the effectiveness of our approach qualitatively and quantitatively. © 2021 IEEE.

Abstract Ammonia nitrogen stress causes massive mortality in industrial aquaculture, making real-time monitoring critical. However, existing methods for recognizing fish stress behaviors often focus on state classification while neglecting the interpretability of behavioral response patterns. To address the above issue, an interpretable behavioral response analysis method based on the spatial distribution quantification of single-frame images was proposed. Cultured sturgeon under ammonia nitrogen stress were used as the experimental subject. The proposed method first constructed a lightweight object detection model, MD-YOLO, to precisely extract fish spatial positions and provide high-quality coordinate data for spatial distribution quantification. Subsequently, seven biologically meaningful quantitative indicators were constructed to characterize the spatial distribution of fish schools from three perspectives: population aggregation, spatial coverage, and distribution uniformity. Unlike end-to-end deep learning methods, these indicators quantitatively characterize the spatial behavioral patterns of stressed fish, thereby significantly improving the interpretability of behavioral analysis. By combining these indicators into a feature

vector and utilizing a Random Forest (RF) classifier, accurate analysis of stress behavior was achieved. The experimental results showed that the MD-YOLO model outperformed the baseline model YOLOv10n by 1.1% and 4.4% in mAP@0.5 and mAP@0.75, respectively. Furthermore, the proposed method successfully characterized fish behavioral responses to ammonia nitrogen stress and achieved a recognition accuracy of 97.2%. The single-frame spatial distribution quantification method proposed in this study does not require cross-frame trajectory modeling, providing a high-precision, low-complexity, and interpretable solution for fish behavior monitoring in industrial aquaculture. © 2026 Elsevier B.V.

Interpretable Educational AI Practice: Dynamic Optimization of Personalized Teaching Based on Neural Collaborative Filtering and Causal Reasoning

Item Type Conference Paper

Author M. Dong

Abstract This paper proposes an educational artificial intelligence framework that integrates neural collaborative filtering with causal reasoning, aiming to achieve explainable dynamic personalized teaching optimization. The system employs

deep neural networks to construct a nonlinear interaction model between students and resources for accurately predicting individual learning needs, while establishing a causal reasoning engine to dissect the effect mechanisms of teaching interventions, achieving counterfactual decision optimization. Key technologies include a hybrid architecture of generalized matrix factorization and multi-layer perceptrons to handle the complexity of educational scenarios, double machine learning to quantify individual treatment effects, and modular explanation templates to generate educationally logical decision attribution chains. Experimental validation demonstrates that this framework significantly enhances the explainability and long-term learning efficiency of teaching decisions while maintaining large-scale recommendation efficiency, providing a solution robust in both technology and ethical compliance. © 2025 Copyright held by the owner/author(s).

Interpretable Ensemble Prediction of Thermally Induced Long-Term Pile Settlement from Limited Monitoring Data

Item Type Journal Article**Author** B. Sun**Author** C. Shi

Abstract Energy piles are a promising green building technology that combines traditional pile foundations with ground heat exchangers, providing both structural support and thermal regulation for buildings. Predicting long-term pile settlement induced by seasonal heating and cooling cycles is crucial for the safety and serviceability of energy piles. However, traditional numerical methods are limited by the inadequacies of soil constitutive models, and machine learning approaches typically require large datasets and lack interpretability. To address these challenges, this study proposes an interpretable sparse ensemble learning (ISEL) method that integrates finite element model outputs with limited monitoring data to dynamically predict thermally induced long-term pile displacement. The method employs orthogonal matching pursuit for adaptive model selection and adopts sparse Bayesian learning to quantify prediction uncertainty. The performance of the proposed framework is illustrated using centrifuge model tests, and sensitivity analyses are conducted to investigate the robustness of the model under operational uncertainty and varying thermal conditions. Results indicate that the ISEL method can accurately predict pile displacement, even with limited monitoring data. More importantly, the incorporation of physical laws significantly improves prediction reliability and efficiency, making it a handy tool for the design and analysis of energy piles subjected to cyclic thermal loading. © 2025 American Society of Civil Engineers.

Interpretable Minority Synthesis for Imbalanced Classification

Item Type Conference Paper

Author Y. He

Author F. Lin

Author X. Yuan

Author N.-F. Tzeng

Editor Zhou Z.-H.

Abstract This paper proposes a novel oversampling approach that strives to balance the class priors with a considerably imbalanced data distribution of high dimensionality. The crux of our approach lies in learning interpretable latent representations that can model the synthetic mechanism of the minority samples by using a generative adversarial network (GAN). A Bayesian regularizer is imposed to guide the GAN to extract a set of salient features that are either disentangled or intensionally entangled, with their interplay controlled by a prescribed structure, defined with human-in-the-loop. As such, our GAN enjoys an improved sample complexity, being able to synthesize high-quality minority samples even if the sizes of minority classes are extremely small during training. Empirical studies substantiate that our approach can empower simple classifiers to achieve superior imbalanced classification performance over the state-of-the-art competitors and is robust across various imbalance settings. Code is released in github.com/fudonglin/IMSIC. © 2021 International Joint Conferences on Artificial Intelligence. All rights reserved.

Interpretable Quantification of Scene-Induced Driver Visual Load: Linking Eye-Tracking Behavior to Road Scene Features via SHAP Analysis

Item Type Journal Article

Author J. Ni

Author Y. Shao

Author Y. Guo

Author Y. Gu

Abstract Road traffic accidents remain a major global public health concern, where complex urban driving environments significantly elevate drivers’ visual load and accident risks. Unlike existing research that adopts a macro perspective by considering multiple factors such as the driver, vehicle, and road, this study focuses on the driver’s visual load, a key safety factor, and its direct source—the driver’s visual environment. We have developed an interpretable framework combining computer vision and machine learning to quantify how road scene features influence oculomotor behavior and scene-induced visual load, establishing a complete and interpretable link between scene features, eye movement behavior, and visual load. Using the DR(eye)VE dataset, visual attention demand is established through occlusion experiments and confirmed to correlate with eye-tracking metrics. K-means clustering is applied to classify visual load levels based on discriminative oculomotor features, while semantic segmentation extracts quantifiable road scene features such as the Green Visibility Index, Sky Visibility Index and Street Canyon Enclosure. Among multiple machine learning models (Random Forest, Ada-Boost, XGBoost, and SVM), XGBoost demonstrates optimal performance in visual load detection. SHAP analysis reveals critical thresholds: the probability of high visual load increases when pole density exceeds 0.08%, signage surpasses 0.55%, or buildings account for more than 14%; while blink duration/rate decrease when street enclosure exceeds 38% or road congestion goes beyond 25%, indicating elevated visual load. The proposed framework provides actionable insights for urban design and driver assistance systems, advancing traffic safety through data-driven optimization of road environments. © 2025 by the authors.

Editor Deligiannidis L.

Abstract In this survey, we will summarize our recent representative research studies toward interpretable, adaptive, and robust online machine learning for data streams with multiple streaming natures, such as skewed distributions, concept drifts, and streaming or mix-typed features, which are four vital components towards intelligent online machine learning. I will also discuss some potential streaming applications for online anomaly detection, and future work on online semi-supervised learning, online label shift learning, online continuous learning, and large language model enhanced online machine learning for data streams. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2027.

Interpretable, calibrated neural networks for analysis and understanding of inelastic neutron scattering data

Item Type Journal Article

Author K.T. Butler

Author M.D. Le

Author J. Thiyaalingam

Author T.G. Perring

Abstract Deep neural networks (NNs) provide flexible frameworks for learning data representations and functions relating data to other properties and are often claimed to achieve 'super-human' performance in inferring relationships between input data and desired property. In the context of inelastic neutron scattering experiments, however, as in many other scientific scenarios, a number of issues arise: (i) scarcity of labelled experimental data, (ii) lack of uncertainty quantification on results, and (iii) lack of interpretability of the deep NNs. In this work we examine approaches to all three

issues. We use simulated data to train a deep NN to distinguish between two possible magnetic exchange models of a half-doped manganite. We apply the recently developed deterministic uncertainty quantification method to provide error estimates for the classification, demonstrating in the process how important realistic representations of instrument resolution in the training data are for reliable estimates on experimental data. Finally we use class activation maps to determine which regions of the spectra are most important for the final classification result reached by the network. © 2021 The Author(s). Abstract Deep learning has started to have an impact on sports analytics. Several papers have applied action-value Q learning to quantify a team's chance of success, given the current match state. However, the black-box opacity of neural networks prohibits understanding why and when some actions are more valuable than others. This paper applies interpretable Mimic Learning to distill knowledge from the opaque neural net model to a transparent regression tree model. We apply Deep Reinforcement Learning to compute the Q function, and action impact under different game contexts, from 3M play-by-play events in the National Hockey League (NHL). The impact of an action is the change in Q-value due to the action. The play data along with the associated Q functions and impact are fitted by a mimic regression tree. We learn a general mimic regression tree for all players, and player-specific trees. The transparent tree structure facilitates understanding the general action values by feature influence and partial dependence plots, and player's exceptional characteristics by identifying player-specific relevant state regions. © Springer Nature Switzerland AG 2019.

Abstract Quantification learning is a relatively new deep learning task. Differing from a classic classification problem where the class of a single instance is predicted, a quantification model predicts the distribution of classes within a given set of instances. Quantification learning has applications in various domains. For example, in designing political campaign ads, it is important to know the proportion of different aspects voters care about. QuaNet is a recent deep learning quantification model that was shown to achieve good quantification performance. Like many deep learning models, there is no explanation about the contributions of different inputs QuaNet uses to predict a class distribution. In this study, we propose a method to provide such an explanation, which is important to increase users' trust in the model. Our method is the first work on interpreting deep learning quantification models. © 2023, The Author(s), under exclusive license to Springer Nature Switzerland AG.

Abstract Introduction: Colposcopy is an important tool in the diagnosis of cervical precancer and early cancer. The assessment of women with abnormal cytology and selection of those who require further therapy or follow up depends on the colposcopic assessment of the Transformation Zone (TZ). Identification of the TZ is thus an important part of this examination. Intra and inter-observer variability is known to be relatively high in the colposcopic interpretation of abnormal features. However, there are hardly any studies on the observer variability in the assessment of the type of TZ. Aim: The present study was conducted with the aim to compare the intra and inter-observer variability of the TZ type classification and the Squamo-Columnar Junction (SCJ) visibility and to quantitatively measure the intra and inter-observer correlations of drawings of the TZ contours. Materials and Methods: Colposcopy images were obtained for a total of 170 cases. They were reviewed by three colposcopists independently. The colposcopists classified the TZ type and also marked the SCJ contours on the images. Each observer independently reviewed the cases at two different instances (few weeks apart) and the result was compiled for intra-observer variation. The intra and inter observer variability on the TZ type was compared using Cohen's Kappa. This was followed by a quantitative measurement of TZ observation variability using Hausdorff distance. Results: Inter-observer agreement for the TZ

type classification was moderate (Kappa= 0.53 to 0.66). Intra-observer agreement was moderate to strong (0.60 to 0.86). Conclusion: Colposcopic in vivo examination increases variability of identification of the TZ compared to analysis of recorded images. The disagreement in the TZ type was mostly for categories Type 2 vs. Type 3 followed by Type 1 vs. Type 2. A computerized quantification method can be used for quality control and training purpose in colposcopy. © 2017 Journal of Clinical and Diagnostic Research. All rights reserved.

Intraobserver variability in grading severity of repeated identical cases of mitral regurgitation

Item Type Journal Article

Author N. Thomas

Author B. Unsworth

Author E.A. Ferenczi

Author J.E. Davies

Author J. Mayet

Author D.P. Francis

Abstract Background: In clinical practice, mitral regurgitation (MR) is often assessed from the visual impression of the color Doppler image. It is recognized that repeated scanning can give different images and that different observers may grade the same images differently. In this study, we focus on a more intrinsic source of variability-intraobserver variability in grading of identical images, presented more than once at the same sitting. Furthermore, we look for evidence that observer grading is influenced by the severity of the immediately preceding case viewed. Methods: Anonymous, 4-chamber color Doppler 2-dimensional video clips of MR were obtained from 60 unselected patients with MR. Six clips were identified by 2 observers as of contentious severity (either between mild and moderate or between moderate and severe). A 72-clip sequence was constructed from the 54 "uncontentious" selected cases of MR intermingled with 3 presentations of each of the 6 "contentious" images. Each contentious image was shown once without a designed order, once preceded by 3 clips of less severe MR, and once preceded by 3 clips of more severe MR. Results: Only 1 (8%) of 12 observers gave consistent gradings for the triply presented images. More than 90% (11/12) of the observers reported a different grading of the same clip of MR in at least 1 of the 6 cases. The MR severity was changed in 51.4% of the triplets of identical images shown. Of 12 reporters, 5 (42%) showed classification variability between severe and nonsevere grades in at least 1 of the 6 cases. The direction of change showed no sign of consistency between observers ($P = .375$). Conclusion: Even a skilled observer cannot be relied upon to give an identical grading to an identical simple video clip of MR, when re-presented surreptitiously within a few minutes. Interobserver variability cannot therefore simply be blamed on differential levels of skill. Because, even under these ideal and dramatically simplified conditions, visual assessment is so variable, the future emphasis of echocardiographic MR grading may lie in integrating qualitative analysis with simple quantification methods. © 2008 Mosby, Inc. Intravenous Delayed Gadolinium-Enhanced MR Imaging of the Endolymphatic Space: A Methodological Comparative Study

Item Type Journal Article

Author R. Boegle

Author V. Kirsch

Abstract In-vivo non-invasive verification of endolymphatic hydrops (ELH) by means of intravenous delayed gadolinium (Gd) enhanced magnetic resonance imaging of the inner ear (iMRI) is rapidly developing into a standard clinical tool to investigate peripheral vestibulo-cochlear syndromes. In this context, methodological comparative studies providing standardization and comparability between labs seem even more important, but so far very few are available. One hundred eight participants [75 patients with Meniere's disease (MD; 55.2 ± 14.9 years) and 33 vestibular healthy controls (HC; 46.4 ± 15.6 years)] were examined. The aim was to understand (i) how variations in acquisition protocols influence endolymphatic space (ELS) MR-signals; (ii) how ELS quantification methods correlate to each other or clinical data; and finally, (iii) how ELS extent influences MR-signals. Diagnostics included neuro-otological assessment, video-oculography during caloric stimulation, head-impulse test, audiometry, and iMRI. Data analysis provided semi-quantitative (SQ) visual grading and automatic algorithmic quantitative segmentation of ELS area [2D, mm²] and volume [3D, mm³] using deep learning-based segmentation and volumetric local thresholding. Within the range of 0.1–0.2 mmol/kg Gd dosage and a 4 h $\pm$ 30 min time delay, SQ grading and 2D- or 3D-quantifications were independent of signal intensity (SI) and signal-to-noise ratio (SNR; FWE corrected, $p < 0.05$). The ELS quantification methods used were highly reproducible across raters or thresholds and correlated strongly (0.3–0.8). However, 3D-quantifications showed the least variability. Asymmetry indices and normalized ELH proved the most useful for

predicting quantitative clinical data. ELH size influenced SI (cochlear basal turn $p < 0.001$), but not SNR. SI could not predict the presence of ELH. In conclusion, (1) Gd dosage of 0.1–0.2 mmol/kg after 4 h $\pm$ 30 min time delay suffices for ELS quantification. (2) A consensus is needed on a clinical SQ grading classification including a standardized level of evaluation reconstructed to anatomical fixpoints. (3) 3D-quantification methods of the ELS are best suited for correlations with clinical variables and should include both ears and ELS values reported relative or normalized to size. (4) The presence of ELH increases signal intensity in the basal cochlear turn weakly, but cannot predict the presence of ELH. © Copyright © 2021 Boegle, Gerb, Kierig, Becker-Bense, Ertl-Wagner, Dieterich and Kirsch.

Intrinsic Consistency Preservation with Adaptively Reliable Samples for Source-Free Domain Adaptation

Item Type Journal Article

Author J. Tian

Author A.E. Saddik

Author X. Xu

Author D. Li

Author Z. Cao

Author H.T. Shen

Abstract Unsupervised domain adaptation (UDA) aims to alleviate the domain shift by transferring knowledge learned from a labeled source dataset to an unlabeled target domain. Although UDA has seen promising progress recently, it requires access to data from both domains, making it problematic in source data-absent scenarios. In this article, we investigate a practical task source-free domain adaptation (SFDA) that alleviates the limitations of the widely studied UDA in simultaneously acquiring source and target data. In addition, we further study the imbalanced SFDA (ISFDA) problem, which addresses the intra-domain class imbalance and inter-domain label shift in SFDA. We observe two key issues in SFDA that: 1) target data form clusters in the representation space regardless of whether the target data points are aligned with the source classifier and 2) target samples with higher classification confidence are more reliable and have less variation in their classification confidence during adaptation. Motivated by these observations, we propose a unified method, named intrinsic consistency preservation with adaptively reliable samples (ICPR), to jointly cope with SFDA and ISFDA. Specifically, ICPR first encourages the intrinsic consistency in the predictions of neighbors for unlabeled samples with weak augmentation (standard flip-and-shift), regardless of their reliability. ICPR then generates strongly augmented views specifically for adaptively selected reliable samples and is trained to fix the intrinsic consistency between weakly and strongly augmented views of the same image concerning predictions of neighbors and their own. Additionally, we propose to use a prototype-like classifier to avoid the classification confusion caused by severe intra-domain class imbalance and inter-domain label shift. We demonstrate the effectiveness and general applicability of ICPR on six benchmarks of both SFDA and ISFDA tasks. The reproducible code of our proposed ICPR method is available at https://github.com/CFM-MSG/Code_ICPR. © 2024 IEEE.

Intrinsic logit-based debiasing for class-imbalanced semi-supervised learning

Item Type Journal Article

Author Q. Tang

Author Y. Cheng

Author X. Guo

Author X. Wei

Author S. Zhang

Author W. Pedrycz

Abstract In Class-Imbalanced Semi-Supervised Learning (CISSL), classifiers suffer from severe confirmation bias, particularly when the class distribution of unlabeled set are unknown or mismatched with that of the labeled set. Existing debiasing methods often rely on impractical assumptions for classifier bias estimation, such as known class priors or risky external proxies. To overcome these limitations, we propose Intrinsic Logit-Based Debiasing (ILBD), a robust post-hoc framework that estimates bias directly from task-relevant data without external dependencies and class priors. ILBD constructs a comprehensive bias estimator by decomposing output logits into two distinct components: (1) Label-Free Intrinsic Bias, derived from non-target (Formula presented) logits by masking target-class maximum logits to capture the model's background distributional skew; and (2) Label-Guided Learning Bias, derived from target-class maximum logits to quantify confidence disparities between head and tail classes arising from varying learning difficulties. To ensure estimation reliability, we further employ a class-adaptive threshold to filter noisy pseudo-labels. By subtracting this estimated bias at inference, ILBD effectively rectifies the classifier's bias directly from the inherent statistical patterns of the training data, without the need for target-prior assumptions or external data. Extensive experiments on CIFAR-10/100-LT, STL-10-LT, and Small-ImageNet-127 demonstrate the effectiveness of ILBD. Our code is available at <https://github.com/aroid721/ILBD>. © 2026 Elsevier Ltd. Introduction of an information-theoretic method to predict recovery rates of active compounds for Bayesian in silico screening: Theory and screening trials

Item Type Journal Article

Author M. Vogt

Author J. Bajorath

Abstract We present the first method to predict compound recovery rates from descriptor statistics. A log-odds function is designed that models probability distributions of descriptor values of active and inactive molecules in chemical space and used to

determine the likelihood of database compounds to exhibit a specific activity. The divergence of probability models for active and inactive compounds is applied to evaluate the ability of the log-odds likelihood function to recover active compounds from a background database. The divergence measure, which is closely related to the Kullback - Leibler distance, is strongly correlated with recovery rates of Bayesian virtual screening calculations. It has thus been possible to predict compound recovery rates for different activity classes. Prior to practical virtual screening trials, one can also estimate how likely it would be to recover active compounds from a given screening database. © 2007 American Chemical Society.

Editor Zhang H.

Abstract Due to the diversity of network traffic flow, intrusion detection is usually studied as an anomaly detection problem. In this paper, Positive-unlabeled with Non-negative Risk Estimator(nnPU) learning is introduced for intrusion detection. The cyber attacks is treated as positive samples in PU learning. A risk estimator is raised to estimates the binary classification loss. For data imbalance in intrusion detection, we improve the risk estimator of nnPU through focal loss(FL-nnPU). The dynamic weights in focal loss is used to balance the small class prior. The experiments result show that FL-nnPU have a close performance to binary classification, and it performs better than nnPU under data imbalance problems.

Abstract Invasive species are a leading threat to biodiversity worldwide. *Nypa* palm (*Nypa fruticans*) has emerged as the predominant invasive species in the Niger Delta region of Nigeria. While endemic mangroves have high rates of carbon sequestration, stabilize coastlines and protect biodiversity, *Nypa* does not provide these services outside its native region of Southeast Asia. Oil exploration and urbanization in this region also exacerbate mangrove loss and *Nypa* spread. As *Nypa* is difficult to distinguish from endemic mangrove species in remotely sensed data, estimates of mangrove and ecosystem services losses in Nigeria are highly uncertain. Here, we analyse multisensor satellite data with machine learning to quantify the rapid expansion of *Nypa* from 2015 to 2020 in Nigeria. Using Landsat imagery and random forest classification, we quantify total potential *Nypa* extent in Nigeria in 2019. We then produced a *Nypa* extent map using iterative combinations of Sentinel-1 SAR, Sentinel-2 MSI and ALOS PALSAR. Random forest classifications using SAR data from ALOS and Sentinel-1 were best suited for mapping *Nypa* extent with similar accuracies (78% and 75%, respectively). Based on data availability and accuracy, we focussed our change analysis on Sentinel-1 SAR. Our results show ~28 000 ha of mangroves were converted to *Nypa* in Nigeria by 2020 and covered a larger extent than endemic mangroves, compounding the effect of the existing degradation and deforestation in the region. We also compared forest height and complexity estimates from Global Ecosystem Dynamics Investigation LiDAR to further distinguish between endemic mangroves and *Nypa* in three dimensions. *Nypa* structural variability, measured by top-of-canopy height, vegetation cover, plant area index, and foliage height diversity, was lower than that of mangroves. At current rates of *Nypa* expansion, the entire area of study would be invaded by *Nypa* by 2028, with potentially detrimental consequences to the ecosystem services provided by mangroves. © 2023 The Authors. Investigating and suggesting the evaluation dataset for image classification model

Item Type Journal Article

Author S. Sivamani

Author S.I. Chon

Author D.Y. Choi

Author J.H. Park

Abstract Image processing systems are widespread with the digital transformation of artificial intelligence. Many researchers developed and tested several image classification models using machine learning and statistical techniques. Nevertheless, the current research seldom focuses on the quality assurance of these models. The existing methods lack to verify the quality assurance, with the lack of test cases to prepare the evaluation dataset to test the model, which can cause critical drawbacks in the nuclear field and defense system. In this article, we discuss and suggest the preparation of the evaluation dataset using improved test cases through Cause-Effect Graphing. The proposed method can generate the evaluation dataset with automated test cases through the quantification method, which consists of 1) image characteristic selection 2) creating the Cause-Effect graphing approach of the image with the feature, and 3) generate all possible test coverage. The testing is performed with the COCO dataset, which shows the declining prediction accuracy with the adjusted brightness and sharpness ranging between -75 to 75%, which indicates the negligence of the important characteristics in the existing test dataset. The experiment shows the prediction fails while sharpness is less than the 0%, and the brightness fails at -75% with less number of detection object between -50% and 75%. This indicates that characteristic changes affects the prediction accuracy and the number of detected objects in an image. Our approach proves the importance of the characteristic selection process for the overall image to generate a more efficient model and increase the accuracy of object detection. © 2020 Institute of Electrical and Electronics Engineers Inc.. Investigating the antimicrobial and anticancer potential of culturable fungal endophytes isolated from the stems of *Kirkia acuminata* Oliv

Item Type Journal Article

Author M. Magagula

Author T.E. Motaung

Author Z. Mbita

Author K. Dithebe

Abstract Background: Fungal endophytes produce various structurally and chemically diverse bioactive secondary metabolites including those that are similar to their host plants. However, fungal endophytes from South African medicinal plants are relatively under-explored. The medicinal plant, *Kirkia acuminata* Oliv., is on the decline in the natural environment due to overharvesting. This necessitates the search for novel alternatives to sustainably obtain the plant's bioactive metabolites. Thus, fungal endophytes may serve as suitable candidates as they can produce host-similar bioactive compounds. Results: Eighteen morphologically distinct fungal endophytes were isolated from the surface-sterilised stems of *K. acuminata* Oliv. Sequencing of the internal transcribed spacer (ITS) region revealed that the isolates were distributed among three genera, namely *Diaporthe*, *Neofusicoccum* and *Pseudofusicoccum*. The

broth micro-dilution assay showed that 17 of the 18 ethyl acetate crude extracts exhibited inhibitory activity with minimum inhibitory concentration (MIC) values ranging from 0.31 to 2.5 mg/mL and 1.25 to 2.5 mg/mL against bacterial pathogens and *Candida albicans*, respectively. The 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay revealed that most of the crude extracts had dose-dependent cytotoxicity against non-cancerous human embryonic kidney (HEK-293) cells, with the crude extracts of the *N. parvum* KaS-3, *D. macadamiae* KaS-4, *P. olivaceum* KaS-5 and *D. neotheicola* KaS-6 isolates demonstrating safety against the non-cancerous cells. The alamarBlue assay revealed that the four non-cytotoxic crude extracts had moderate anticancer activity against cervical cancer ME-180 and melanoma A375 cancerous cell lines. Moreover, mycochemical analysis of the non-cytotoxic crude extracts using colourimetric quantification methods revealed that the observed cytotoxic effect could be attributed to the high total phenolic content in the crude extracts. Conclusion: The study highlights that the fungal endophytes inhabiting the stems of *K. acuminata* Oliv. produce secondary metabolites that may serve as leads for novel antimicrobial and non-toxic anticancer agents. © The Author(s) 2025.

Investigating the Behavior and Reliability of Eccentrically Loaded Steel Connections Made with Bolts and Welds in Combination

Item Type Journal Article

Author M.F. Tamimi

Author M. Soliman

Author E. Stringer

Author B.W. Russell

Abstract This paper investigates the behavior of eccentrically loaded connections made by combining fillet welds and high-strength pretensioned bolts. New models are introduced for characterizing the load-deformation behavior of slip-resistant bolted connections with different faying surface conditions. These models are utilized to improve the ability of the instantaneous center of rotation (ICR) method to predict the capacity of eccentrically loaded connections utilizing friction as a load-transfer mechanism including bolted-only and/or bolted-welded combination connections.

Experimental results are used to quantify the accuracy of the ICR method in predicting the capacity of these combination connections considering different connecting elements to be participating in a single load resisting system. Finite-element (FE) analysis is used to investigate the load-transfer mechanisms within the combination connections. Reliability analysis is conducted using FE analysis assisted by machine learning to quantify the reliability level of the investigated connections and establish the resistance factors necessary to maintain the reliability level above prescribed thresholds. The reliability analysis shows that using the ICR method for designing these combination connections leads to a highly reliable connection for different types of faying surfaces. © 2023 American Society of Civil Engineers.

Investigation of Different Free Image Analysis Software for High-Throughput Droplet Detection

Item Type Journal Article

Author I. Sanka

Author S. Bartkova

Author P. Pata

Author O.-P. Smolander

Author O. Scheler

Abstract Droplet microfluidics has revealed innovative strategies in biology and chemistry. This advancement has delivered novel quantification methods, such as droplet digital polymerase chain reaction (ddPCR) and an antibiotic heteroresistance analysis tool. For droplet analysis, researchers often use image-based detection techniques. Unfortunately, the analysis of images may require specific tools or programming skills to produce the expected results. In order to address the issue, we explore the potential use of standalone freely available software to perform image-based droplet detection. We select the four most popular software and classify them into rule-based and machine learning-based types after assessing the software's modules. We test and evaluate the software's (i) ability to detect droplets, (ii) accuracy and precision, and (iii) overall components and supporting material. In our experimental setting, we find that the rule-based type of software is better suited for image-based droplet detection. The rule-based type of software also has a simpler workflow or pipeline, especially aimed for non-experienced users. In our case, CellProfiler (CP) offers the most user-friendly experience for both single image and batch processing analyses. © 2021 The Authors. Published by American Chemical Society

Investigation of Human Factors Using HFACS Framework—A Case Study for Unintended Reactor Trip Events in NPP

Item Type Conference Paper

Author M. Karthick

Author C. Senthil Kumar

Author T. Paul Robert

Editor Varde P.V.

Editor Prakash R.V.

Editor Vinod G.

Abstract Safety remains to be the principal concern in nuclear industry, and layered protective measures are implemented to ensure safety to public and environment. Nevertheless, accidents in a nuclear plant do occur, and human factors are confirmed to be the prime cause of these accidents. Several studies have been carried out for human factor analysis, and still, there is a need for additional methods to model human errors. In this paper, human factor analysis and classification system (HFACS) is used to analyze the causal factors for an accident/incident. HFACS is a validated and reliable model for human factor analysis and provides a simple way to evaluate the causal factors in an accident. Although HFACS framework can be applied to analyze any accident events, in this paper, it is applied to review eighteen unintended reactor trip events due to human error from 2000 to 2006. In this study, experts analyze and rate the events against each hierarchal level in HFACS. Expert judgment is sought as the uncertainty and complexity involved in modeling human and organizational factors are very high. Homogeneity of experts is assessed using inter-rated reliability and Cohen's kappa value. Expert evaluation on human factors is quantified and based on the correlation in rating, most significant factor is identified. Further, based on the information on the reported events and the analysis, statistical tests are employed to confirm the associations between the hierarchal levels in the HFACS framework for reactor trip events. The results indicate four pairs of factors, viz. resource management, planned inappropriate actions, adverse mental states, and skill-based errors have strong associations between adjacent categories. Based on these associations, adverse mental states are deemed the most potent for accident occurrences. Further analysis indicated that slips of attention, memory failures for events such a failure to open or close the valves, and perception failures for visual illumination (i.e., 'skilled based errors') are the most common 'unsafe acts' committed and appear more frequently along with nuclear control room actions. The results reveal that human errors are caused mainly due to potential human factors associated with cognition. Few active failures are also identified. Thus, the analysis highlights the importance of attention toward possible human factors among others. Overall, HFACS tool proves useful in categorizing operator errors from reported events. HFACS framework and the quantification method help to determine which factors are more dominant and influential in the accident sequence and provide additional insight for the analysts into the significance and relative importance of each of the human factors. © 2020, Springer Nature Singapore Pte Ltd.

INVESTIGATION OF MACHINE LEARNING METHOD WITH GENERALIZATION PERFORMANCE FOR AUTOMATIC HAMMERING TEST

Item Type Conference Paper

Author H. Shimbo

Author N. Hasegawa

Author T. Mizobuchi

Author T. Ozeki

Author J.-I. Nojima

Author H. Nakamura

Author S. Tomoto

Abstract The authors investigated the applicability of machine learning-based hammering test quantification methods to laser hammering systems. This method quantitatively evaluates the degree of defects using an anomaly detection technique with CNN (Convolutional Neural Network) features extraction from the imaged hammering sound. The quantitative evaluation and generalization performance for the conventional human hammering test sound were examined. The laser hammering system applies a high-power laser beam to the concrete surface for an extremely short period of time creating a physical impact. This technology enables hammering tests remotely and automatically. As a result of the study, it was shown that capability of quantitative evaluation of the degree of

defects up to around 15mm depth using laser hammering sounds. The capacity may be modifiable with the system parameters. © 2024 International Committee of the SCMT conferences. All rights reserved.

Investigations on classifying pulsed eddy current signals with a neural network

Item Type Journal Article

Author Z. Liu

Author D.S. Forsyth

Author B.A. Lepine

Author I. Hammad

Author B. Farahbakhsh

Abstract This paper investigates the classification of pulsed eddy current signals with neural networks. In the experiments, a pulsed eddy current inspection was carried out to assess the condition of a multi-layered structure, which contains metal loss at various locations. The test specimen is an engineered specimen designed to assist in the development of inspection techniques for corrosion damage detection in aircraft

fuselage splices. Separate neural network classifiers were developed using features extracted in the time domain, the coefficients of a transfer function based on a system identification approach, and the coefficients from a wavelet transform. The experimental results show the potential of applying neural networks to classify pulsed eddy current signals and to quantify the material loss evaluation. The robustness of this approach is also discussed.

Is Efficient PAC Learning Possible with an Oracle That Responds “Yes” or “No”?

Item Type Conference Paper

Author C. Daskalakis

Author N. Golowich

Editor Agrawan S.

Editor Roth A.

Abstract The empirical risk minimization (ERM) principle has been highly impactful in machine learning, leading both to near-optimal theoretical guarantees for ERM-based learning algorithms as well as driving many of the recent empirical successes in deep learning. In this paper, we investigate the question of whether the ability to perform ERM, which computes a hypothesis minimizing empirical

risk on a given dataset, is necessary for efficient learning: in particular, is there a weaker oracle than ERM which can nevertheless enable learnability? We answer this question affirmatively, showing that in the realizable setting of PAC learning for binary classification, a concept class can be learned using an oracle which only returns a single bit indicating whether a given dataset is realizable by some concept in the class. The sample complexity and oracle complexity of our algorithm depend polynomially on the VC dimension of the hypothesis class, thus showing that there is only a polynomial price to pay for use of our weaker oracle. Our results extend to the agnostic learning setting with a slight strengthening of the oracle, as well as to the partial concept, multiclass and real-valued learning settings. In the setting of partial concept classes, prior to our work no oracle-efficient algorithms were known, even with a standard ERM oracle. Thus, our results address a question of (Alon et al., 2021) who asked whether there are algorithmic principles which enable efficient learnability in this setting. © 2024 C. Daskalakis & N. Golowich.

IS IMPORTANCE WEIGHTING INCOMPATIBLE WITH INTERPOLATING CLASSIFIERS?

Item Type Conference Paper

Author K.A. Wang

Author N.S. Chatterji

Author S. Haque

Author T. Hashimoto

Abstract Importance weighting is a classic technique to handle distribution shifts. However, prior work has presented strong empirical and theoretical evidence demonstrating that importance weights can have little to no effect on overparameterized neural networks. Is importance weighting truly incompatible with the training of overparameterized neural networks? Our paper answers this in the negative. We show that importance weighting fails not because of the overparameterization, but instead, as a result of using exponentially-tailed losses like the logistic or cross-entropy loss. As a remedy, we show that polynomially-tailed losses restore the effects of importance reweighting in correcting distribution shift in overparameterized models. We characterize the behavior of gradient descent on importance weighted polynomially-tailed losses with overparameterized linear models, and theoretically demonstrate the advantage of using polynomially-tailed losses in a label shift setting. Surprisingly, our theory shows that using weights that are obtained by exponentiating the classical unbiased importance weights can improve performance. Finally, we demonstrate the practical value of our analysis with neural network experiments on a subpopulation shift and a label shift dataset. When reweighted, our loss function can outperform reweighted cross-entropy by as much as 9% in test accuracy. Our loss function also gives test accuracies comparable to, or even exceeding, well-tuned state-of-the-art methods for correcting distribution shifts. © 2022 ICLR 2022 - 10th International Conference on Learning Representations. Is the Investment Worth it? Using Machine Learning to Quantify Advertising Impact

Item Type	Conference Paper
Author	M. Yin
Author	X. Pan
Author	Z. Yu
Abstract	The scientific quantification of advertising effectiveness on e-commerce platforms is a challenge for many advertisers. In this study, we employed machine learning and data mining techniques, specifically using CatBoost for calculating the original feature weights and OpenFE for calculating composite feature weights. Our findings suggest that, overall, the impact of advertising promotion on e-commerce platforms is minimal compared to other indicators such as store's total sales, ratings, discount intensity, and poster types. However, it is encouraging to note that as the popularity of a store increases, there is a greater need to increase advertising investment in order to gain a competitive advantage over rival stores. From this perspective, advertisers' expenditure is not entirely wasted. (Abstract) © 2024 IEEE.

Abstract Reliable information about the uncertainty of predictions from deep neural networks could greatly facilitate their utilization in safety-critical applications. Current approaches for uncertainty quantification usually focus on in-distribution data, where a high uncertainty should be assigned to incorrect predictions. In contrast, we focus on out-of-distribution data where a network cannot make correct predictions and therefore should always report high uncertainty. In this paper, we compare several state-of-the-art uncertainty quantification methods for deep neural networks regarding their ability to detect novel inputs. We evaluate them on image classification tasks with regard to metrics reflecting requirements important for safety-critical applications. Our results show that a portion of out-of-distribution inputs can be detected with reasonable loss in overall accuracy. However, current uncertainty quantification approaches alone are not sufficient for an overall reliable out-of-distribution detection. © 2020 for this paper by its

Abstract Photosynthetic rate which acts as a vital limiting factor largely affects the potential of soybean production, especially during the senescence phase. However, the physiological and molecular mechanisms that underlying the change of photosynthetic rate during the developmental process of soybean leaves remain unclear. In this study, we compared the protein dynamics during the developmental process of leaves between the soybean cultivar Hobbit and the high-photosynthetic rate cultivar JD 17 using the iTRAQ (isobaric tags for relative and absolute quantification) method. A total number of 1269 proteins were detected in the leaves of these two cultivars at three different developmental stages. These proteins were classified into nine expression patterns depending on the expression levels at different developmental stages, and the proteins in each pattern were also further classified into three large groups and 20 small groups depending on the protein functions. Only 3.05–6.53 % of the detected proteins presented a differential expression pattern between these two cultivars. Enrichment factor analysis indicated that proteins involved in photosynthesis composed an important category. The expressions of photosynthesis-related proteins were also further confirmed by western blotting. Together, our results suggested that the reduction in photosynthetic rate as well as chloroplast activity and composition during the developmental process was a highly regulated and complex process which involved a serial of proteins that function as potential candidates to be targeted by biotechnological approaches for the improvement of photosynthetic rate and production. © 2016, Springer-Verlag Berlin Heidelberg.

JaxSGMC: Modular stochastic gradient MCMC in JAX

Item Type Journal Article

Author S. Thaler

Author P. Fuchs

Author A. Cukarska

Author J. Zavadlav

Abstract We present JaxSGMC, an application-agnostic library for stochastic gradient Markov chain Monte Carlo (SG-MCMC) in JAX. SG-MCMC schemes are uncertainty quantification (UQ) methods that scale to large datasets and high-dimensional models, enabling trustworthy neural network predictions via Bayesian deep learning. JaxSGMC implements several state-of-the-art SG-MCMC samplers to promote UQ in deep learning by reducing the barriers of entry for switching from stochastic optimization to SG-MCMC sampling. Additionally, JaxSGMC allows users to build custom samplers from standard SG-MCMC building blocks. Due to this modular structure, we anticipate that JaxSGMC will accelerate research into novel SG-MCMC schemes and facilitate their application across a broad range of domains. © 2024 The Author(s)

Joint space narrowing progression quantification with joint angle correction in rheumatoid arthritis

Item Type Conference Paper

Author Y. Ou

Author P. Ambalathankandy

Author R. Furuya

Author S. Kawada

Author T. Kamishima

Abstract Rheumatoid arthritis is a form of autoimmune disease characterized by synovitis that can ultimately cause joint deformities and impaired functioning. The cartilage destruction is one of the most important indicators for diagnosis and treatment of Rheumatoid arthritis, and it is radiographically manifested as joint space narrowing. In this study, we propose a joint location detection method and a sub-pixel accurate method for quantifying joint space narrowing progression with a joint angle correction. The proposed joint location detection method can detect the location of 14 joints from a given hand radiographic image, the error of 89.13% joints is less than 3 pixels (spatial resolution: 0.175 mm/pixel). In our previous works, we measured joint space narrowing progression between a baseline and its follow-up finger joint images by using partial image phase only correlation. We found that the inconsistency of joint angles may lead to characteristic mismatch and thus affect the accuracy of joint space narrowing quantification. In this work, we introduce rotation invariant phase only correlation in joint space narrowing quantification for joint angle correction. In our experiment, the improved quantification method can effectively manage the mismatch due to the inconsistency of joint angles. © 2022 IEEE.

Kernel density estimation for multiclass quantification

Item Type Journal Article

Author A. Moreo

Author P. González

Author J.J. del Coz

Abstract Several disciplines, like the social sciences, epidemiology, sentiment analysis, or market research, are interested in knowing the distribution of the classes in a population rather than the individual labels of the members thereof. Quantification is the supervised machine learning task concerned with obtaining accurate predictors of class prevalence, and to do so particularly in the presence of label shift. The distribution-matching (DM) approaches represent one of the most important families among the quantification methods that have been proposed in the literature so far. Current DM approaches model the involved populations using histograms of posterior probabilities. In this paper, we argue that their application to the multiclass setting is suboptimal since the histograms become class-specific, thus missing the opportunity to model inter-class information that may exist in the data. We propose a new representation mechanism based on multivariate densities that we model via kernel density estimation (KDE). The experiments we have carried out show our

method, dubbed KDEy, yields superior quantification performance compared to previous DM approaches and other state-of-the-art quantification systems. © The Author(s), under exclusive licence to Springer Science+Business Media LLC, part of Springer Nature 2025.

Key Features and Considerations for Using Automated Long-Term Monitoring of Heat-Seeking Behavior of Mosquitoes

Item Type Journal Article

Author C. Sakuma

Author E. Maekawa

Author H. Kanuka

Abstract Mosquitoes are vectors of various deadly infectious diseases, including malaria and dengue fever. Because these pathogens are transmitted by mosquito blood-feeding behavior, it is important to understand how mosquitoes are attracted to their hosts and how they feed on blood. The simplest method is to observe their behavior with the naked eye or video recording. Furthermore, various devices have been invented to

assay mosquito behavior, such as olfactometers. Although each method has distinctive advantages, all have disadvantages, such as limitations in the number of individuals that can be assayed at one time and in observable durations, objective quantification methods, and others. To solve these problems, we have developed an automated device to quantify the carbon dioxide- activated heat-seeking behavior of *Anopheles stephensi* and *Aedes aegypti* with continuous monitoring for up to 1 week. This device, which is detailed in an accompanying protocol, can be applied to search for substances and molecules that affect heat-seeking behavior. It may also be applicable to other hematophagous insects. © 2023 Cold Spring Harbor Laboratory Press. All rights reserved.

Key Findings on the Role of Corner Frequency in Site-Based Stochastic Ground Motion Models

Item Type Journal Article

Author M. Su

Author M. Dabaghi

Author M. Broccardo

Abstract Site-based stochastic ground motion models (GMMs) are essential for representing seismic input in uncertainty quantification methods for earthquake engineering. A key element controlling the long-period spectral behavior of these models is the high-pass filter's corner frequency (f_c), which must thus be included as a free parameter. In fact, our previous study demonstrated the need to optimize f_c to effectively control the long-period response spectra. This paper builds on and complements our previous study by presenting three key findings. First, for site-based stochastic GMMs, not only f_c 's values but also f_c 's correlation with other GM parameters (e.g., Arias intensity, predominant frequency, and duration) significantly impact the correlation of linear-response spectra $S_a(T)$ at different spectral periods. Second, using a modulated filtered-white-noise GMM with 11 parameters, including the optimized f_c , we effectively fit a large data set comprising 3,243 strong motion records. Specifically, a visual classification indicates that circa 93% of the recorded spectra $S_a(T)$ closely fall within the 2-sigma confidence bounds of the simulated $S_a(T)$. Third, the fitted f_c values contain unrealistic information when the records downloaded from strong-motion databases are overfiltered to remove signal noises. © 2025 American Society of Civil Engineers.

Knowledge Graph-K-modes Clustering Algorithm for Archival Text Categorization

Item Type Journal Article

Author X.-J. Wu

Author H.-B. Zhang

Abstract Automated classification of electronic archive text's can improve document management efficiency, support rapid information retrieval, and enhance data analysis capabilities, thus helping to achieve efficient use of information resources and knowledge management. However, medium-scale archival text classification needs to deal with complex natural languages as well as deal with noise, ambiguity and sparsity in unstructured text data. In order to solve the above problems, this work proposes a knowledge graph-K-modes clustering algorithm-CTransR-Full-K-Modes for archival text classification. Firstly, existing knowledge representation learning modes and dissimilarity measures in clustering algorithms are analysed. Next, we provide a representation learning model called CTransR. This model is based on hyperparameter tuning and relation matrix projection. Its major purpose is to address the issue of poor recognition capacity in the current TransR model while dealing with distinct entities that have great resemblance. Allocate items and relations into distinct vector spaces. The hyperparameter tuning principle and a priori probability based on the use of relations are employed to distinguish relations that encode similarity, thus facilitating the process of knowledge fusion in archival knowledge mapping. Finally, a full attribute-valued K-Modes algorithm-Full-K-Modes for archival knowledge graphs is proposed to achieve clustering processing of archival texts using preclustering-based multi-attribute-valued clustering centres and their corresponding dissimilarity measures to mitigate the effects of local optimal cases. The experimental results show that the proposed CTransR-Full-K-Modes algorithm can effectively improve the accuracy of the clustering results of ordered-type categorical data, and achieve the purpose of automatic categorisation mining for medium-sized digital archives. © 2025 J. Abstract	In many decision-making applications it is of particular interest to obtain aggregated properties about the data sample. Quantification learning (or prevalence estimation) is the task of training predictors via supervised learning to estimate the class distribution of an unlabelled test set. In this paper, we describe our perspective on the "LeQua 2022: Learning to Quantify" challenge, and our entry in "the vector task - T1A," which achieved 1st place on the leaderboard in terms of relative absolute error, and 2nd place in terms of absolute error. We explored the relationship between probabilistic calibration and quantification, concluding that calibration can help with quantification, but this typically requires an i.i.d. assumption or known distribution shift. © 2022 Copyright for this paper by its authors.

Label Shift Correction via Bidirectional Marginal Distribution Matching

Item Type Conference Paper**Author** R. Fan**Author** X. Ouyang**Author** H. Tao**Author** C. Hou

Abstract Due to the timeliness and uncertainty of data acquisition, label shift, which assumes that the source (training) and target (test) label distributions differ, occurs with the changing environment and reduces the generalization ability of traditional models. To correct the label shift, existing methods estimate the true label distribution by prediction of target data from a source classifier, which results in high variance, especially with large label shift. In this paper, we tackle this problem by proposing a novel approach termed as Label Shift Correction via Bidirectional Marginal Distribution Matching (BMDM). Our approach matches the label and feature marginal distributions simultaneously to ensure the stability of estimated class proportions. We prove theoretically that there is a unique optimal solution, i.e., true target label distribution, for our approach under mild conditions, and an efficient optimization strategy is also proposed. On this basis, in multi-shot scenario where label distribution changes continuously, we extend BMDM by designing a new distribution matching mechanism and constructing a regularization term that constrains the direction of label distribution change.

Extensive experimental results validate the effectiveness of our approach over existing state-of-the-arts methods. © 2024 Copyright held by the owner/author(s). Publication rights licensed to ACM.

Label Shift Estimation for Class-Imbalance Problem: A Bayesian Approach

Item Type	Conference Paper
Author	C. Ye
Author	R. Tsuchida
Author	L. Petersson
Author	N. Barnes
Abstract	As a type of distribution shift, label shift occurs when the source and target domains have different label distributions $P(Y)$ but identical conditional distributions of data given labels $P(X Y)$. Under a Bayesian framework, we

propose a novel Maximum A Posteriori (MAP) model and a novel posterior sampling model for the label shift problem. We prove the MAP objective admits a unique optimum and derive an EM algorithm that converges to the global optimum. We propose a novel Adaptive Prior Learning (APL) model to adaptively select prior parameters given data. We use the Markov Chain Monte Carlo (MCMC) method in our posterior sampling model to estimate and correct for label shift. Our methods can effectively resolve class imbalance problems on large-scale datasets without fine-tuning the classifier. Experiments show that our model outperforms existing methods on a variety of label shift settings. Our code is available at <https://github.com/ChangkunYe/MAPLS/>. © 2024 IEEE.

Label Shift Estimation With Incremental Prior Update

Item Type Conference Paper

Author Y. Zhang

Author G. Batista

Author S.S. Kanhere

Abstract An assumption often made in supervised learning is that the training and testing sets have the same label distribution. However, in real-life scenarios, this assumption rarely holds. For example, medical diagnosis result distributions change over time and across locations; fraud detection models must adapt as patterns of fraudulent activity shift; the category distribution of social media posts changes based on trending topics and user demographics. In the task of label shift estimation, the goal is to estimate the changing label distribution $p(y)$ in the testing set, assuming the likelihood $p(x|y)$ does not change, implying no concept drift. In this paper, we propose a new approach for post-hoc label shift estimation, unlike previous methods that perform moment matching with confusion matrix estimated from a validation set or maximize the likelihood of the new data with an expectation-maximization algorithm. We aim to incrementally update the prior on each sample, adjusting each posterior for more accurate label shift estimation. The proposed method is based on intuitive assumptions on classifiers that are generally true for modern probabilistic classifiers. The proposed method relies on a weaker notion of calibration compared to other methods. As a post-hoc approach for label shift estimation, the proposed method is versatile and can be applied to any black-box probabilistic classifier. Experiments on CIFAR-10 and MNIST show that the proposed method consistently outperforms the current state-of-the-art maximum likelihood-based methods under different calibrations and varying intensities of label shift. Label Shift Meets Online Learning: Ensuring Consistent Adaptation with Universal Dynamic Regret

Item Type Conference Paper

Author Y. Dai

Author S. Gu

Author R. Fan

Author C. Xu

Author C. Hou

Abstract Label shift, which investigates the adaptation of label distributions between the fixed source and target domains, has attracted significant research interests and broad applications in offline settings. In real-world scenarios, however, data often arrives as a continuous stream. Addressing label shift in online learning settings is paramount. Existing strategies, which tailor traditional offline label shift techniques to online settings, have degraded performance due to the inconsistent estimation of label distributions and violation of convex assumption for theoretical guarantee. In this paper, we propose a novel method to ensure consistent adaptation to online label shift. We construct a new convex risk estimator that is pivotal for both online optimization and theoretical analysis. Furthermore, we enhance an optimistic online algorithm as the base learner and refine the classifier using an ensemble method. Theoretically, we derive a universal dynamic regret which achieves minimax optimal. Extensive experiments on both real-world datasets and human motion task demonstrate the superiority of our method comparing existing methods. © 2025 IEEE.

Abstract Hyperspectral imaging (HSI) is a relatively new modality in medicine and can have many potential applications. In this study, we developed label-free hyperspectral imaging for tumor margin assessment. HSI data, hypercube (x, y, λ) , consists of a series of images of the same field of view that are acquired at different wavelengths. Every pixel in the hypercube has an optical spectrum. We collected surgical tissue specimens from 16 human subjects who underwent head and neck (H&N) cancer surgery. We acquired both HSI, autofluorescence images, and fluorescence images with 2-NBDG and proflavine from the specimens. Digitized histologic slides were examined by an H&N pathologist. We developed image preprocessing and classification methods for HSI data and differentiate cancer from benign tissue. The hyperspectral imaging and classification method was able to distinguish between cancer and normal tissue from oral cavity with an average accuracy of $90 \pm 8\%$, sensitivity of $89 \pm 9\%$, and specificity of $91 \pm 6\%$. This study suggests that label-free hyperspectral imaging has great potential for surgical margin assessment in tissue specimens of H&N cancer patients. Further development of the imaging technology and quantification methods is warranted

for its application in image-guided surgery. © 2017 IEEE.

Abstract Macrophages (MΦs) are important immune effector cells that promote (M1 MΦs) or inhibit (M2 MΦs) inflammation and are involved in numerous physiological and pathogenic immunoresponses. Their precise role and relevance, however, are not fully understood for lack of noninvasive quantification methods. Here, we show that two-photon excited fluorescence lifetime imaging (TPE-FLIM), a label-free noninvasive method, can visualize MΦs in the human dermis *in vivo*. We demonstrate *in vitro* that human dermal MΦs exhibit specific TPE-FLIM properties that distinguish them from the main components of the extracellular matrix and other dermal cells. We visualized MΦs, their phenotypes and phagocytosis in the skin of healthy individuals *in vivo* using TPE-FLIM. Additionally, machine learning identified M1 and M2 MΦs with a sensitivity of 0.88 ± 0.04 and 0.82 ± 0.03 and a specificity of 0.89 ± 0.03 and 0.90 ± 0.03 , respectively. In clinical research, TPE-FLIM can advance the understanding of the role of MΦs in health and disease. © Kröger et al.

Abstract A label-free, hyperspectral imaging (HSI) approach has been proposed for tumor margin assessment. HSI data, i.e., hypercube (x, y, λ) , consist of a series of high-resolution images of the same field of view that are acquired at different wavelengths. Every pixel on an HSI image has an optical spectrum. In this pilot clinical study, a pipeline of a machine-learning-based quantification method for HSI data was implemented and evaluated in patient specimens. Spectral features from HSI data were used for the classification of cancer and normal tissue. Surgical tissue specimens were collected from 16 human patients who underwent head and neck (H&N) cancer surgery. HSI, autofluorescence images, and fluorescence images with 2-deoxy-2-[(7-nitro-2,1,3-benzoxadiazol-4-yl)amino]-D-glucose (2-NBDG) and proflavine were acquired from each specimen. Digitized histologic slides were examined by an H&N pathologist. The HSI and classification method were able to distinguish between cancer and normal tissue from the oral cavity with an average accuracy of $90\% \pm 8\%$, sensitivity of $89\% \pm 9\%$, and specificity of $91\% \pm 6\%$. For tissue specimens from the thyroid, the method achieved an average accuracy of $94\% \pm 6\%$, sensitivity of $94\% \pm 6\%$, and specificity of $95\% \pm 6\%$. HSI outperformed autofluorescence imaging or fluorescence imaging with vital dye (2-NBDG or proflavine). This study demonstrated the feasibility of label-free, HSI for tumor margin assessment in surgical tissue specimens of H&N cancer patients. Further development of the HSI technology is warranted for its application in image-guided surgery. © 2021 The Authors.

LAMDA: Label Matching Deep Domain Adaptation

Item Type Conference Paper

Author T. Le

Author T. Nguyen

Author N. Ho

Author H. Bui

Author D. Phung

Abstract Deep domain adaptation (DDA) approaches have recently been shown to perform better than their shallow rivals with better modeling capacity on complex domains (e.g., image, structural data, and sequential data). The underlying idea is to learn domain invariant representations on a latent space that can bridge the gap between source and target domains. Several theoretical studies have established insightful understanding and the benefit of learning domain invariant features; however, they are usually limited to the case where there is no label shift, hence hindering its applicability. In this paper, we propose and study a new challenging setting that allows us to use a Wasserstein distance (WS) to not only quantify the data shift but also to define the label shift directly. We further develop a theory to demonstrate that minimizing the WS of the data shift leads to closing the gap between the source and target data distributions on the latent space (e.g., an intermediate layer of a deep net), while still being able to quantify the label shift with respect to this latent space. Interestingly, our theory can consequently

explain certain drawbacks of learning domain invariant features on the latent space. Finally, grounded on the results and guidance of our developed theory, we propose the Label Matching Deep Domain Adaptation (LAMDA) approach that outperforms baselines on real-world datasets for DA problems. Land Resources for Wind Energy Development Requires Regionalized Characterizations

Item Type Journal Article

Author T. Dai

Author V.M. Patel

Author S.M. Jordaan

Abstract Estimates of the land area occupied by wind energy differ by orders of magnitude due to data scarcity and inconsistent methodology. We developed a method that combines machine learning-based imagery analysis and geographic information systems and examined the land area of 318 wind farms (15,871 turbines) in the U.S. portion of the Western Interconnection. We found that prior land use and human modification in the project area are critical for land-use efficiency and land transformation of wind projects. Projects developed in areas with little human modification have a land-use efficiency of 63.8 ± 8.9 W/m² (mean $\pm$ 95% confidence interval) and a land transformation of 0.24 ± 0.07 m²/MWh, while values for projects in areas with high human modification are 447 ± 49.4 W/m² and 0.05 ± 0.01 m²/MWh, respectively. We show that land resources for wind can be quantified consistently with our replicable method, a method that obviates >99% of the workload using machine learning. To quantify the peripheral impact of a turbine, buffered geometry can be used as a proxy for measuring land resources and metrics when a large enough impact radius is assumed (e.g., >4 times the rotor diameter). Our analysis provides a necessary first step toward regionalized impact assessment and improved comparisons of energy alternatives. © 2024 American Chemical Society.

LaSCal: Label-Shift Calibration without target labels**Item Type** Conference Paper**Author** T. Popordanoska**Author** G. Radevski**Author** T.T.M.B. Blaschko**Editor** Globerson A.**Editor** Mackey L.**Editor** Belgrave D.**Editor** Fan A.**Editor** Paquet U.**Editor** Tomczak J.**Editor** Zhang C.

Abstract When machine learning systems face dataset shift, model calibration plays a pivotal role in ensuring their reliability. Calibration error (CE) provides insights into the alignment between the predicted confidence scores and the classifier accuracy. While prior works have delved into the implications of dataset shift on calibration, existing CE estimators either (i) assume access to labeled data from the target domain, often unavailable in practice, or (ii) are derived under a covariate shift assumption. In this work we propose a novel, label-free, consistent CE estimator under label shift. Label shift is characterized by changes in the marginal label distribution $p(Y)$, with a constant conditional $p(X|Y)$ distribution between the source and target. We introduce a novel calibration method, called LaSCal, which uses the estimator in conjunction with a post-hoc calibration strategy, to perform unsupervised calibration on the target distribution. Our thorough empirical analysis demonstrates the effectiveness and reliability of the proposed approach across different modalities, model architectures and label shift intensities. © 2024 Neural information processing systems foundation. Abstract Laser-induced breakdown spectroscopy (LIBS) has played a critical role in Mars exploration missions, substantially contributing to the geochemical analysis of Martian surface substances. However, the complex nonlinearity of LIBS processes can considerably limit the quantification accuracy of conventional LIBS chemometric methods. Hence chemometrics based on artificial neural network (ANN) algorithms have become increasingly popular in LIBS analysis due to their extraordinary ability in nonlinear feature modeling. The hidden layer activation functions are key to ANN model performance, yet common activation functions usually suffer from problems such as gradient vanishing (e.g., Sigmoid and Tanh) and dying neurons (e.g., ReLU).

In this study, we propose a novel LIBS quantification method, named the Bayesian optimization-based tunable Softplus backpropagation neural network (BOTS-BPNN). Based on a dataset comprising 1800 LIBS spectra collected by a laboratory duplicate of the MarSCoDe instrument onboard the Zhurong Mars rover, we have revealed that a BPNN model adopting a tunable Softplus activation function can achieve higher prediction accuracy than BPNN models adopting other common activation functions if the tunable Softplus parameter β is properly selected. Moreover, the way to find the proper β value has also been investigated. We demonstrate that the Bayesian optimization method surpasses the traditional grid search method regarding both performance and efficiency. The BOTS-BPNN model also shows superior performance over other common machine learning models like random forest (RF). This work indicates the potential of BOTS-BPNN as an effective chemometric method for analyzing Mars in situ LIBS data and sheds light on the use of chemometrics for data analysis in future planetary explorations. © 2025 by the authors.

LEAP: Linear equations for classifier accuracy prediction under prior probability shift

Item Type Journal Article

Author L. Volpi

Author A. Moreo

Author F. Sebastiani

Abstract The standard technique for predicting the accuracy that a classifier will have on unseen data (classifier accuracy prediction—CAP) is cross-validation (CV). However, CV relies on the assumption that the training data and the test data are sampled from the same distribution, an assumption that is often violated in many real-world scenarios. When such violations occur (i.e., in the presence of dataset shift), the estimates returned by CV are unreliable. The contribution of this paper is three-fold. First, we propose a CAP method specifically designed to work under prior probability shift (PPS), an instance of dataset shift in which the training and test distributions are characterized by different class priors. This method estimates the entries of the contingency table of the test data (thus allowing to estimate the value of any specific evaluation measure) by solving a system of independent linear equations, with n the number of classes. Second, we show that the equations that the cells of the contingency table must satisfy are actually more than, which gives rise to an overconstrained problem, and present a family of methods each based on a different selection of such equations. Third, we observe that, since a key step of the above methods involves predicting the class priors of the test data, one can exploit intuitions from the field of class prior estimation (a.k.a. “quantification”). Our experiments show that, when combined with state-of-the-art quantification techniques, under PPS our methods tend to outperform existing CAP methods. © The Author(s) 2025.

Learn to classify and count: A unified framework for object classification and counting

Item Type Conference Paper**Author** Z. Song**Author** Q. Qiu

Abstract In this paper, we focus on the problem of object classification and counting in natural scenes. The existing methods of instance detection can be utilized to classify and count. These works depend on the bounding box annotations, which requires time-consuming human labeling effort. Meanwhile, traditional methods of object counting are mostly based on the class-insensitive density map, therefore they are only able to count one specific category. We propose a unified framework for object classification and counting to overcome these drawbacks of existing works. We employ a two-stream convolutional neural network (CNN), which consists of classification and counting branches. Considering the correlation between classification and counting tasks, we propose a novel correlation loss function to coordinate representations learned by both two branches of network. Without hand-labeled bounding box annotations as supervision information, our end-to-end model can recognize the category of objects in the image and count object numbers per category. The proposed method is evaluated on PASCAL VOC 2007 dataset in multi-label classification and object counting tasks. We have achieved improved performance on both two tasks, which shows the effectiveness of our proposed method. © 2018 Association for Computing Machinery.

Learning automata based classifier

Item Type Journal Article**Author** S.-H. Zahiri

Abstract In this paper a new classifier has been designed based on the learning automata. This classifier can efficiently approximate the decision hyperplanes in the feature space without need to know the class distributions and the a priori probabilities. The performance of the proposed classifier has been tested on different kinds of benchmarks with nonlinear, overlapping class boundaries and different feature space dimensions. Extensive experimental results on these data sets are provided to show that the performance of the proposed classifier is comparable to, sometimes better than multi-layer perceptron, k-nearest neighbor classifier, genetic classifier, and particle swarm classifier. Also the comparative results are provided to show the effectiveness of the proposed method in comparison to similar researches. Furthermore the effect of the number of training points on the performance of the designed classifier is investigated. It is found that as the number of training data increases, the performance of the classifier tends to the performance of Bayes classifier which is an optimal one. © 2007 Elsevier B.V. Learning Bayesian classifiers from positive and unlabeled examples

Item Type Journal Article

Author B. Calvo

Author P. Larrañaga

Author J.A. Lozano

Abstract The positive unlabeled learning term refers to the binary classification problem in the absence of negative examples. When only positive and unlabeled instances are available, semi-supervised classification algorithms cannot be directly applied, and thus new algorithms are required. One of these positive unlabeled learning algorithms is the positive naive Bayes (PNB), which is an adaptation of the naive Bayes induction algorithm that does not require negative instances. In this work we propose two ways of enhancing this algorithm. On one hand, we have taken the concept behind PNB one step further, proposing a procedure to build more complex Bayesian classifiers in the absence of negative instances. We present a new algorithm (named positive tree augmented naive Bayes, PTAN) to obtain tree augmented naive Bayes models in the positive unlabeled domain. On the other hand, we propose a new Bayesian approach to deal with the a priori probability of the positive class that models the uncertainty over this parameter by means of a Beta distribution. This

approach is applied to both PNB and PTAN, resulting in two new algorithms. The four algorithms are empirically compared in positive unlabeled learning problems based on real and synthetic databases. The results obtained in these comparisons suggest that, when the predicting variables are not conditionally independent given the class, the extension of PNB to more complex networks increases the classification performance. They also show that our Bayesian approach to the a priori probability of the positive class can improve the results obtained by PNB and PTAN. © 2007 Elsevier B.V. All rights reserved.

Abstract Existing algorithms aiming to learn a binary classifier from positive (P) and unlabeled (U) data generally require estimating the class prior or label noises ahead of building a classification model. However, the estimation and classifier learning are normally conducted in a pipeline instead of being jointly optimized. In this paper, we propose to alternatively train the two steps using reinforcement learning. Our proposal adopts a policy network to adaptively make assumptions on the labels of unlabeled data, while a classifier is built upon the output of the policy network and provides rewards to learn a better strategy. The dynamic and interactive training between the policy maker and the classifier can exploit the unlabeled data in a more effective manner and yield a significant improvement on the classification performance. Furthermore, we present two different approaches to represent the actions sampled from the policy. The first approach considers continuous actions as soft labels, while the other uses discrete actions as hard assignment of labels for unlabeled examples. We validate the effectiveness of the proposed method on two benchmark datasets as well as one e-commerce dataset. The result shows the proposed method is able to consistently outperform state-of-the-art methods in various settings. © 2019 IEEE.

Learning From Incomplete and Inaccurate Supervision

Item Type Journal Article

Author Z.-Y. Zhang

Author P. Zhao

Author Y. Jiang

Author Z.-H. Zhou

Abstract In plenty of real-life tasks, strongly supervised information is hard to obtain, and thus weakly supervised learning has drawn considerable attention recently. This paper investigates the problem of learning from incomplete and inaccurate supervision, where only a limited subset of training data is labeled but potentially with noise. This setting is challenging and of great importance but rarely studied in the literature. We notice that in many applications, the limited labeled data are with certain structures, which paves us a way to design effective methods. Specifically, we observe that labeled data are usually with one-sided noise such as the bug detection task, where the identified buggy codes are indeed with defects, while codes checked many times or newly fixed may still have other flaws. Furthermore, when there occurs two-sided noise in the labeled data, we exploit the class-prior information of unlabeled data, which is typically available in practical tasks. We propose novel approaches for the incomplete and inaccurate supervision learning tasks and effectively alleviate the negative influence of label noise with the help of a vast number of unlabeled data. Both theoretical analysis and extensive experiments justify and validate the effectiveness of the proposed approaches. © 1989-2012 IEEE.

Learning from positive and unlabeled data without explicit estimation of class prior

Item Type Conference Paper

Author C. Zhang

Author Y. Hou

Author Y. Zhang

Abstract Learning a classifier from positive and unlabeled data may occur in various applications. It differs from the standard classification problems by the absence of labeled negative examples in the training set. So far, two main strategies have typically been used for this issue: the likely negative examples-based strategy and the class prior-based strategy, in which the likely negative examples or the class prior is required to be obtained in a preprocessing step. In this paper, a new strategy based on the Bhattacharyya coefficient is put forward, which formalizes this learning problem as an optimization problem and does not need a preprocessing step. We first show that with the given positive class conditional probability density function (PDF) and the mixture PDF of both the positive class and the negative class, the class prior can be estimated by minimizing the Bhattacharyya coefficient of the positive class with respect to the negative class. We then show how to use this result in an implicit mixture model of restricted Boltzmann machines to estimate the positive class conditional PDF and the negative class conditional PDF directly to obtain a classifier without the explicit estimation of the class prior. Many experiments on real and synthetic datasets illustrated the superiority of the proposed approach. Copyright © 2020, Association for the Advancement of Artificial Intelligence (www.aaai.org). Learning from positive and unlabeled examples -Finite size sample bounds

Item Type Conference Paper
Author F. Mansouri
Author S. Ben-David
Abstract PU (Positive Unlabeled) learning is a variant of supervised classification learning in which the only labels revealed to the learner are of positively labeled instances. PU learning arises in many real-world applications. Most existing work relies on the simplifying assumptions that the positively labeled training data is drawn from the restriction of the data generating distribution to positively labeled instances and/or that the proportion of positively labeled points (a.k.a. the class prior) is known apriori to the learner. This paper provides a theoretical analysis of the statistical complexity of PU learning under a wider range of setups. Unlike most prior work, our study does not assume that the class prior is known to the learner. We prove upper and lower bounds on the required sample sizes (of both the positively labeled and the unlabeled samples). © 2025 Neural information processing systems foundation. All rights reserved.

Author M.V. Butz

Author W. Nowak

Abstract Improved understanding of complex hydrosystem processes is key to advance water resources research. Nevertheless, the conventional way of modeling these processes suffers from a high conceptual uncertainty, due to almost ubiquitous simplifying assumptions used in model parameterizations/closures. Machine learning (ML) models are considered as a potential alternative, but their generalization abilities remain limited. For example, they normally fail to predict accurately across different boundary conditions. Moreover, as a black box, they do not add to our process understanding or to discover improved parameterizations/closures. To tackle this issue, we propose the hybrid modeling framework FINN (finite volume neural network). It merges existing numerical methods for partial differential equations (PDEs) with the learning abilities of artificial neural networks (ANNs). FINN is applied on discrete control volumes and learns components of the investigated system equations, such as numerical stencils, model parameters, and arbitrary closure/constitutive relations. Consequently, FINN yields highly interpretable results. We demonstrate FINN's potential on a diffusion-sorption problem in clay. Results on numerically generated data show that FINN outperforms other ML models when tested under modified boundary conditions, and that it can successfully differentiate between the usual, known sorption isotherms. Moreover, we also equip FINN with uncertainty quantification methods to lay open the total uncertainty of scientific learning, and then apply it to a laboratory experiment. The results show that FINN performs better than calibrated PDE-based models as it is able to flexibly learn and model sorption isotherms without being restricted to choose among available

parametric models. © 2022. The Authors.

Learning individual roles from video in a smart home

Item Type Conference Paper

Author O. Brdiczka

Author J. Maisonnasse

Author P. Reignier

Author J.L. Crowley

Abstract This paper addresses learning and recognition of individual roles from video data in a smart home environment. The proposed approach is part of a framework for acquiring a high-level contextual model for human behaviour in an intelligent environment. The proposed methods for role learning and recognition are based on Bayesian models. The input is the targets and their properties generated and tracked by a robust video tracking system in the environment. The output is the roles "walking", "standing", "sitting", "interacting with table", "sleeping" for each target. A Bayesian classifier produced good results for a framewise classification of these roles, while a hidden Markov model had even better performance taking into account a priori probabilities of roles and role transitions. A support vector machine produced best classification results. The classifiers had, however, problems to distinguish ambiguous roles like "walking" and "standing" in the environment. The obtained results permit to pass to the next step in future work: learning and recognizing relations and situation.

Abstract Long-tail learning primarily focuses on mitigating the label distribution shift between long-tailed training data and uniformly distributed test data. However, in real-world applications, we often encounter a more intricate challenge where the test label distribution is agnostic. To address this problem, we first theoretically establish the substantial potential for reducing the generalization error if we can precisely estimate the test label distribution. Motivated by the theoretical insight, we introduce a simple yet effective solution called label shift correction (LSC). LSC estimates the test label distribution within the proposed framework of generalized black box shift estimation, and adjusts the predictions from a pre-trained model to align with the test distribution. Theoretical analyses confirm that accurate estimation of test label distribution can effectively reduce the generalization error. Extensive experimental results demonstrate that our method significantly outperforms previous state-of-the-art approaches, especially when confronted with non-uniform test label distribution. Notably, the proposed method is general and complements existing long-tail learning approaches, consistently improving their performance. Learning Minority Class prior to Minority Oversampling

Item Type Conference Paper

Author P. Sadhukhan

Abstract The success of minority oversampling in dealing with class-imbalanced dataset is well manifested by existing approaches. But that do not guarantee the true class of the synthetic minority points. We address the given context in this paper, Learning Minority Class prior to Minority Oversampling (LMCMO). To guarantee the class information of synthetic minority points, we estimate the minority spaces before generating the synthetic minority points. The performance efficiency of the LMCMO oversampled dataset is tested on C4.5 decision tree and Linear Support Vector Machine (SVM) classifier. Empirical evaluations on 21 datasets using four diversified metrics indicate substantial improvement in Linear SVM outcomes of the proposed method over four competing methods. A modest but still significant gain is achieved by our method over other methods on classification using C4.5 decision tree. © 2019 IEEE.

Learning self-driven collective dynamics with graph networks

Item Type Journal Article

Author R. Wang

Author F. Fang

Author J. Cui

Author W. Zheng

Abstract Despite decades of theoretical research, the nature of the self-driven collective motion remains indigestible and controversial, while the phase transition process of its dynamic is a major research issue. Recent methods propose to infer the phase transition process from various artificially extracted features using machine learning. In this thesis, we propose a new order parameter by using machine learning to quantify the synchronization degree of the self-driven collective system from the perspective of the number of clusters. Furthermore, we construct a powerful model based on the graph network to determine the long-term evolution of the self-driven collective system from the initial position of the particles, without any manual features. Results show that this method has strong predictive power, and is suitable for various noises. Our method can provide reference for the research of other physical systems with local interactions. © 2022, The Author(s).

Learning the Regulatory Code of Gene Expression

Item Type Journal Article

Author J. Zrimec

Author F. Buric

Author M. Kokina

Author V. Garcia

Author A. Zelezniak

Abstract Data-driven machine learning is the method of choice for predicting molecular phenotypes from nucleotide sequence, modeling gene expression events including protein-DNA binding, chromatin states as well as mRNA and protein levels. Deep neural networks automatically learn informative sequence representations and interpreting them enables us to improve our understanding of the regulatory code governing gene expression. Here, we review the latest developments that apply shallow or deep learning to quantify molecular phenotypes and decode the cis-regulatory grammar from prokaryotic and eukaryotic sequencing data. Our approach is to build from the ground up, first focusing on the initiating protein-DNA interactions, then specific coding and non-coding regions, and finally on advances that combine multiple parts of the gene and mRNA regulatory structures, achieving unprecedented performance. We thus provide a quantitative view of gene expression regulation from nucleotide sequence, concluding with an information-centric overview of the central dogma of molecular biology. © Copyright © 2021 Zrimec, Buric, Kokina, Garcia and Zelezniak.

Learning to identify container contents through tactile vibration signatures

Item Type Conference Paper

Author C.L. Chen

Author J.O. Snyder

Author P.J. Ramadge

Abstract We examine using a simple contact sensor coupled with standard machine learning algorithms to classify and count objects shaken in a container. The contact sensor measures the resulting vibrations, and these signatures are used to learn a classifier that maps vibration signatures to known object categories. A linear support vector machine trained on labeled vibration signatures achieves a mean binary classification accuracy of 99% over 66 pairs of objects and a mean multi-class classification accuracy of 94% over 12 classes. It is also shown that useful tasks such as approximate counting of objects over the range 1 to 10 is possible. We see potential applications of these ideas in service robots engaged in cleanup and inventory control in labs, workshops, stores, warehouses and homes. © 2016 IEEE.

Learning to Quantify Emphysema Extent: What Labels Do We Need?

Item Type Journal Article

Author S.N. Orting

Author J. Petersen

Author L.H. Thomsen

Author M.M.W. Wille

Author M. De Bruijne

Abstract Accurate assessment of pulmonary emphysema is crucial to assess disease severity and subtype, to monitor disease progression, and to predict lung cancer risk. However, visual assessment is time-consuming and subject to substantial inter-rater variability while standard densitometry approaches to quantify emphysema remain inferior to visual scoring. We explore if machine learning methods that learn from a large dataset of visually assessed CT scans can provide accurate estimates of emphysema extent and if methods that learn from emphysema extent scoring can outperform algorithms that learn only from emphysema presence scoring. Four Multiple Instance Learning classifiers, trained on emphysema presence labels, and five Learning with Label Proportions classifiers, trained on emphysema extent labels, are compared. Performance is evaluated on 600 low-dose CT scans from the Danish Lung Cancer Screening Trial and we find that learning from emphysema presence labels, which are much easier to obtain, gives equally good performance to learning from emphysema extent labels. The best performing Multiple Instance Learning and Learning with Label Proportions classifiers, achieve intra-class correlation coefficients around 0.90 and average overall agreement with raters of 78% and 79% compared to an inter-rater agreement of 83%. © 2013 IEEE.

Learning to Quantify: Methods and Applications (LQ 2021)

Item Type Conference Paper

Author J.J. Del Coz

Author P. González

Author A. Moreo

Author F. Sebastiani

Abstract Learning to Quantify (LQ) is the task of training class prevalence estimators via supervised learning. The task of these estimators is to estimate, given an unlabelled set of data items D and a set of classes $C = \{c_1, \dots, c_{|C|}\}$, the prevalence (i.e., relative frequency) of each class c_i in D . LQ is interesting in all applications of classification in which the final goal is not determining which class (or classes) individual unlabelled data items belong to, but estimating the distribution of the unlabelled data items across the classes of interest. Example disciplines whose interest in labelling data items is at the aggregate level (rather than at the individual level) are the social sciences, political science, market research, ecological modelling, and epidemiology. While LQ may in principle be solved by classifying each data item in D and counting how many such items have been labelled with c_i , it has been shown that this "classify and count" (CC) method yields suboptimal quantification accuracy. As a result, quantification is now no longer considered a mere byproduct of classification and has evolved as a task of its own. The goal of this workshop is bringing together all researchers interested in methods, algorithms, and evaluation measures and methodologies for LQ, as well as practitioners interested in their practical application to managing large quantities of data. © 2021 Owner/Author.

Learning to sample: Counting with complex queries

Item Type Conference Paper**Author** B. Walenz**Author** S. Sintos**Author** S. Roy**Author** J. Yang

Abstract We study the problem of efficiently estimating counts for queries involving complex filters, such as user-defined functions, or predicates involving self-joins and correlated subqueries. For such queries, traditional sampling techniques may not be applicable due to the complexity of the filter preventing sampling over joins, and sampling after the join may not be feasible due to the cost of computing the full join. The other natural approach of training and using an inexpensive classifier to estimate the count instead of the expensive predicate suffers from the difficulties in training a good classifier and giving meaningful confidence intervals. In this paper we propose a new method of learning to sample where we combine the best of both worlds by using sampling in two phases. First, we use samples to learn a probabilistic classifier, and then use the classifier to design a stratified sampling method to obtain the final estimates. We theoretically analyze algorithms for obtaining an optimal stratification, and compare our approach with a suite of natural alternatives like quantification learning, weighted and stratified sampling, and other techniques from the literature. We also provide extensive experiments in diverse use cases using multiple real and synthetic datasets to evaluate the quality, efficiency, and robustness of our approach.

Learning under nonstationarity: Covariate shift and class-balance change

Item Type Journal Article

Author M. Sugiyama

Author M. Yamada

Author M.C. du Plessis

Abstract One of the fundamental assumptions behind many supervised machine-learning algorithms is that training and test data follow the same probability distribution. However, this important assumption is often violated in practice, for example, because of an unavoidable sample selection bias or nonstationarity of the environment. Owing to violation of the assumption, standard machine-learning methods suffer a significant estimation bias. In this article, we consider two scenarios of such distribution change-the covariate shift where input distributions differ and class-balance change where class-prior probabilities vary in classification-and review semi-supervised adaptation techniques based on importance weighting. © 2013 Wiley Periodicals, Inc.

Learning-based epsilon most stringent test for Gaussian samples classification

Item Type Conference Paper
Author L. Fillatre
Author I. Nikiforov
Abstract This paper studies the problem of classifying some Gaussian samples into one of two parametric probabilistic models, also called sources, when the parameter and the a priori probability of each source are unknown. Each source is governed by an univariate normal distribution whose mean is unknown. A training sequence is available for each source in order to compensate the lack of prior information. An almost optimal most stringent test is proposed to solve this classification problem subject to a constrained false alarm probability. This learning-based test minimizes its maximum shortcoming with respect to the most powerful test which knows exactly the parameters of the sources. It also guarantees a prescribed false alarm probability whatever the size of the training sequences. The threshold, the probability of false alarm and the probability of correct detection are calculated analytically. © 2017 IEEE.

Abstract Automatic quantification of the left ventricle (LV) from cardiac magnetic resonance (CMR) images plays an important role in making the diagnosis procedure efficient, reliable, and alleviating the laborious reading work for physicians. Considerable efforts have been devoted to LV quantification using different strategies that include segmentation-based (SG) methods and the recent direct regression (DR) methods. Although both SG and DR methods have obtained great success for the task, a systematic platform to benchmark them remains absent because of differences in label information during model learning. In this paper, we conducted an unbiased evaluation and comparison of cardiac LV quantification methods that were submitted to the Left Ventricle Quantification (LVQuan) challenge, which was held in conjunction with the Statistical Atlases and Computational Modeling of the Heart (STACOM) workshop at the MICCAI 2018. The challenge was targeted at the quantification of 1) areas of LV cavity and myocardium, 2) dimensions of the LV cavity, 3) regional wall thicknesses (RWT), and 4) the cardiac phase, from mid-ventricle short-axis CMR images. First, we constructed a public quantification dataset Cardiac-DIG with ground truth labels for both the myocardium mask and these quantification targets across the entire cardiac cycle. Then, the key techniques employed by each submission were described. Next, quantitative validation of these submissions were conducted with the constructed dataset. The evaluation results revealed that both SG and DR methods can offer good LV quantification performance, even though DR methods do not require densely labeled masks for supervision. Among the 12 submissions, the DR method LDAMT offered the best performance, with a mean estimation error of 301 mm² for the two areas, 2.15 mm for the cavity dimensions, 2.03 mm for RWTs, and a 9.5% error rate for the cardiac phase classification. Three of the SG methods also delivered comparable performances. Finally, we discussed the advantages and disadvantages of SG and DR methods, as well as the unsolved problems in automatic cardiac quantification for clinical practice applications. © 2013 IEEE.

Editor Khan E.

Abstract Despite the increasing demand for safer machine learning practices, the use of Uncertainty Quantification (UQ) methods in production remains limited. This limitation is exacerbated by the challenge of validating UQ methods in absence of UQ ground truth. In classification tasks, when only a usual set of test data is at

hand, several authors suggested different metrics that can be computed from such test points while assessing the quality of quantified uncertainties. This paper investigates such metrics and proves that they are theoretically well-behaved and actually tied to some uncertainty ground truth which is easily interpretable in terms of model prediction trustworthiness ranking. Equipped with those new results, and given the applicability of those metrics in the usual supervised paradigm, we argue that our contributions will help promoting a broader use of UQ in deep learning. Abstract LeQua 2022 is a new lab for the evaluation of methods for “learning to quantify” in textual datasets, i.e., for training predictors of the relative frequencies of the classes of interest in sets of unlabelled textual documents. While these predictions could be easily achieved by first classifying all documents via a text classifier and then counting the numbers of documents assigned to the classes, a growing body of literature has shown this approach to be suboptimal, and has proposed better methods. The goal of this lab is to provide a setting for the comparative evaluation of methods for learning to quantify, both in the binary setting and in the single-label multiclass setting. For each such setting we provide data either in ready-made vector form or in raw document form. © 2022, The Author(s), under exclusive license to Springer Nature Switzerland AG.

Abstract Background: Multiple sclerosis (MS) is a neurologic disease of the central nervous system which affects almost three million people worldwide. MS is characterized by a demyelination process that leads to brain lesions, allowing these affected areas to be visualized with magnetic resonance imaging (MRI). Deep learning techniques, especially computational algorithms based on convolutional neural networks (CNNs), have become a frequently used algorithm that performs feature self-learning and enables segmentation of structures in the image useful for quantitative analysis of MRIs, including quantitative analysis of MS. To obtain quantitative information about lesion volume, it is important to perform proper image preprocessing and accurate segmentation. Therefore, we propose a method for volumetric quantification of lesions on MRIs of MS patients using automatic segmentation of the brain and lesions by two CNNs. Methods: We used CNNs at two different moments: the first to perform brain extraction, and the second for lesion segmentation. This study includes four independent MRI datasets: one for training the brain segmentation models, two for training the lesion segmentation model, and one for testing. Results: The proposed brain detection architecture using binary cross-entropy as the loss function achieved a 0.9786 Dice coefficient, 0.9969 accuracy, 0.9851 precision, 0.9851 sensitivity, and 0.9985 specificity. In the second proposed framework for brain lesion segmentation, we obtained a 0.8893 Dice coefficient, 0.9996 accuracy, 0.9376 precision, 0.8609 sensitivity, and 0.9999 specificity. After quantifying the lesion volume of all patients from the test group using our proposed method, we obtained a mean value of 17,582 mm³. Conclusions: We concluded that the proposed algorithm achieved accurate lesion detection and segmentation with reproducibility corresponding to state-of-the-art software tools and manual segmentation. We believe that this quantification method can add value to treatment monitoring and routine clinical evaluation of MS patients. © 2022 by the authors. Licensee MDPI, Basel, Switzerland.

Leveraging advanced ensemble models to increase building energy performance prediction accuracy in the residential building sector

Item Type Journal Article

Author K. Konhäuser

Author S. Wenninger

Author T. Werner

Author C. Wiethe

Abstract Accurate predictions for buildings' energy performance (BEP) are crucial for retrofitting investment decisions and building benchmarking. With the increasing data availability and popularity of machine learning across disciplines, research started investigating machine learning for BEP predictions. While stand-alone machine learning models showed first promising results, a comprehensive analysis of advanced ensemble models to increase prediction accuracy is missing for annual BEP predictions. We implement and thoroughly tune twelve machine learning models to bridge this research gap, ranging from stand-alone to homogeneous and heterogeneous ensemble learning models. We benchmark their prediction accuracy based on an extensive real-world dataset of over 25,000 German residential buildings. The results provide strong evidence that ensemble models substantially outperform stand-alone machine learning models both on average and in the case of the best-performing model. All models are tested for robustness and systematic bias by evaluating their prediction performance along different building age classes, living

space bins, and several error measures. Extreme gradient boosting as an ensemble model exhibits the highest prediction accuracy, followed by a multilayer perceptron ahead of further ensemble models. We conclude that ensemble models for annual BEP prediction are advantageous compared to stand-alone models and outperform their results in most cases. © 2022 Elsevier B.V.

Leveraging explainable AI for informed building retrofit decisions: Insights from a survey

Item Type Journal Article

Author D. Leuthe

Author J. Mirlach

Author S. Wenninger

Author C. Wiethe

Abstract Accurate predictions of building energy consumption are essential for reducing the energy performance gap. While data-driven energy quantification methods based on machine learning deliver promising results, the lack of Explainability prevents their

widespread application. To overcome this, Explainable Artificial Intelligence (XAI) was introduced. However, to this point, no research has examined how effective these explanations are concerning decision-makers, i.e., property owners. To address this, we implement three transparent models (Linear Regression, Decision Tree, QLattice) and apply four XAI methods (Partial Dependency Plots, Accumulated Local Effects, Local Interpretable Model-Agnostic Explanations, Shapley Additive Explanations) to an Artificial Neural Network using a real-world dataset of 25,000 residential buildings. We evaluate their Prediction Accuracy and Explainability through a survey with 137 participants considering the human-centered dimensions of explanation satisfaction and perceived fidelity. The results quantify the Explainability-Accuracy trade-off in building energy consumption forecasting and how it can be counteracted by choosing the right XAI method to foster informed retrofit decisions. For research, we set the foundation for further increasing the Explainability of data-driven energy quantification methods and their human-centered evaluation. For practice, we encourage using XAI to reduce the acceptance gap of data-driven methods, whereby the XAI method should be selected carefully, as the Explainability within the methods varies by up to 10 %. © 2024 The Author(s)

Leveraging Google Earth Engine and Machine Learning to Estimate Evapotranspiration in a Commercial Forest Plantation

Item Type Journal Article

Author S. Gokool

Author R. Kunz

Author A. Clulow

Author M. Toucher

Abstract Estimation of actual evapotranspiration (ETa) based on reference evapotranspiration (ETo) and the crop coefficient (Kc) remains one of the most widely used ETa estimation approaches. However, its application in non-agricultural and natural environments has been limited, largely due to the lack of well-established Kc coefficients in these environments. Alternate Kc estimation approaches have thus been proposed in such instances, with techniques based on the use of leaf area index (LAI) estimates being quite popular. In this study, we utilised satellite-derived estimates of LAI acquired through the Google Earth Engine geospatial cloud computing platform and machine learning to quantify the water use of a commercial forest plantation situated within the eastern region of South Africa. Various machine learning-based models were trained and evaluated to predict Kc as a function of LAI, with the Kc estimates derived from the best-performing model then being used in conjunction with in situ measurements of ETo to estimate ETa. The ET estimates were then evaluated through comparisons against in situ measurements. An ensemble machine learning model showed the best performance, yielding RMSE and R2 values of 0.05 and 0.68, respectively, when compared against measured Kc. Comparisons between estimated and measured ETa yielded RMSE and R2 values of 0.51 mm d⁻¹ and 0.90, respectively. These results were quite promising and further demonstrate the potential of geospatial cloud computing and machine learning-based approaches to provide a robust and efficient means of handling large volumes of data so that they can be optimally utilised to assist planning and management decisions. © 2024 by the authors.

Abstract Industry 4.0 targets the conversion of the traditional industries into intelligent ones through technological revolution. This revolution is only possible through innovation, optimization, interconnection, and rapid decision-making capability. Numerical models are believed to be the key components of Industry 4.0, facilitating quick decision-making through simulations instead of costly experiments. However, numerical investigation of precise, high-fidelity models for optimization or decision-making is usually time-consuming and computationally expensive. In such instances, data-driven surrogate models are excellent substitutes for fast computational analysis and the probabilistic prediction of the output parameter for new input parameters. The emergence of Internet of Things (IoT) and machine learning (ML) has made the concept of surrogate modeling even more viable. However, these surrogate models contain intrinsic uncertainties, originate from modeling defects, or both. These uncertainties, if not quantified and minimized, can produce a skewed result. Therefore, proper implementation of uncertainty quantification techniques is crucial during optimization, cost reduction, or safety enhancement processes analysis. This chapter begins with a brief overview of the concept of surrogate modeling, transfer learning, IoT, and digital twins. After that, a detailed overview of uncertainties, uncertainty quantification frameworks, and specifics of uncertainty quantification methodologies for a surrogate model linked to a digital twin is presented. Finally, the use of uncertainty quantification approaches in the nuclear industry has been

addressed. © Springer Nature Switzerland AG 2023.

Abstract Maintaining the efficient and dependable operation of power systems requires load forecasting. Integrating Internet of Things (IoT) technologies provides a great opportunity to improve load forecasting accuracy by utilizing detailed data from smart meters, environmental sensors, and grid monitoring devices. This study examines the utilization of IoT-enabled load forecasting models, which encompass machine learning and deep learning techniques, as well as ensemble and hybrid models, to capture intricate patterns and nonlinear associations in

energy usage. This paper focuses on the attributes of IoT-enabled load forecasting, including real-time data processing, scalability, and adaptability. These features allow for a wide range of applications in short-term, medium-term, and long-term forecasting, demand response, renewable energy integration, and energy trading strategies. Although there are notable advantages, there are also problems that need to be acknowledged and resolved, including those related to the accuracy of data, privacy concerns, the ability of different systems to work together, and the complexity of computing processes. Case studies and applications exemplify the effective utilization of IoT-enabled load forecasting in many areas such as short-term grid operations, demand response programs, renewable energy integration, and energy trading. The study explores future research directions, such as advanced data analytics methodologies, edge computing architectures, blockchain integration, and uncertainty quantification methods. Suggestions are given for promoting cooperation among individuals or groups involved in addressing difficulties and promoting the widespread acceptance of smart grids and sustainable energy practices. © The Author(s), under exclusive license to Springer Nature Singapore Pte Ltd. 2026.

Leveraging machine learning predicted confidence for boosting assay submission and decision-making efficiencies

Item Type Journal Article

Author D. Bassani

Author M. Reutlinger

Author H. Fischer

Abstract Machine learning (ML) has become very popular, and its benefits are widely recognized within the scientific community. The ability of ML approaches to leverage large datasets to find patterns among composite single data points has made these approaches widespread across different fields. Small molecule pharmaceutical research has experienced the advantages of these methods for tasks such as molecular property prediction, secondary pharmacology analysis, de novo generation, and compound clustering. Coupling efficient ML models with robust uncertainty quantification methods gives the additional advantage of discriminating among predictions to identify the ones that can be truly reliable. Herein, the Roche experience with ML uncertainty quantification for influencing decision making in pharmacokinetic assay submission is described. After setting up an initial threshold for error acceptance via nonadditivity analysis, the combined efforts of ML and experimental scientists developed an optimal uncertainty threshold in ML models. By excluding compounds with predicted properties that were within a confidence level equal to or greater than the agreed one, the analysis highlights how significant numbers of molecules could potentially be excluded from assay submission (up to 25 % of the normal submission rate), allowing significant time and cost savings for the organization. © 2025 The Authors

Leveraging machine learning to quantify the effect of porosity on mode I delamination in ceramic matrix composites

Item Type Journal Article

Author J. Gunst

Author B. Prorok

Author S. Gururaja

Abstract This work examines the effect of pores on mode I delamination in plain woven ceramic matrix composite (CMC) in the presence of process-induced porosity under a double cantilever beam (DCB) test. A cohesive zone modeling (CZM) approach within a finite element (FE) numerical framework has been used to simulate mode I crack growth. Pore distributions along the crack path have been explicitly modeled at varying porosities between 10%–30%, varying pore geometry, orientation, and location. A Monte Carlo simulation approach has been used to generate reaction load-displacement plots and resistance curves (R-curves) for the stochastic porous distribution within the FE-CZM numerical approach. A subset of the FE-CZM results is used to train a long-short-term memory (LSTM) machine learning (ML) model that considers the pore parameters as variables. The trained ML model is then used to predict reaction load-displacement plots for the remaining porous microstructures, yielding a fairly good match with a considerable speed up in run time. In addition to rapidly predicting material behavior when given a specific pore distribution, the ML model quantifies the impact of different pore parameters, such as size and location, on mode I delamination behavior in woven CMCs. © 2025 Elsevier Ltd

LIBS basics, part III: Deriving the analytical answer - Calibrated solutions with LIBS

Item Type Journal Article
Author S. Buckley
Abstract There are obviously many methods to come to both quantitative calibration and qualitative classification with LIBS. I am often asked what to expect in terms of overall performance. With real-world samples, typical relative standard deviation (RSD) numbers are in the range of 2-3% for many types of analysis. For the most homogenous samples, RSDs less than 1% can be achieved, for example, on obsidian glass samples or gemstones. With both classification and quantification methods, one must be sure to avoid over-fitting and rigorously test any model before deployment. Following the general guidelines here, with a bit of experimentation, should get you a good way toward successful implementation of LIBS.

Life-Cycle Cost Analysis of Exclusive Lanes for Autonomous Trucks Considering the Risk of Intrusion into Adjacent Lanes under Crosswinds: Joint Decision of Lane Width and Lateral Control Modes

Item Type Journal Article

Author J. Chen

Author F. Chen

Abstract To quantify the impact of lane width and truck lateral control modes on the life-cycle cost (LCC) and operational safety of exclusive lanes for autonomous trucks (ATs), this study proposes a LCC framework that considers the risk of ATs intruding into adjacent lanes under crosswind. Based on the maximum lateral deviation data obtained from XFlow-TruckSim, the gradient boosting decision trees (GBDT) model, which performed best among five machine learning methods, was utilized as the risk quantification method. The study considered three lateral control modes for ATs: central distribution, uniform distribution, and normal distribution, evaluating both their safety and the damage they cause to the exclusive lanes. Furthermore, with lane width and truck lateral control modes as decision variables, a multiobjective optimization model was established to incorporate vehicle risk into the life-cycle costs analysis of the exclusive lanes. The trend of risk probability was generally similar to the variation in total life-cycle costs, primarily due to the overwhelming importance of user safety cost. Adopting a exclusive lane width of 3.54 m for AT operation under crosswind is a favorable decision. For already constructed exclusive lanes with a width less than 3.05 m, it is preferable for ATs to adopt a uniform distribution lateral control mode. When the lane width exceeds 3.21 m, centrally traveling ATs become a better choice. If the lane width is between 3.05 and 3.21 m, central travel is generally superior, and it is least recommended for ATs to follow a

uniform distribution lateral control mode. The findings provide crucial guidance for the design of exclusive lanes for ATs and the lateral control modes adopted in their operation postconstruction. The study addresses the conflicting challenge of increasing lane width, which can raise institutional costs while reducing the risk of lateral vehicle accidents. © 2025 American Society of Civil Engineers.

Lightning UQ Box: Uncertainty Quantification for Neural Networks

Item Type Journal Article

Author N. Lehmann

Author N.M. Gottschling

Author J. Gawlikowski

Author A.J. Stewart

Author S. Depeweg

Author E. Nalisnick

Abstract Although neural networks have shown impressive results in a multitude of application domains, the “black box” nature of deep learning and lack of confidence estimates have led to scepticism, especially in domains like medicine and physics where such estimates are critical. Research on uncertainty quantification (UQ) has helped elucidate the reliability of these models, but existing implementations of these UQ methods are sparse and difficult to reuse. To this end, we introduce Lightning UQ Box, a PyTorch-based Python library for deep learning-based UQ methods powered by PyTorch Lightning. Lightning UQ Box supports classification, regression, semantic segmentation, and pixelwise regression applications, and UQ methods from a variety of theoretical motivations. With this library, we provide an entry point for practitioners new to UQ, as well as easy-to-use components and tools for scalable deep learning applications. ©2025 Nils Lehmann, Nina Maria Gottschling, Jakob Gawlikowski, Adam J. Stewart, Stefan Depeweg, and Eric Nalisnick.

Lightweight Conditional Model Extrapolation for Streaming Data under Class-Prior Shift

Item Type Conference Paper

Author P. Tomaszewska

Author C.H. Lampert

Abstract We introduce LIMES, a new method for learning with non-stationary streaming data, inspired by the recent success of meta-learning. The main idea is not to attempt to learn a single classifier that would have to work well across all occurring data distributions, nor many separate classifiers, but to exploit a hybrid strategy: we learn a single set of model parameters from which a specific classifier for any specific data distribution is derived via classifier adaptation. Assuming a multiclass classification setting with class-prior shift, the adaptation step can be performed analytically with only the classifier's bias terms being affected. Another contribution of our work is an extrapolation step that predicts suitable adaptation parameters for future time steps based on the previous data. In combination, we obtain a lightweight procedure for learning from streaming data with varying class distribution that adds no trainable parameters and almost no memory or computational overhead compared to training a single model. Experiments on a set of exemplary tasks using Twitter data show that LIMES achieves higher accuracy than alternative approaches, especially with respect to the relevant real-world metric of lowest within-day accuracy. © 2022 IEEE.

Lipid droplet distribution quantification method based on lipid droplet detection by constrained reinforcement learning

Item Type Journal Article

Author Y. Harada

Author H. Nishida

Author K. Matsuura

Abstract We previously proposed the lipid droplet detection by reinforcement learning (LiDRL) method using a limited dataset of pathological images. The method automatically detects lipid droplets using reinforcement learning to optimize filter combinations based on their size and grayscale contrast. In this study, we aimed to detect lipid droplets reliably and analyze their distribution patterns across pathological tissue images. For this purpose, we improved the environmental and agent-side functions in LiDRL to obtain a revised method. These improvements increased the stability and robustness of the system, enabling consistent extraction of lipid droplets of similar sizes across all rank levels in the pathological tissue images. We quantified the lipid droplet distribution using average probability density and entropy and visualized it as a heat map. This analysis facilitates the extraction of lipid droplet characteristics that could serve as indicators of liver disease. © 2025 Harada et al. “Lipidomics”: Mass spectrometric and chemometric analyses of lipids

Item Type Journal Article

Author Z. Wu

Author G.I. Bagarolo

Author S. Thoröe-Boveleth

Author J. Jankowski

Abstract Lipids are ubiquitous in the human organism and play essential roles as components of cell membranes and hormones, for energy storage or as mediators of cell signaling pathways. As crucial mediators of the human metabolism, lipids are also involved in metabolic diseases, cardiovascular and renal diseases, cancer and/or hepatological and neurological disorders. With rapidly growing evidence supporting the impact of lipids on both the genesis and progression of these diseases as well as patient wellbeing, the characterization of the human lipidome has gained high interest and importance in life sciences and clinical diagnostics within the last 15 years. This is mostly due to technically advanced molecular identification and quantification methods, mainly based on mass spectrometry. Mass spectrometry has become one of the most powerful tools for the identification of lipids. New lipidic mediators or biomarkers of diseases can be analysed by state-of-the art mass spectrometry techniques supported by sophisticated bioinformatics and biostatistics. The lipidomic approach has developed dramatically in the realm of life sciences and clinical diagnostics due to the available mass spectrometric methods and in particular due to the adaptation of biostatistical methods in recent years. Therefore, the current knowledge of lipid extraction methods, mass-spectrometric approaches, biostatistical data analysis, including workflows for the interpretation of lipidomic high-throughput data, are reviewed in this manuscript. © 2020 The Authors

Living apart-together: Microhabitat differentiation of cryptic nematode species in a saltmarsh habitat

Item Type Journal Article

Author R.M. Guden

Author A.-M. Vafeiadou

Author N. De Meester

Author S. Derycke

Author T. Moens

Abstract Coexistence of highly similar species is at odds with ecological theory of competition; coexistence, then, requires stabilizing mechanisms such as differences in ecological niche. In the bacterivore nematode *Litoditis marina* species complex, which occurs associated with macro-algae, four cryptic lineages (Pm I-IV) co-occur in the field along the south-western coast and estuaries of The Netherlands. Here we investigate the temporal and/or spatial niche differentiation in their natural environment using a qPCR-based detection and relative quantification method. We collected different algal species (i.e. two *Fucus* species and *Ulva* sp.) and separated algal structures (i.e. receptacula, thalli, non-fertile tips and bladders) at different

sampling months and times (i.e. twice per sampling month), to examine differences in microhabitat use between coexisting *L. marina* species. Results demonstrate that the cryptic species composition varied among different algal species and algal structures, which was also subject to temporal shifts. Pm I dominated on *Fucus* spp., Pm II showed dominance on *Ulva* sp., while Pm III overall had the lowest frequencies. Microhabitat partitioning was most pronounced between the two cryptic species which had similar microbiomes (Pm I and Pm II), and less so between the two species which had significantly different microbiomes (Pm I and Pm III), suggesting that species which share the same microhabitats may avoid competition through resource partitioning. The interplay of microhabitat differentiation and temporal dynamics among the cryptic species of *L. marina* implies that there is a complex interaction between biotic components and abiotic factors which contributes to their coexistence in the field. © 2018 Guden et al. Abstract This paper presents an innovative and interpretable LiDAR-based architecture for weather condition detection and identification, leveraging the Gray-Level Co-occurrence Matrix (GLCM) and a dedicated AI model. By exploiting the unique spatial characteristics of LiDAR point cloud data, the proposed approach enhances the accuracy and robustness of detecting three distinct weather conditions: clear, rainy, and foggy. The LiDAR point cloud is preprocessed and projected into a discretized map, from which GLCMs are computed and used as input for model training. In addition, interpretability is a core feature of the method, addressed through two complementary techniques. First, an ante-hoc analysis estimates the 2D conditional probability distribution of GLCM features given the weather class prior to training. Second, a post-hoc visualization is enabled via a reshaped weight map that reveals the information learned by the model. The model is evaluated on the RADIATE dataset and benchmarked against three state-of-the-art weather classifiers. Results demonstrate the effectiveness of the LiDAR-GLCM approach and its strong potential for real-time, embedded weather recognition systems. © 2025 IEEE.

LLM Performance Predictors: Learning When to Escalate in Hybrid Human-AI Moderation Systems

Item Type Conference Paper

Author O. Ben-Porat

Author E. Sheetrit

Author J. Morra

Abstract As LLMs are increasingly integrated into human-in-the-loop content moderation systems, a central challenge is deciding when their outputs can be trusted versus when escalation for human review is preferable. We propose a novel framework for supervised LLM uncertainty quantification, learning a dedicated meta-model based on LLM Performance Predictors (LPPs) derived from LLM outputs: log-probabilities, entropy, and novel uncertainty attribution indicators. We demonstrate that our method enables cost-aware selective classification in real-world human-AI workflows: escalating high-risk cases while automating the rest. Experiments across state-of-the-art LLMs, including both off-the-shelf (Gemini, GPT) and open-source (Llama, Qwen), on multimodal and multilingual moderation tasks, show significant improvements over existing uncertainty estimators in accuracy-cost trade-offs. Beyond uncertainty estimation, the LPPs enhance explainability by providing new insights into failure conditions (e.g., ambiguous content vs. under-specified policy). This work establishes a principled framework for uncertainty-aware, scalable, and responsible human-AI moderation workflows. © 2026 International Foundation for Autonomous Agents and Multiagent Systems.

Abstract Traditional cancer rate estimations are often limited in spatial resolutions and lack considerations of environmental factors. Satellite imagery has become a vital data source for monitoring diverse urban environments, supporting applications across environmental, socio-demographic, and public health domains. However, while deep learning (DL) tools, particularly convolutional neural networks, have demonstrated strong performance in extracting features from high-resolution imagery, their reliance on local spatial cues often limits their ability to capture complex, non-local, and higher-order structural information. To overcome this limitation, we propose a novel LLM-based multi-agent coordination system for satellite image analysis, which integrates visual and contextual reasoning through a simplicial contrastive learning framework (Agent-SNN). Our Agent-SNN

contains two augmented superpixel-based graphs and maximizes mutual information between their latent simplicial complex representations, thereby enabling the system to learn both local and global topological features. The LLM-based agents generate structured prompts that guide the alignment of these representations across modalities. Experiments with satellite imagery of Los Angeles and San Diego demonstrate that Agent-SNN achieves significant improvements over state-of-the-art baselines in regional cancer prevalence estimation tasks. © 2025 Copyright held by the owner/author(s).

Loading classification proposal for fatigue design of automotive chassis-parts: A relevant process for variable amplitude and multi-input load cases

Item Type Journal Article

Author E. Bellec

Author C. Doudard

Author M.L. Facchinetti

Author S. Calloch

Author S. Moyne

Abstract It is essential for car manufacturers to ensure their vehicle robustness under a daily usage. As no detailed method nor standard prevails, each manufacturer is expected to setup its own methodology for safety parts life-assessment. The early stages of a renewed methodology are proposed in this study. This is based on proving-grounds measurements analysis to quantify the impact of various loads. The method, developed from the load measured at the vehicle wheels, considers the multi-input load case and its variable amplitude content. Measured time-series are analyzed and partitioned into two main categories depending on the time-correlation between the load axes. The driver-induced loads, Driven-Road, (DR) loads, are separated from the effects of random road conditions, Random-Road, (RR) loads. Then, for partition validation, a suitable life quantification method is applied in parallel to the two types of loading. On one hand, an assumption based on strong physical meaning eases the Rainflow Counting method application on the DR load. On the other hand, the use of spectral methods is explored to handle the random loads. This paper details the partition process of the time-series and each of the subsequent validation steps of the method to apply such a partition. Such a validation is performed via a comparison of the pseudo-damage between a referenced signal and the one issued from the partition. © 2022 Elsevier Ltd

Local similarity discriminant analysis

Item Type Conference Paper

Author L. Cazzanti

Author M.R. Gupta

Abstract We propose a local, generative model for similarity-based classification. The method is applicable to the case that only pairwise similarities between samples are available. The classifier models the local class-conditional distribution using a maximum entropy estimate and empirical moment constraints. The resulting exponential class conditional-distributions are combined with class prior probabilities and misclassification costs to form the local similarity discriminant analysis (local SDA) classifier. We compare the performance of local SDA to a non-local version, to the local nearest centroid classifier, the nearest centroid classifier, k-NN, and to the recently-developed potential support vector machine (PSVM). Results show that local SDA is competitive with k-NN and the computationally-demanding PSVM while offering the advantages of a generative classifier.

Long term analysis of alpine swamp meadow: area and water balance

Item Type Journal Article

Author J. Yang

Author X. Jin

Author Y. Jin

Author X. Mao

Abstract Background and aims: Alpine swamp meadows play a vital role in water conservation and maintaining ecological balance. However, the response mechanisms of its area and hydrological functions under global climate change remain unclear, particularly the impact of permafrost degradation on water storage capacity, which urgently requires quantification. Methods: We integrated multi—temporal Landsat data (2000—2023) and phenological features to construct a classification framework for alpine swamp meadows. A multi—source remote sensing—based water balance assessment method was developed. Random forest importance evaluation and piecewiseSEM were employed to quantify the impacts and pathways of multidimensional driving factors on changes in alpine swamp meadow area and water storage. Results: The phenology—based classification method effectively extracted alpine swamp meadows with a mean producer's accuracy of 92.84%, user's accuracy of 92.14%, and a Kappa coefficient of 0.95. The study found that the spatial expansion of alpine swamp meadows in the watershed showed an "initial decrease followed by an increase" trend, while the water storage capacity continued to decline, indicating a significant decoupling between the two. Conclusion: Under climate change, increased precipitation and reduced snow cover albedo have led to the expansion of alpine swamp meadows, while enhanced evapotranspiration and the degradation of permafrost aquicludes have caused a systematic decline in their water storage capacity. These findings provide a scientific basis for assessing the health of alpine ecosystems and managing water resources under climate change. © The Author(s), under exclusive licence to Springer Nature Switzerland AG 2025.

Long-term vehicle motion prediction

Item Type Conference Paper

Author C. Hermes

Author C. Wohler

Author K. Schenk

Author F. Kummert

Abstract Future driver assistance systems will have to cope with complex traffic situations, especially in the road crossing scenario. To detect potentially hazardous situations as early as possible, it is therefore desirable to know the position and motion of the ego-vehicle and vehicles around it for several seconds in advance. For this purpose, we propose in this study a long-term prediction approach based on a combined trajectory classification and particle filter framework. As a measure for the similarity between trajectories, we introduce the quaternion-based rotationally invariant longest common subsequence (QRLCS) metric. The trajectories are classified by a radial basis function (RBF) classifier with an architecture that is able to process trajectories of arbitrary non-uniform length. The particle filter framework simultaneously tracks and assesses a large number of motion hypotheses (~ 102), where the class-specific probabilities estimated by the RBF classifier are used as a-priori probabilities for the hypotheses of the particle filter. The hypotheses are clustered with a mean-shift technique and are assigned a likelihood value. Motion prediction is performed based on the cluster centre with the highest likelihood. While traditional motion prediction based on curve radius and acceleration is inaccurate especially during turning manoeuvres, we show that our approach achieves a reasonable motion prediction even for long prediction intervals of 3 s for these complex motion patterns. © 2009 IEEE.

LooM: An anonymity quantification method in pervasive computing environments

Item Type Journal Article

Author M. Imada

Author M. Ohta

Author M. Yamaguchi

Author S.Y. Kim

Abstract Purpose: The paper's aim is to present a novel anonymity quantification method, LooM (loosely managed privacy protection method) for achieving privacy protection in pervasive computing environments. Design/methodology/approach: The main feature is that the method quantitatively controls anonymity by a single value (disclosure threshold value) using a classification algorithm of the decision tree. The value is not affected by the set size of users or the distribution of users' private information. The effectiveness of this method is confirmed by simulation using sample databases of attribute-value pairs. Proposes a model of privacy information disclosure that achieves a balance between users' privacy protection requirements and service providers' disclosure requirements and applies web questionnaire survey data to this model. Findings: LooM can be applicable to a variety of pervasive computing and communication services handling a huge amount of data containing privacy information. Originality/value: The paper proposes a model of privacy information disclosure that achieves a balance between users' privacy protection requirements and service providers' disclosure requirements. © Emerald Group Publishing Limited.

LooM: An anonymity quantification method in pervasive computing environments

Item Type Conference Paper

Author M. Imada

Author M. Ohta

Author M. Yamaguchi

Abstract We propose a novel anonymity quantification method for privacy protection in pervasive computing environments. Its main feature is that it can quantitatively control anonymity by a single value (disclosure threshold value) using a classification algorithm of the decision tree. The value is not affected by the user set size or the contents of private information. This property was confirmed by evaluation using sample databases. In order to decide the disclosure threshold value for controlling anonymity, we established a model of privacy information disclosure that achieves a balance (equilibrium point) between users' privacy protection requirements and service providers' disclosure requirements. Applying web questionnaire data to this model, we found the equilibrium point for each service. © 2006 IEEE.

LotBoNC: Novel Botnet Traffic Classification under Long-tailed Distributions

Item Type Conference Paper

Author H. Hu

Author Z. Li

Author C. Doerr

Abstract Botnets are a persistent cyber threat, leveraging global infrastructures to launch large-scale attacks. Yet, most existing classification methods are evaluated under balanced and closed-set assumptions, which fail to capture real-world conditions. In practice, botnet traffic is both long-tailed and open-world: unknown variants continually emerge, and rare threats are buried under dominant traffic, often evading detection. To reflect real-world conditions, we define a deployment-oriented setting where unlabeled traffic follows a long-tailed distribution, with dominant known classes in the head and rare novel botnet variants in the tail. We propose LotBoNC, a unified framework for encrypted traffic classification under long-tailed open-world conditions. LotBoNC first performs self-supervised pre-training to learn transferable representations, then applies entropy-regularized optimal transport to assign pseudo-labels aligned with estimated class priors. An EM-style loop iteratively refines prototypes and priors, improving class

separation between frequent and rare categories. We evaluate LotBoNC on three public encrypted traffic datasets with diverse long-tailed scenarios. LotBoNC consistently outperforms prior state-of-the-art methods and accurately classifies known botnets and discovers unseen botnet variants in diverse, unbalanced open-world scenarios. © 2026 Copyright held by the owner/author(s).

Low Complexity, Low Probability Patterns and Consequences for Algorithmic Probability Applications

Item Type Journal Article

Author M. Alaskandarani

Author K. Dingle

Abstract Developing new ways to estimate probabilities can be valuable for science, statistics, engineering, and other fields. By considering the information content of different output patterns, recent work invoking algorithmic information theory inspired arguments has shown that a priori probability predictions based on pattern complexities can be made in a broad class of input-output maps. These algorithmic probability predictions do not depend on a detailed knowledge of how output patterns were produced, or historical statistical data. Although quantitatively fairly accurate, a main weakness of these predictions is that they are given as an upper bound on the probability of a pattern, but many low complexity, low probability patterns occur, for which the upper bound has little predictive value. Here, we study this low complexity, low probability phenomenon by looking at example maps, namely a finite state transducer, natural time series data, RNA molecule structures, and polynomial curves. Some mechanisms causing low complexity, low probability behaviour are identified, and we argue this behaviour should be assumed as a default in the real-world algorithmic probability studies. Additionally, we examine some applications of algorithmic probability and discuss some implications of low complexity, low probability patterns for several research areas including simplicity in physics and biology, a priori probability predictions, Solomonoff induction and Occam's razor, machine learning, and password guessing. © 2023 Mohammad Alaskandarani and Kamaludin Dingle.

Low-Resource Text Processing with Lightweight Multi-modal Agents: Enhanced Entity Recognition based on Few-Shot Learning

Item Type Conference Paper

Author Y. Zhang

Abstract In the context of low-resource text processing, the scarcity of labeled samples, insufficient semantic expression capabilities, and limited model knowledge calibration abilities are common practical challenges. The named entity recognition task generally faces issues such as decreased generalization performance and insufficient prediction stability. To address this core problem, this paper proposes a lightweight multimodal intelligent entity recognition framework for low-resource text processing. This method first constructs a multi-scale semantic plane representation mechanism, extending the traditional one-dimensional sequence encoding to a two-dimensional span-level semantic modeling structure. This paradigm can enhance the model's ability to express entity boundaries and context-dependent relationships. On this basis, this paper designs the Adaptive Biaffine Span Synthesis (ABSS) algorithm. This algorithm achieves context information fusion through multi-scale expansion convolution and dynamically estimates the importance of different semantic scales using the Scale-Gating Calibration Network (SGCN). Subsequently, this paper proposes a few-shot knowledge injection mechanism based on the Label Semantic Field (LSF). This mechanism realizes dynamic semantic alignment between text span representation and label knowledge by continuously modeling the label description information. At the same time, it enhances the classification ability through the Contrast-Calibrated Interaction (CCI) function. To solve the conflict between internal parameter knowledge and external context knowledge in low-resource environments, this paper constructs a lightweight knowledge reasoning intelligent agent. This paradigm introduces a knowledge conflict quantification method based on Jensen-Shannon divergence and an adaptive uncertainty decision-making mechanism based on information gain. This paper conducted systematic experiments on datasets such as Few-NERD INTRA, Few-NERD INTER, MIT-Restaurant Low-Resource, and a self-built dataset. The experimental results showed that in the 1-shot task of Few-NERD INTER, the method proposed in this paper achieved an F1 value of 42.05%. This result was 6.43 percentage points higher than the optimal baseline AugGPT-NER. Under the conditions of 5-shot and 10-shot, the F1 performance reached 53.96% and 62.38% respectively. On the noisy SME dataset, the method proposed in this paper outperformed StructShot by 8.09 percentage points in the 1-shot scenario. The ablation experiment results indicated that the model performance decreased by 7.75 percentage points after removing the label semantic field module. Meanwhile, the knowledge conflict analysis results showed that the uncertainty-aware reasoning mechanism proposed in this paper could significantly improve the recognition stability of high-conflict samples. © 2026 IEEE.

LUMA: A Benchmark Dataset for Learning from Uncertain and Multimodal Data

Item Type Conference Paper

Author G. Bezirganyan

Author S. Sellami

Author L. Berti-Équille

Author S. Fournier

Abstract Multimodal Deep Learning enhances decision-making by integrating diverse information sources, such as texts, images, audio, and videos. To develop trustworthy multimodal approaches, it is essential to understand how uncertainty impacts these models. We propose LUMA, a unique multimodal dataset, featuring audio, image, and textual data from 50 classes, specifically designed for learning from uncertain data. It extends the well-known CIFAR 10/100 dataset with audio samples extracted from three audio corpora, and text data generated using the Gemma-7B Large Language Model (LLM). The LUMA dataset enables the controlled injection of varying types and degrees of uncertainty to achieve and tailor specific experiments and benchmarking initiatives. LUMA is also available as a Python package including the functions for generating multiple variants of the dataset with controlling the diversity of the data, the amount of noise for each modality, and adding out-of-distribution samples. A baseline pre-trained model is also provided alongside three uncertainty quantification methods: Monte-Carlo Dropout, Deep Ensemble, and Reliable Conflicting Multi-View Learning. This comprehensive dataset and its tools are intended to promote and support the

development, evaluation, and benchmarking of trustworthy and robust multimodal deep learning approaches. We anticipate that the LUMA dataset will help the research community to design more trustworthy and robust machine learning approaches for safety critical applications. The code and instructions for downloading and processing the dataset can be found at: <https://github.com/bezorganyan/LUMA>. © 2025 Copyright held by the owner/author(s).

Lumen segmentation and stenosis quantification of atherosclerotic carotid arteries in CTA utilizing a centerline intensity prior

Item Type Journal Article

Author H. Tang

Author T. Van Walsum

Author R. Hameeteman

Author R. Shahzad

Author L.J. Van Vliet

Author W.J. Niessen

Abstract Purpose: The degree of stenosis is an important biomarker in assessing the severity of cardiovascular disease. The purpose of our work is to develop and evaluate a semiautomatic method for carotid lumen segmentation and subsequent carotid artery stenosis quantification in CTA images. Methods: The authors present a semiautomatic stenosis detection and quantification method following lumen segmentation. The lumen of the carotid arteries is segmented in three steps. First, centerlines of the internal and external carotid arteries are extracted with an iterative minimum cost path approach in which the costs are based on a measure of medialness and intensity similarity to lumen. Second, the lumen boundary is delineated using a level set procedure which is steered by gradient information, regional intensity information, and spatial information. Special effort is made in adding terms based on local centerline intensity prior so as to exclude all possible plaque tissues from the segmentation. Third, side branches in the segmented lumen are removed by applying a shape constraint to the envelope of the maximum inscribed spheres of the segmentation. From the segmented lumen, the authors detect and quantify the cross-sectional area-based and cross-sectional diameter-based stenosis degrees according to the North American Symptomatic Carotid Endarterectomy Trial criterion. Results: The method is trained and tested on a publicly available database from the cls2009 challenge. For the segmentation, the authors obtain a Dice similarity coefficient of 90.2% and a mean absolute surface distance of 0.34 mm. For the stenosis quantification, the authors obtain an average error of 15.7% for cross-sectional diameter-based stenosis and 19.2% for cross-sectional area-based stenosis quantification. Conclusions: With these results, the method ranks second in terms of carotid lumen segmentation accuracy, and first in terms of carotid artery stenosis quantification. © 2013 American Association of Physicists in Medicine.

Abstract Quantification of biofouling is a complex task that often involves counting both isolated and tightly packed groups of organisms on a test surface. Mussel larvae, which settle as both individuals and as clumps, are an important fouling organism because adult mussel colonies form via the settlement of larvae, making the settlement or repellence of mussel larvae a good indicator of a surface's antifouling performance. Manual quantification methods are time-consuming, and existing

automatic machine learning-based methods are poorly suited for use by coding non-experts and often lack the ability to detect both isolated and grouped organisms in one workflow. The objective of this work was to develop a machine learning-based application that is user-friendly and well-suited to the quantification of biofouling. We developed M-Count, an application that combines a neural network object detection model for individual organism detection and a color thresholding algorithm for grouped organism detection. M-Count was demonstrated on the quantification of mussel larvae on sample surface images obtained from a previously developed mussel larvae fouling assay. This study revealed three important characteristics of M-Count: speed, consistency, and accuracy. The primary benefit of M-Count is its speed, being 60× faster than manual counting. The secondary benefit of M-Count is consistency, as it performs the same task repeatedly without bias. Finally, these benefits are obtained while maintaining good accuracy, with the normalized average maximum residual being 0.220 for M-Count and 0.209 for manual counting. Author S.M.A. Zaidi

Author A. Abu-Dayya

Author A. Imran

Abstract In the wake of network densification and multi-band operation in emerging cellular networks, mobility and handover management is becoming a major bottleneck. The problem is further aggravated by the fact that holistic mobility management solutions for different types of handovers, namely inter-frequency and intra-frequency handovers, remain scarce. This paper presents a first mobility management solution that concurrently optimizes inter-frequency related A5 parameters and intra-frequency related A3 parameters. We analyze and optimize five parameters namely A5-time to trigger (TTT), A5-threshold1, A5-threshold2, A3-TTT, and A3-offset to jointly maximize three critical key performance indicators (KPIs): edge user reference signal received power (RSRP), handover success rate (HOSR) and load between frequency bands. In the absence of tractable analytical models due to system level complexity, we leverage machine learning to quantify the KPIs as a function of the mobility parameters. An XGBoost based model has the best performance for edge RSRP and HOSR while random forest outperforms others for load prediction. An analysis of the mobility parameters provides several insights: 1) there exists a strong coupling between A3 and A5 parameters; 2) an optimal set of parameters exists for each KPI; and 3) the optimal parameters vary for different KPIs. We also perform a SHAP based sensitivity to help resolve the parametric conflict between the KPIs. Finally, we formulate a maximization problem, show it is non-convex, and solve it utilizing simulated annealing (SA). Results indicate that ML-based SA-aided solution is more than 14x faster than the brute force approach with a slight loss in optimality. © 2022 IEEE.

Machine learning algorithm based battery modeling and management method: A Cyber-Physical System perspective

Item Type Conference Paper

Author S. Li

Author H. He

Author J. Li

Author P. Yin

Author H. Wang

Abstract In recent years, in order to realize the accurate state monitoring and management of battery, the development of a flexible, self-reconfigurable and reliable model has become one of the most crucial technologies for electric vehicles. This paper mainly focuses on the battery management issues in new energy vehicles, in which the concept of artificial intelligence and grid-connected vehicle is introduced. Firstly, the concept of Cyber-Physical system (CPS) is applied in battery management issues in our work for a better use of battery data. To establish a precise battery model in cloud, the Support vector regression (SVR) algorithm, a classical artificial intelligence algorithm, is used in our work to model the battery. Finally, a rain-flow cycle counting algorithm-based battery degradation quantification method is proposed to deal with the influence of battery aging phenomenon during modeling the battery. © 2019 IEEE.

Machine Learning Algorithms Predict Achievement of Clinically Significant Outcomes After Orthopaedic Surgery: A Systematic Review

Item Type Journal Article

Author K.N. Kunze

Author L.M. Krivich

Author I.M. Clapp

Author B.M. Bodendorfer

Author B.U. Nwachukwu

Author J. Chahla

Author S.J. Nho

Abstract Purpose: To determine what subspecialties have applied machine learning (ML) to predict clinically significant outcomes (CSOs) within orthopaedic surgery and to determine whether the performance of these models was acceptable through assessing discrimination and other ML metrics where reported. Methods: The PubMed, EMBASE, and Cochrane Central Register of Controlled Trials databases were queried for articles that used ML to predict achievement of the minimal clinically important difference (MCID), patient acceptable symptomatic state (PASS), or substantial clinical benefit (SCB) after orthopaedic surgical procedures. Data pertaining to demographic characteristics, subspecialty, specific ML algorithms, and algorithm performance were analyzed. Results: Eighteen articles met the inclusion

criteria. Seventeen studies developed novel algorithms, whereas one study externally validated an established algorithm. All studies used ML to predict MCID achievement, whereas 3 (16.7%) predicted SCB achievement and none predicted PASS achievement. Of the studies, 7 (38.9%) concerned outcomes after spine surgery; 6 (33.3%), after sports medicine surgery; 3 (16.7%), after total joint arthroplasty (TJA); and 2 (11.1%), after shoulder arthroplasty. No studies were found regarding trauma, hand, elbow, pediatric, or foot and ankle surgery. In spine surgery, concordance statistics (C-statistics) ranged from 0.65 to 0.92; in hip arthroscopy, 0.51 to 0.94; in TJA, 0.63 to 0.89; and in shoulder arthroplasty, 0.70 to 0.95. Most studies reported C-statistics at the upper end of these ranges, although populations were heterogeneous. Conclusions: Currently available ML algorithms can discriminate the propensity to achieve CSOs using the MCID after spine, TJA, sports medicine, and shoulder surgery with a fair to good performance as evidenced by C-statistics ranging from 0.6 to 0.95 in most analyses. Less evidence is available on the ability of ML to predict achievement of SCB, and no evidence is available for achievement of the PASS. Such algorithms may augment shared decision-making practices and allow clinicians to provide more appropriate patient expectations using individualized risk assessments. However, these studies remain limited by variable reporting of performance metrics, CSO quantification methods, and adherence to predictive modeling guidelines, as well as limited external validation. Level of Evidence: Level III, systematic review of Level III studies. © 2021 Arthroscopy Association of North America

Machine Learning and Intelligent Diagnostics in Dental and Orofacial Pain Management: A Systematic Review

Item Type Journal Article

Author T.H. Farook

Author N.B. Jamayet

Author J.Y. Abdullah

Author M.K. Alam

Abstract Purpose. The study explored the clinical influence, effectiveness, limitations, and human comparison outcomes of machine learning in diagnosing (1) dental diseases, (2) periodontal diseases, (3) trauma and neuralgias, (4) cysts and tumors, (5) glandular disorders, and (6) bone and temporomandibular joint as possible causes of dental and orofacial pain. Method. Scopus, PubMed, and Web of Science (all databases) were searched by 2 reviewers until 29th October 2020. Articles were screened and narratively synthesized according to PRISMA-DTA guidelines based on predefined eligibility criteria. Articles that made direct reference test comparisons to human clinicians were evaluated using the MI-CLAIM checklist. The risk of bias was assessed by JBI-DTA critical appraisal, and certainty of the evidence was evaluated using the GRADE approach. Information regarding the quantification method of dental pain and disease, the conditional characteristics of both training and test data cohort in the machine learning, diagnostic outcomes, and diagnostic test comparisons with clinicians, where applicable, were extracted. Results. 34 eligible articles were found for data synthesis, of which 8 articles made direct reference comparisons to human clinicians. 7 papers scored over 13 (out of the evaluated 15 points) in the MI-CLAIM approach with all papers scoring 5+ (out of 7) in JBI-DTA appraisals. GRADE approach revealed serious risks of bias and inconsistencies with most studies containing more positive cases than their true prevalence in order to facilitate machine learning. Patient-perceived symptoms and clinical history were generally found to be less reliable than radiographs or histology for training accurate machine learning models. A low agreement level between clinicians training the models was suggested to have a negative impact on the prediction accuracy. Reference comparisons found nonspecialized clinicians with less than 3 years of experience to be disadvantaged against trained models. Conclusion. Machine learning in dental and orofacial healthcare has shown respectable results in diagnosing diseases with symptomatic pain and with improved future iterations and can be used as a diagnostic aid in the clinics. The current review did not internally analyze the machine learning models and their respective algorithms, nor consider the confounding variables and factors responsible for shaping the orofacial disorders responsible for eliciting pain. © 2021 Taseef Hasan Farook et al.

Machine learning approaches for brain morphology analysis in MR images

Item Type Conference Paper

Author S. Kobashi

Author S.B. Alam

Author M. Nii

Abstract Brain shape deforms by aging and/or brain disorders. In order to reduce the radiologists' subjective evaluation, automated quantification method of brain magnetic resonance (MR) images is required. This paper introduces a machine learning algorithm into automated quantification of the brain morphology condition. The first application is to estimate the brain age, and the second application is to estimate Mini-Mental State Examination (MMSE). The method is applied to OASIS database. © 2016, Fuji Technology Press. All rights reserved.

Machine Learning Assisted Image Analysis for Microalgae Prediction

Item Type Journal Article

Author K. Meenatchi Sundaram

Author S. Sravan Kumar

Author A. Deshpande

Author S. Chinnadurai

Author K. Rajendran

Abstract Microalgae-based wastewater treatment has resulted in a paradigm shift toward nutrient removal and simultaneous resource recovery. However, traditionally used microalgal biomass quantification methods are time-consuming and costly, limiting their large-scale use. The aim of this study is to develop a simple and cost-effective image-based method for microalgae quantification, replacing cumbersome traditional techniques. In this study, preprocessed microalgae images and associated optical density data were utilized as inputs. Three feature extraction methods were compared alongside eight machine learning (ML) models, including linear regression (LR), random forest (RF), AdaBoost, gradient boosting (GB), and various neural networks. Among these algorithms, LR with principal component analysis achieved an R^2 value of 0.97 with the lowest error of 0.039. Combining image analysis and ML removes the need for expensive equipment in microalgae quantification. Sensitivity analysis was performed by varying the train-test splitting ratio. Training time was included in the evaluation, and accounting for energy consumption in the study leads to the achievement of high model performance and energy-efficient ML model utilization. © 2024 American Chemical Society.

Machine learning enhanced predictions of ICRF heating: Overcoming numerical limitations via data curation

Item Type Journal Article**Author** A. Sanchez-Villar**Author** Z. Bai**Author** N. Bertelli**Author** E.W. Bethel**Author** J. Hillairet**Author** T. Perciano**Author** S. Shiraiwa**Author** G.M. Wallace**Author** J.C. Wright

Abstract In this work, we present the development of robust surrogate models for Ion Cyclotron Range of Frequencies (ICRF) and High-Harmonic Fast Wave (HHFW) heating predictions in fusion plasmas. Building upon our previous efforts to achieve real-time capable models, we identify the cause of the outliers found using TORIC in certain HHFW heating scenarios. The outliers are observed to be spurious ion Bernstein wave (IBW)-like modes caused by a wavelength control algorithm designed to address challenging scenarios with high perpendicular wavenumbers. The effect arises from the modulation in the perpendicular susceptibility, which can induce sign reversal and IBW-like propagation for scenarios featuring normalized ion Larmor radius $\lambda_i \gg 1$. We use TORIC with this algorithm disabled to generate a novel HHFW-NSTX database that is free of outliers. Surrogate models trained on this database, including Random Forest Regressor (RFR), Multi-Layer Perceptrons, and Gaussian Process Regressors (GPR), demonstrate the ability to accurately predict HHFW heating profiles, with regression scores of $R^2 \in [0.93 - 0.99]$. Additionally we demonstrate that it is possible to generalize predictions beyond training data by the use of both RFR and GPR models, enabling the prediction of scenarios previously

limited to the original model. GPR models also provide uncertainty quantification, offering insights into model confidence. This work introduces a comprehensive Verification, Validation, and Uncertainty Quantification methodology for surrogate modeling, applicable not only to ICRF heating but also to other RF heating challenges and fusion physics problems. Beyond accelerated inference, these models show effective extrapolation capabilities, providing an alternative for addressing numerical challenges. © 2025 Author(s).

Author W. Fu

Abstract The combined strategy of vehicle electrification and traffic intelligence is a viable option for decarbonizing road transport and improving energy efficiency. However, the difficulty in quantifying the energy saving potential hinders the sustainability of this strategy. This study combines Markov chains and machine learning to quantify the energy saving potential of new energy vehicles (NEVs) under all-mode Intelligent Transportation Speed Guidance System (ITSGS). The combined strategy of Multi-Intersection ITSGS (MITSGS) and NEVs (plug-in hybrid electric vehicle, PHEV and battery electric vehicle, BEV) has significant energy saving potentials of up to 21% and 79%, respectively, when compared to Internal Combustion Engine Vehicle (ICEV) without ITSGS. For the PHEV, the energy consumption model and reported results correspond to charge-sustaining operation. The energy consumption of other combination strategies is as follows. When without ITSGS, the average energy consumption of ICEV, PHEV and BEV is 0.62 ± 0.07 kWh/km, 0.56 ± 0.05 kWh/km and 0.15 ± 0.01 kWh/km, respectively. When with single-intersection ITSGS (SITSGS), these values are 0.56 ± 0.04 kWh/km, 0.52 ± 0.04 kWh/km, 0.14 ± 0.01 kWh/km. When with MITSGS, these values are 0.54 ± 0.04 kWh/km, 0.49 ± 0.04 kWh/km, 0.13 ± 0.01 kWh/km. ITSGS reduces energy consumption by improving vehicle driving behavior at intersections. The framework harmonizes the energy consumption assessment scales of full-mode ITSGS and NEVs combination strategies, which is helpful for the promotion and popularization of combination strategies. This framework uniquely harmonizes scenario-based driving cycles with machine learning to enable consistent, quantifiable evaluation of energy saving potentials across different ITSGS modes and vehicle types. © 2026 Taylor & Francis Group, LLC.

Machine learning in the prediction of cardiac epicardial and mediastinal fat volumes

Item Type Journal Article

Author É.O. Rodrigues

Author V.H.A. Pinheiro

Author P. Liatsis

Author A. Conci

Abstract We propose a methodology to predict the cardiac epicardial and mediastinal fat volumes in computed tomography images using regression algorithms. The obtained results indicate that it is feasible to predict these fats with a high degree of correlation, thus alleviating the requirement for manual or automatic segmentation of both fat volumes. Instead, segmenting just one of them suffices, while the volume of the other may be predicted fairly precisely. The correlation coefficient obtained by the Rotation Forest algorithm using MLP Regressor for predicting the mediastinal fat based on the epicardial fat was 0.9876, with a relative absolute error of 14.4% and a root relative squared error of 15.7%. The best correlation coefficient obtained in the prediction of the epicardial fat based on the mediastinal was 0.9683 with a relative absolute error of 19.6% and a relative squared error of 24.9%. Moreover, we analysed the feasibility of using linear regressors, which provide an intuitive interpretation of the underlying approximations. In this case, the obtained correlation coefficient was 0.9534 for predicting the mediastinal fat based on the epicardial, with a relative absolute error of 31.6% and a root relative squared error of 30.1%. On the prediction of the epicardial fat based on the mediastinal fat, the correlation coefficient was 0.8531, with a relative absolute error of 50.43% and a root relative squared error of

52.06%. In summary, it is possible to speed up general medical analyses and some segmentation and quantification methods that are currently employed in the state-of-the-art by using this prediction approach, which consequently reduces costs and therefore enables preventive treatments that may lead to a reduction of health problems. © 2017 Elsevier Ltd

Machine learning of three-dimensional subsurface geological model for a reclamation site in Hong Kong

Item Type Journal Article

Author C. Shi

Author Y. Wang

Abstract Land reclamation from ocean is a major solution to deal with land shortage in coastal megacities such as Hong Kong. The primary geotechnical risk associated with land reclamation is consolidation of fine-grained materials, e.g., soft marine deposit, and a sound understanding of spatial distribution of three-dimensional (3D) subsurface soil layer boundaries, or interfaces, and their stratigraphic connectivity to surrounding drainage boundaries is a prerequisite for an effective reclamation design. In practice, accurate delineation of 3D subsurface stratigraphic boundaries is challenging due to a lack of effective tools for building 3D subsurface geological domains from limited site-specific data while taking full account of geological uncertainty. In this study, a novel stratigraphic modelling and uncertainty quantification method, called 3D iterative convolution eXtreme Gradient Boosting (IC-XGBoost3D), is adopted for automatically developing 3D subsurface geological domains from limited measurements. IC-XGBoost3D roots in deep learning and learns typical stratigraphic features from a pair of perpendicular training images reflecting local prior geological knowledge. The method is physics-informed and data-driven and can efficiently build and update subsurface geological models from limited site-specific data with quantified uncertainty. The method is applied to develop the 3D subsurface geological domain of a reclamation site in Hong Kong. The model performance is evaluated statistically using leave-one-out cross-validation. Results indicate that complex depositional stratigraphic patterns of fine-grained materials at the reclamation site can reasonably be replicated. Effects of measurement data number on the model performance are investigated, and useful insights are gained for developing subsurface geological domains of reclamation sites. © 2022, Springer-Verlag GmbH Germany, part of Springer Nature.

Abstract The COVID-19 pandemic sparked an online “infodemic” of potentially dangerous misinformation. We use machine learning to quantify COVID-19 content from opponents of establishment health guidance, in particular vaccination. We quantify this content in two different ways: number of topics and evolution of keywords. We find that, even in the early stages of the pandemic, the anti-vaccination community had the infrastructure to more effectively garner support than their pro-vaccination counterparts by exhibiting a broader array of discussion topics. This provided an advantage in terms of attracting new users seeking COVID-19 guidance online. We also find that our machine learning framework can pick up on the adaptive nature of discussions within the anti-vaccination community, tracking distrust of authorities, opposition to lockdown orders, and an interest in early vaccine trials. Our approach is scalable and hence tackles the urgent problem facing social media platforms of having to analyze huge volumes of online health misinformation. With vaccine booster shots being approved and vaccination rates stagnating, such an automated approach is key in understanding how to combat the misinformation that slows the eradication of the pandemic. © 2022, The Author(s), under exclusive license to Springer Nature Switzerland AG.

Machine learning techniques to increase the performance of indirect methane quantification from a single, stationary sensor

Item Type Journal Article**Author** R.S. Heltzel**Author** D.R. Johnson**Author** M.T. Zaki**Author** A.K. Gebreslase**Author** O.I. Abdul-Aziz

Abstract Researchers are searching for ways to better quantify methane emissions from natural gas infrastructure. Current indirect quantification techniques (IQTs) allow for more frequent or continuous measurements with fewer personnel resources than direct methods but lack accuracy and repeatability. Two IQTs are Other Test Method (OTM) 33A and Eddy Covariance (EC). We examined a novel approach to improve the accuracy of single sensor IQT whereby the results from both OTM and EC were combined with two machine learning (ML) models, a random forest (RF) and a neural network (NN). Then, models were enhanced with feature reduction and hyperparameter tuning and compared to traditional quantification methods. The NN and RF

improved upon the default OTM by an average of 44% and 78%, respectively. When compared to traditional OTM estimates with low Data Quality Indicators (DQIs), RF and NN models reduced 1σ errors from $\pm 66\%$ to $\pm 13\%$ and $\pm 34\%$, respectively. Models also reduced the standard deviation of estimates with 93% and 85% of estimates falling within $\pm 50\%$ of the known release rate. This approach can be deployed with single sensor systems at well sites to improve confidence in reported emissions, reducing the number of anomalous overestimates that would trigger unnecessary site evaluations. Additional improvements could be realized by expanding training datasets with more methane release rates. Further, deployment of such models in a variety of situations could enhance their ability help close the gap between bottom-up inventory and top-down studies by enabling continuous monitoring of temporal emissions that could identify with improved confidence, atypically higher emissions. Accurate remote single sensor systems are key in developing an improved understanding of methane emissions to enable industry to identify and reduce methane emissions. © 2022

Machine learning to detect, classify, and count blackbirds damaging agriculture using drone-based imagery: Supporting AI-driven automation for deployment of damage management tools

Item Type Journal Article**Author** J.L. Duttonhefner**Author** A.A. ElSaid**Author** P.E. Klug

Abstract As human populations expand and land use changes, human-wildlife conflicts are increasing, requiring cost-effective management tools that balance human well-being and wildlife conservation. Hazing devices are often used to mitigate conflicts between wildlife and agriculture with drones serving as both frightening devices and monitoring systems. Artificial intelligence (AI) enables automated detection, identification, and counting of wildlife, allowing for field-based Internet of Things (IoT) systems to selectively deploy tools when target species reach a critical threshold. We acquired drone imagery of mixed-species blackbird flocks – dominated by red-winged blackbirds (RWBL) *Agelaius phoeniceus* – damaging sunflowers (*Helianthus annuus*) in North Dakota (September–October 2021–2022). We trained a ResNet-18 Convolutional Neural Network (CNN) model to A) detect flocks (accuracy = 95.0 %); and Faster Region-based Convolutional Neural Network (Faster-RCNN) models to B) detect individual blackbirds (accuracy = 65.7 %, precision = 97.6 %), C) classify individual blackbirds by species and for RWBL sex and age class, and D) count blackbirds (% difference: birds = 37.5 %; male RWBL = 39.6 %; female RWBL = 43.1 %). The model correctly classified RWBL to species (87.6 %), sex, and age class (adult males = 89.8 %; hatch-year males = 27.6 %; females = 80.0 %). The RWBL were misclassified as other blackbirds that inflict crop damage, not non-target species. Variability in background (e.g., sky, green vegetation, tan vegetation) and complexity (e.g., contrast, texture), along with bird camouflage, required background removal to enhance performance when moving drones captured still images of moving targets. Camera orientation (e.g., depth perception, target overlap) and image quality (e.g., blurred, shadowed objects) affected detection, classification, and counts. Automated deployment reduces labor and wildlife habituation, increasing longevity and efficacy of management tools. Copyright © 2025. Published by Elsevier B.V.

Machine learning to quantify habitual physical activity in children with cerebral palsy

Item Type Journal Article**Author** B.I. Goodlich**Author** E.L. Armstrong**Author** S.A. Horan**Author** E. Baque**Author** C.P. Carty**Author** M.N. Ahmadi**Author** S.G. Trost

Abstract Aim: To investigate whether activity-monitors and machine learning models could provide accurate information about physical activity performed by children and adolescents with cerebral palsy (CP) who use mobility aids for ambulation. Method: Eleven participants (mean age 11y [SD 3y]; six females, five males) classified in Gross Motor Function Classification System (GMFCS) levels III and IV, completed six physical activity trials wearing a tri-axial accelerometer on the wrist, hip, and thigh. Trials included supine rest, upper-limb task, walking, wheelchair propulsion, and cycling. Three supervised learning algorithms (decision tree, support vector machine [SVM], random forest) were trained on features in the raw-acceleration signal. Model-performance was evaluated using leave-one-subject-out cross-validation accuracy. Results: Cross-validation accuracy for the single-placement models ranged from 59% to 79%, with the best performance achieved by the random forest wrist model (79%). Combining features from two or more accelerometer placements significantly improved classification accuracy. The random forest wrist and hip model achieved an overall accuracy of 92%, while the SVM wrist, hip, and thigh model achieved an overall accuracy of 90%. Interpretation: Models trained on features in the raw-acceleration signal may provide accurate recognition of clinically relevant physical activity behaviours in children and adolescents with CP who use mobility aids for ambulation in a controlled setting. What this paper adds: Machine learning may assist clinicians in evaluating the efficacy of surgical and therapy-based interventions. Machine learning may help researchers better understand the short- and long-term benefits of physical activity for children with more severe motor impairments. © 2020 Mac Keith Press

Abstract In human lupus nephritis, tubulointerstitial inflammation (TII) is associated with in situ expansion of B cells expressing anti-vimentin antibodies (AVAs). The mechanism by which AVAs are selected is unclear. Herein, we demonstrate that AVA somatic hypermutation (SHM) and selection increase affinity for vimentin. Indeed, germline reversion of several antibodies demonstrated that higher affinity AVAs can be selected from both low affinity B cell germline clones and even those that are strongly reactive with other autoantigens. While we demonstrated affinity maturation, enzyme-linked immunosorbent assays (ELISAs) suggested that affinity maturation might be a consequence of increasing polyreactivity or even non-specific binding. Therefore, it was unclear if there was also selection for increased specificity. Subsequent multi-color confocal microscopy studies indicated that while TII AVAs often appeared polyreactive by ELISA, they bound selectively to vimentin fibrils in whole cells or inflamed renal tissue. Using a novel machine learning pipeline (CytoSkaler) to quantify the cellular distribution of antibody staining, we demonstrated that TII AVAs were selected for both enhanced binding and specificity in situ. Furthermore, reversion of single predicted amino acids in antibody variable regions indicated that we could use CytoSkaler to capture both negative and positive selection events. More broadly, our data suggest a new approach to assess and define antibody polyreactivity based on quantifying the distribution of binding to native and contextually relevant antigens. © Copyright © 2020 Kinloch, Asano, Mohsin, Henry, Abraham, Chang, Labno, Wilson and Clark.

Author R.N. Boyd

Author S.G. Trost

Abstract Pattern recognition methodologies, such as those utilizing machine learning (ML) approaches, have the potential to improve the accuracy and versatility of accelerometer-based assessments of physical activity (PA). Children with cerebral palsy (CP) exhibit significant heterogeneity in relation to impairment and activity limitations; however, studies conducted to date have implemented “one-size fits all” group (G) models. Group-personalized (GP) models specific to the Gross Motor Function Classification (GMFCS) level and fully-personalized (FP) models trained on individual data may provide more accurate assessments of PA; however, these

approaches have not been investigated in children with CP. In this study, 38 children classified at GMFCS I to III completed laboratory trials and a simulated free-living protocol while wearing an ActiGraph GT3X+ on the wrist, hip, and ankle. Activities were classified as sedentary, standing utilitarian movements, or walking. In the cross-validation, FP random forest classifiers (99.0–99.3%) exhibited a significantly higher accuracy than G (80.9–94.7%) and GP classifiers (78.7–94.1%), with the largest differential observed in children at GMFCS III. When evaluated under free-living conditions, all model types exhibited significant declines in accuracy, with FP models outperforming G and GP models in GMFCS levels I and II, but not III. Future studies should evaluate the comparative accuracy of personalized models trained on free-living accelerometer data. © 2020 by the authors. Licensee MDPI, Basel, Switzerland.

Machine learning to quantify techno-functional properties - A case study for gel stiffness with pea ingredients

Item Type Journal Article

Author A. Lie-Piang

Author A. Garre

Author T. Nissink

Author N. van Beek

Author A. van der Padt

Author R. Boom

Abstract Mildly refined ingredients are included more easily in food products when selected based on techno-functional properties instead of composition. We assess different machine learning methods that quantitatively link relevant techno-functional properties to the composition and processing history of the ingredient in a case study using the gel stiffness (Young's modulus) by conventionally and mildly refined ingredients of yellow pea. Linear (multiple, log transformed and polynomial) and non-linear models (spline regression, decision trees, and neural networks) were explored. The final model selection was based on 1) the statistical model metrics (RMSE, R2, and MAE) of the training and independent test set and 2) expert knowledge to evaluate the plausibility of the model predictions. In this case, neural networks can describe the gel stiffness of yellow pea ingredients most accurately. The approach that we follow can be applied to other techno-functional properties to improve the chain sustainability while ensuring the full functionality of the products. © 2022

Abstract Micron-scale metal-based composite powders are promising for energetic applications due to their tailored ignition and combustion properties. In particular, ball-milled Al/Zr composites exhibit lower ignition thresholds than pure aluminum, driven by exothermic intermetallic formation reactions and have demonstrated enhanced combustion properties. However, the extent to which this heat release governs ignition and combustion remains unclear, especially when progressively removed through annealing. To systematically investigate this effect, we synthesized Al/Zr powders (3Al:Zr, Al:Zr, and Al:3Zr) via ball milling, annealed them in argon up to 1000 °C to partially complete the formation reactions, and characterized their ignition and combustion behavior. Ignition thresholds were measured using a hot wire method across different environments, while high-speed hyperspectral imaging tracked single-particle burn durations and temperatures. A machine-learning approach utilizing convolutional neural networks (CNNs) was developed to quantify the frequency of microexplosions. Results show that annealing – and thus reducing available reaction heat – increases ignition thresholds, most significantly for Al-rich compositions. In contrast, Zr-rich powders exhibit little change in ignition thresholds due to oxidation aiding ignition. Despite removing the available heat that drives ignition, average combustion temperatures range from 2400 K to 3000 K and increased with annealing for Al- and Zr-rich powders. Average maximum temperatures are 100 to 400 K higher. The frequency of microexplosions remains high (>46%) and increases with annealing for all but the Al-rich powders. These findings suggest that while homogeneous Al/Zr powders (e.g., atomized) may exhibit higher ignition thresholds, they can achieve comparable combustion performance once ignited. **Novelty and Significance Statement** While previous studies have explored how powder chemistry and milling conditions affect the ignition behavior of ball-milled composites, none have directly examined how removing exothermic heat from intermixing and formation reactions influences ignition thresholds and combustion behavior. This is the first study to investigate multiple Al/Zr

stoichiometries in ball-milled composite powders that were annealed to form pre-existing intermetallics, and to evaluate how this controlled intermetallic formation affects combustion performance by comparing as-milled and annealed powders at each stoichiometry. Microexplosion frequency of single particles was quantified using a novel convolutional neural network pipeline; to our knowledge, this is the first application of deep learning to quantify microexplosions in single-particle or plume experiments. © 2025

Machine learning-assisted intelligent interpretation of distributed fiber optic sensor data for automated monitoring of pipeline corrosion

Item Type Journal Article

Author Y. Liu

Author X. Tan

Author Y. Bao

Abstract Distributed fiber optic sensor (DFOS) offers unique capabilities of monitoring corrosion for long pipelines. However, manually interpreting DFOS data is labor-intensive and time-consuming. To address this challenge, this paper presents a machine learning approach for real-time automatic interpretation of DFOS data used to monitor both uniform and non-uniform corrosion in pipeline. A machine learning model is developed to automatically detect corrosion based on DFOS data, and a corrosion quantification method is developed based on the output of the machine learning model. The proposed approaches are evaluated using laboratory experiments in terms of accuracy and robustness to pipeline diameter, spatial resolution of DFOS, type of fiber optic cable, and sensor installation methods. The results show that the F1 score for corrosion detection and the R2 value for corrosion quantification are 0.986 and 0.953, respectively. This research will facilitate pipeline corrosion monitoring by enabling automatic distributed sensor data interpretation. © 2024 Elsevier Ltd

Machine learning-based acoustic emission technique for corrosion-induced damage monitoring in reinforced concrete structures

Item Type Journal Article

Author A. Thirumalaiselvi

Author S. Sasmal

Abstract Early-stage detection of corrosion in reinforcement embedded inside concrete, generally considered as the major problem in structures under extreme marine environments, can help to schedule timely maintenance/repair and to avoid any catastrophic failure. However, quantitative evaluation of the degree of deterioration, especially at a very early stage, i.e., before its appearance on the surface, is extremely difficult due to the complex process in heterogeneous material. This study aims to characterize the critical damage stages in reinforced concrete specimens under accelerated conditions using the Acoustic emission (AE) damage quantification methods supported by machine learning (ML) techniques. The stages of corrosion-induced damage are predicted by a two-step predictive model that involve both regression and classification tasks. Three supervised regression models — support vector regression (SVR), relevance vector machine (RVM) and kernel ridge regression (KRR) — are first adopted to evaluate the amount of current. Then the output from regression model is given as an input to the classification problem to predict the discrete class label output. Characterized damage stages are validated based on mass loss and crack width measurements. The results show that the corrosion initiation (at day 3) and crack formation (at day 7) can be determined from the sudden change in acoustic parameters. Further, a double layer (supervised-unsupervised) model is proposed which is found to be more effective in correctly detecting the progression of damage. The findings indicate that the proposed approach that combines corrosion detection by analysing AE signals with ML technique can accurately and robustly predict corrosion severity. © 2024 Elsevier Ltd

Abstract Introduction: Neuroinflammation evaluation after acute ischemic stroke is a promising option for selecting an appropriate post-stroke treatment strategy. To assess neuroinflammation in vivo, translocator protein PET (TSPO PET) can be used. However, the gold standard TSPO PET quantification method includes a 90 min scan and continuous arterial blood sampling, which is challenging to perform on a routine basis. In this work, we determine what information is required for a simplified

quantification approach using a machine learning algorithm. **Materials and Methods:** We analyzed data from 18 patients with ischemic stroke who received 0–90 min [18F]GE-180 PET as well as T1-weighted (T1w), FLAIR, and arterial spin labeling (ASL) MRI scans. During PET scans, five manual venous blood samples at 5, 15, 30, 60, and 85 min post injection (p.i.) were drawn, and plasma activity concentration was measured. Total distribution volume (VT) was calculated using Logan plot with the full dynamic PET and an image-derived input function (IDIF) from the carotid arteries. IDIF was scaled by a calibration factor derived from all the measured plasma activity concentrations. The calculated VT values were used for training a random forest regressor. As input features for the model, we used three late PET frames (60–70, 70–80, and 80–90 min p.i.), the ASL image reflecting perfusion, the voxel coordinates, the lesion mask, and the five plasma activity concentrations. The algorithm was validated with the leave-one-out approach. To estimate the impact of the individual features on the algorithm's performance, we used Shapley Additive Explanations (SHAP). Having determined that the three late PET frames and the plasma activity concentrations were the most important features, we tested a simplified quantification approach consisting of dividing a late PET frame by a plasma activity concentration. All the combinations of frames/samples were compared by means of concordance correlation coefficient and Bland-Altman plots. **Results:** When using all the input features, the algorithm predicted VT values with high accuracy ($87.8 \pm 8.3\%$) for both lesion and non-lesion voxels. The SHAP values demonstrated high impact of the late PET frames (60–70, 70–80, and 80–90 min p.i.) and plasma activity concentrations on the VT prediction, while the influence of the ASL-derived perfusion, voxel coordinates, and the lesion mask was low. Among all the combinations of the late PET frames and plasma activity concentrations, the 70–80 min p.i. frame divided by the 30 min p.i. plasma sample produced the closest VT estimate in the ischemic lesion. **Conclusion:** Reliable TSPO PET quantification is achievable by using a single late PET frame divided by a late blood sample activity concentration. © 2022

Machine Learning-based Modeling and Uncertainty Quantification for Radar Cross Section of a Cone-like Target

Item Type Conference Paper

Author D. Guo

Author J. Zhai

Author X. Xie

Author H. Yin

Author Y. Zhu

Abstract Radar cross section (RCS) plays an important role in the recognition of targets. RCS varies dramatically with the incident angle and the size of targets, and it is difficult to accurately predict the RCS values. In this paper, an efficient modeling and uncertainty quantification method based on the support vector machine and the k-nearest neighbor is proposed for the RCS prediction of cone-like targets. The proposed method is compared with two uncertainty quantification methods, an ensemble based on lower upper bound estimation and a neural network with dropout. The root mean square error, the prediction interval coverage probability, the mean prediction interval width and the computation time are used as the

performance metrics, and the experimental results demonstrate that the proposed method is superior to the compared methods in accuracy and efficiency. © 2022 IEEE.

Machine Learning-Based Monitoring of Chemical Contamination from Drilling Leaks

Item Type Journal Article

Author J. Sun

Author Y. Ai

Author K. Tang

Author Z. Zhang

Abstract With the increasing requirements for environmental protection in oil and gas field development, the leakage during drilling and the chemical pollution caused by it have become the key technical difficulties restricting sustainable development. In this study, a set of intelligent monitoring and risk assessment system integrating multi-

source data is constructed, based on three uncertainty quantification methods, namely, Dropout Bayesian Approximation, Density Network Integration, and Mixed Density Network (MDN), to deeply mine and distribute the drilling parameter and chemical detection data of 17 wells. To address the limitations of the traditional methods, which are difficult to take into account the nonlinearity, multiple peaks and uncertainty, SHAP value and BPCA are introduced for feature selection and dimensionality reduction, and the MDN model is optimised based on maximum likelihood and entropy regularisation strategies. The experimental results show that the MDN outperforms other methods in terms of negative log-likelihood (NLL), mean square error (MSE) and confidence interval coverage (PICP), and achieves accurate fitting of the pollution concentration distribution and risk warning. Finally, combining the pollution probability distribution and well control scheduling rules output from the model, the parameter optimisation and operation recommendation scheme is proposed, which achieves an early warning accuracy of more than 93% in the field deployment, and provides strong support for green drilling and environmental protection. © Springer Science+Business Media, LLC, part of Springer Nature 2025.

Abstract Introduction: The marine microalga *Isochrysis galbana* is prolific producer of fucoxanthin, which is a xanthophyll carotenoid with substantial global market value boasting extensive applications in the food, nutraceutical, pharmaceutical, and cosmetic industries. This study presented a novel integrated experimental approach coupled with machine learning (ML) models to predict the fucoxanthin content in *I. galbana* by altering the type and concentration of phytohormone supplementation, thus overcoming the multiple methodological limitations of conventional fucoxanthin quantification. Methods: A novel integrated experimental approach was developed, analyzing the effect of varying phytohormone types and concentrations on fucoxanthin production in *I. galbana*. Morphological analysis was conducted to assess changes in microalgal structure, while growth rate and fucoxanthin yield correlations were explored using statistical analysis and machine learning models. Several ML models were employed to predict fucoxanthin content, with and without hormone descriptors as variables. Results: The findings revealed that the Random Forest (RF) model was highly significant with a high (Formula presented.) of 0.809 and (Formula presented.) of 0.776 when hormone descriptors were excluded, and the inclusion of hormone descriptors further improved prediction accuracy to (Formula presented.) of 0.839, making it a useful tool for predicting the fucoxanthin yield. The model that fitted the experimental data indicated methyl jasmonate (0.2 mg/L) as an effective phytohormone. The combined experimental and ML approach demonstrated rapid, reliable, and cost-efficient prediction of fucoxanthin yield. Discussion: This study highlights the potential of machine learning models, particularly Random Forest, to optimize parameters influencing microalgal growth and fucoxanthin production. This approach offers a more efficient alternative to conventional methods, providing valuable insights into improving fucoxanthin production in microalgal cultivation. The findings suggest that leveraging diverse ML models can enhance the predictability and efficiency of fucoxanthin production, making it a promising tool for industrial applications. Machine learning-driven design of high-entropy alloys: Phase prediction, performance optimization, and challenges

Item Type Journal Article

Author F. Yu

Author B. Yang

Author A. Liu

Author E. Zhu

Author W. Zhang

Abstract High-entropy alloys (HEAs) have become a revolutionary breakthrough in the field of materials design due to their excellent mechanical properties, thermal stability, and corrosion resistance. However, their large compositional space poses a significant challenge to traditional design paradigms. This paper elucidates the fundamentals of machine learning (ML) -assisted HEAs design from a synergistic perspective integrating intrinsic HEAs mechanisms and ML methodology, systematically reviewing progress in ML application for HEAs research with a focus on three pivotal aspects: phase structure prediction, performance optimization, and critical bottleneck breakthrough. This review demonstrates that the deep integration of ML and HEAs research enables efficient construction of quantitative “component-structure-property” correlations while exhibiting significant advantages in mitigating data scarcity and enhancing model interpretability. Nevertheless, key challenges persist—model opacity, experimental validation delays, and multi-objective

optimization complexity. Future research should prioritize developing inverse material design frameworks, establishing uncertainty quantification methods, and constructing digital twin validation platforms to bridge computational prediction and experimental verification. The deep fusion of data-driven techniques with thermodynamic parameters, material intrinsic features, and engineering process parameters will propel HEAs into a performance-driven intelligent customization era, delivering breakthrough solutions for biomedical, energy, and aerospace applications.

Machine Learning-Driven Quantification of CO2 Plume Dynamics at Illinois Basin Decatur Project Sites Using Microseismic Data

Item Type Journal Article

Author I. Iyegbekedo

Author E. Fathi

Author T.R. Carr

Author F. Belyadi

Abstract This study utilizes machine learning to quantify CO₂ plume extents by analyzing microseismic data from the Illinois Basin Decatur Project (IBDP). Leveraging a unique dataset of well logs, microseismic records, and CO₂ injection metrics, this work aims to predict the temporal evolution of subsurface CO₂ saturation plumes. The findings illustrate that machine learning can predict plume dynamics, revealing vertical clustering of microseismic events over distinct time periods within certain proximities to the injection well, consistent with an invasion percolation model. The buoyant CO₂ plume partially trapped within sandstone intervals periodically breaches localized barriers or baffles, which act as leaky seals and impede vertical migration until buoyancy overcomes gravity and capillary forces, leading to breakthroughs along vertical zones of weakness. Between different unsupervised clustering techniques, K-Means and DBSCAN were applied and analyzed in detail, where K-means outperformed DBSCAN in this specific study by indicating the combination of the highest Silhouette Score and the lowest Davies–Bouldin Index. The predictive capability of machine learning models in quantifying CO₂ saturation plume extension is significant for real-time monitoring and management of CO₂ sequestration sites. The models exhibit high accuracy, validated against physical models and injection data from the IBDP, reinforcing the viability of CO₂ geological sequestration as a climate change mitigation strategy and enhancing advanced tools for safe management of these operations. © 2024 by the authors.

Abstract Human milk oligosaccharides (HMOs) are bioactive components of human breast milk (HBM), but their concentrations vary with maternal secretor phenotype and lactation stage, making individual HMO quantification analytically demanding. Here, we present a reference-guided benchtop 60 MHz NMR workflow integrating chemometrics and machine learning to quantify major fucosylated HMOs in HBM. A total of 111 HBM samples from 37 donors across lactation stages were analyzed. Using 800 MHz NMR-derived concentrations as references, predictive models were developed from benchtop NMR spectra for 2'-fucosyllactose (2'-FL), 3-fucosyllactose (3-FL), and lacto-N-fucopentaose I (LNFP-I). Unlike conventional peak-fitting-based NMR quantification, this workflow recovered HMO-specific quantitative information from highly overlapped 60 MHz carbohydrate signals that were not directly resolvable in authentic HBM. Elastic Net yielded practical models, particularly for lower-abundance 3-FL and LNFP-I. These results support benchtop NMR combined with machine learning as an accessible platform for HMO screening. © 2026 American Chemical Society

Machine Learning–Driven prediction of wettability in brine–co₂–mineral systems: A step toward reliable geological carbon storage

Item Type Journal Article
Author M. Ahmadi

Abstract Understanding wettability behavior in brine–CO₂–mineral systems is fundamental to predicting the efficiency and long-term security of geological carbon storage. In this study, we combine statistical characterization, mechanistic interpretation, and advanced machine learning to quantify the thermodynamic, geochemical, and mineralogical controls on contact angle variability. Exploratory analyses reveal strong mineral-specific heterogeneity, with quartz and feldspar exhibiting predominantly hydrophilic behavior, mica displaying intermediate tendencies, and calcite showing the largest variability, consistent with its sensitivity to geochemical reactions and surface chemistry. Pressure emerges as a dominant driver of wettability alteration, but its effect is nonlinear and mineral-dependent, with increasing pressure promoting CO₂-wet tendencies in some regimes while showing weaker or even opposite trends in others due to coupled temperature, salinity, and mineralogical influences. Machine learning models, including ensemble learners and neural approaches, demonstrate strong predictive capacity for contact angle estimation (R² up to 0.91), with stacking ensembles achieving the highest accuracy and most balanced residual patterns. Feature attribution using Shapley Additive Explanations (SHAP) consistently highlights contact angle at ambient condition (θ₀) and pressure as the most influential predictors, while mineral type, temperature, and salinity exert complementary roles in shaping wettability outcomes. Importantly, SHAP interaction analyses reveal synergistic effects, whereby elevated temperature and salinity amplify the predictive importance of pressure, underscoring the nonlinear, coupled nature of wettability controls. These findings establish a robust, interpretable framework that integrates physicochemical mechanisms with interpretable machine learning, providing robust predictive insights into wettability evolution under reservoir-relevant conditions. The outcomes advance fundamental understanding of multiphase interfacial processes and offer practical tools for risk assessment, capacity estimation, and secure implementation of carbon storage strategies. © 2026 Elsevier B.V. Machine-learning and scRNA-Seq-based diagnostic and prognostic models illustrating survival and therapy response of lung adenocarcinoma

Item Type Journal Article

Author Q. Cheng

Author W. Zhao

Author X. Song

Author T. Jin

Abstract Lung cancer is a major cause accounting for cancer-related mortalities, with lung adenocarcinoma (LUAD) being the most prevalent subtype. Given the high clinical and cellular heterogeneities of LUAD, accurate diagnosis and prognosis are crucial to avoid overdiagnosis and overtreatment. Taking full advantage of scRNA-Seq data to resolve the tumor heterogeneities, we explored the overall landscape of LUAD microenvironment. Utilizing the stage-specific tumor cell markers, we have developed highly accurate diagnostic and prognostic models with elevated sensitivity and specificity. The diagnostic model, developed through random forest algorithms with a thirteen-gene signature, achieved an accuracy of 96.4% and an AUC of 0.993. These metrics were further demonstrated by benchmarking with available models and scoring systems in independent cohorts. Concurrently, the prognostic model, formulated via Cox regression with a six-gene signature, effectively predicted overall survival, with elevated risk scores associated with increased fractions of cancer-associated fibroblasts, and higher likelihood of immune escape and T-cell exclusion. Subsequently, two nomograms were developed to predict survival and drug responses, facilitating their integration into clinical practice. Overall, this study underscores the potential of our models for efficient, rapid, and cost-effective diagnosis and prognosis of LUAD, adaptable to multiple expression profiling platforms and quantification methods. Machine-learning based study on the on-site renewable electrical performance of an optimal hybrid PCMs integrated renewable system with high-level parameters' uncertainties

Item Type Journal Article

Author Y. Zhou

Author S. Zheng

Author G. Zhang

Abstract The uncertainty and sensitivity analyses for multivariables of the optimal system based on deterministic parameters are necessary, as multivariables are full of uncertainties in the real operation. However, the generic methodology for multi-dimensional uncertainties quantification is rare, and the energy performance simulation is normally at high computational cost, especially considering a huge amount of parameters' uncertainties. In this study, the on-site renewable electricity generation of an optimal hybrid renewable system based on deterministic parameters, was investigated, under high-level parameters' uncertainties. A generic uncertainty quantification methodology was proposed using the two-dimensional Markov Chain Monte Carlo to quantify multi-dimensional uncertainties. A machine-learning based data-driven model, using the supervised machine learning with high computational efficiency, was developed to predict the on-site renewable electricity generation, and thereafter used for the uncertainty and sensitivity analyses. Compared with the deterministic scenario parameters, the cases with the scenario uncertainties can increase the peak power and the total amount of the on-site renewable electricity generation. This study proposes a novel generic uncertainty quantification methodology, together with a machine-learning based data-driven model for conducting the uncertainty analysis of an optimal renewable system based on deterministic parameters, which are important for the promotion of renewable and sustainable buildings. © 2019 Elsevier Ltd

MAESTRO: A Multi-Scale Ensemble Framework with GAN-Based Data Refinement for Robust Malicious Tor Traffic Detection

Item Type Journal Article

Author J. Geng

Author Y. Xie

Author J. Li

Author X. Yu

Author L. He

Abstract Malicious Tor traffic data contains deep domain-specific knowledge, which makes labeling challenging, and the lack of labeled data degrades the accuracy of learning-based detectors. Real-world deployments also exhibit severe class imbalance, where malicious traffic constitutes a small minority of network flows, which further reduces detection performance. In addition, Tor’s fixed 512-byte cell architecture removes packet-size diversity that many encrypted-traffic methods rely on, making feature extraction difficult. This paper proposes an efficient three-stage framework, MAESTRO v1.0, for malicious Tor traffic detection. In Stage 1, MAESTRO extracts multi-scale behavioral signatures by fusing temporal, positional, and directional embeddings at cell, direction, and flow granularities to mitigate feature homogeneity; it then compresses these representations with an autoencoder into compact latent features. In Stage 2, MAESTRO introduces an ensemble-based quality quantification method that combines five complementary anomaly detection models to produce robust discriminability scores for adaptive sample weighting, helping the classifier to emphasize high-quality samples. MAESTRO also trains three specialized GANs per minority class and applies strict five-model ensemble validation to synthesize diverse high-fidelity samples, addressing extreme class imbalance. We evaluate MAESTRO under systematic imbalance settings, ranging from the natural distribution to an extreme 1% malicious ratio. On the CCS’22 Tor malware dataset, MAESTRO

achieves 92.38% accuracy, 64.79% recall, and 73.70% F1-score under the natural distribution, improving F1-score by up to 15.53% compared with state-of-the-art baselines. Under the 1% malicious setting, MAESTRO maintains 21.1% recall, which is 14.1 percentage points higher than the best baseline, while conventional methods drop below 10%. © 2026 by the authors.

Abstract Objective: Short-TE Proton Magnetic Resonance Spectroscopy (SPMRS) allows non-invasive, radiation-free detection of biomolecules including key brain metabolic biomarkers for neurological diseases. However, SPMRS also contains signals from macromolecules, lipids and baseline. Existing Deep Learning (DL) quantification methods for SPMRS overlook baseline interference. Methods: To address this, we proposed a novel DL quantification incorporating macromolecules, lipids and baseline (called background signal). First, background signal generators were built by capturing feature distributions of 200 in vivo background signals. Then, the synthetic SPMRS spectra were generated, composed of synthetic metabolite components based on the quantum mechanical and exponential models, background signal generated by the background generator and noise. Finally, the synthetic SPMRS were used to train the advanced DL quantification model QNet (our earlier study). Results: The proposed DL method was validated on a large-scale healthy human brain dataset (BigGABA) and our collected data from different manufacturers (totaling 216 spectra). Furthermore, it was applied to classification of minimal hepatic encephalopathy (totaling 176 spectra), highlighting its clinical potential. Conclusion: We proposed and validated a novel deep learning-based quantification method for SPMRS which is explicitly taken into account the background effect. Significance: The proposed method is incorporated the background effect into the DL framework of SPMRS quantification, and DL quantification of SPMRS is utilized for the clinical diagnosis of minimal hepatic encephalopathy. © 1964-2012 IEEE.

Magnetic Resonance Spectroscopy Signal Analysis Based on Fingerprinting Dictionary Approaches

Item Type Conference Paper

Author I. Venglovskyi

Editor Benedicenti L.

Editor Liu Z.

Abstract Magnetic resonance spectroscopy (MRS) is a technique applicable in medical diagnosis or research, which has the unique capability to give non-invasive access to the biochemical content (metabolites) of scanned organs. Up to recent times, all the proposed methods solved metabolite quantification as an optimization problem attempting to minimize the difference between the data and a given parameterized model function. This paper proposes quantification of metabolites in MR spectroscopic imaging using a fingerprinting method, whose function is based on the creation of a dictionary of linear combinations of metabolite signals. Experimental results demonstrate the accuracy of the proposed method, compared to data obtained by a standard quantification method (QUEST), on concentration estimates of 8 metabolites from signals with macromolecule background and noise. The prototype results indicate that the concept of MR fingerprinting dictionary, useful also for preparing data for machine learning, can serve as an alternative method for metabolite quantification by NMR signal analysis. © 2021 Avestia Publishing. Manifold Embedding Induced by Multidimensional Scaling and Its Application to Alzheimer's Disease and Mild Cognitive Impairment

Item Type Journal Article

Author H. Park

Abstract Quantifying shape information related to a disease such as Alzheimer's disease (AD) is an important area of brain research. Neuroimaging data are highly dimensional and are thus cumbersome to analyze. Manifold learning techniques, which find a low-dimensional representation for highdimensional data, have been applied to brain magnetic resonance imaging (MRI). A shape quantification method based on multidimensional scaling (MDS), a well-known manifold learning technique, was proposed. The method successfully distinguished between AD and normal patients. We extended the MDS-based quantification method by 1) applying it to distinguish patients with mild cognitive impairment (MCI) from normal patients, and 2) showing the effectiveness of the induced low-dimensional embedding space in predicting key clinical variables such as mini-mental-state exam scores and clinical diagnosis by using a standard multiple linear regression. Distinguishing patients with MCI from normal patients is also important as it is related to early detection of AD. We were able to 1) classify not only AD/normal patients but also MCI/normal patients better than we could with the traditional classification based on the hippocampus volume, and to 2) show good statistical power for predicting key clinical variables. Our test group consisted of 25 normal, 25 AD, and 25 MCI patients.

Author F. Cendes

Author A.V. Faria

Author G. Castellano

Abstract In vivo proton magnetic resonance spectroscopy (^1H -MRS) is a technique capable of assessing biochemical content and pathways in normal and pathological tissue. In the brain, ^1H -MRS complements the information given by magnetic resonance images. The main goal of the present study was to assess the accuracy of ^1H -MRS for the classification of brain tumors in a pilot study comparing results obtained by manual and semi-automatic quantification of metabolites. In vivo single-voxel ^1H -MRS was performed in 24 control subjects and 26 patients with brain neoplasms that included meningiomas, high-grade neuroglial tumors and pilocytic astrocytomas. Seven metabolite groups (lactate, lipids, N-acetyl-aspartate, glutamate and glutamine group, total creatine, total choline, myo-inositol) were evaluated in all spectra by two methods: a manual one consisting of integration of manually defined peak areas, and the advanced method for accurate, robust and efficient spectral fitting (AMARES), a semi-automatic quantification method implemented in the jMRUI software. Statistical methods included discriminant analysis and the leave-one-out cross-validation method. Both manual and semi-automatic analyses detected differences in metabolite content between tumor groups and controls ($P < 0.005$). The classification accuracy obtained with the manual method was 75% for high-grade neuroglial tumors, 55% for meningiomas and 56% for pilocytic astrocytomas, while for the semi-automatic method it was 78, 70, and 98%, respectively. Both methods classified all control subjects correctly. The study demonstrated that ^1H -MRS accurately differentiated normal from tumoral brain tissue and confirmed the superiority of the semi-automatic quantification method.

Many-to-Many Prediction for Effective Modeling of Frequent Label Transitions in Time Series

Item Type Conference Paper

Author A. Katrompas

Author V. Metsis

Editor Karim E.

Editor Nikanfar S.

Editor Pavel H.R.

Abstract Time-series classification is vital in health monitoring and human activity recognition, as well as in areas such as financial forecasting, process control, and a wide array of forecasting tasks. Traditional time-series models segment data into windows and assign one label per window, often missing label transitions within those windows. This paper presents a novel many-to-many time-series

model and post-processing using hybrid recurrent neural networks with attention mechanisms, which more effectively captures label transitions over traditional many-to-one models. Further, unlike typical other many-to-many models, our approach doesn't require a decoder. Instead, it employs an RNN, generating a label for every input time step. During inference, a weighted voting scheme consolidates overlapping predictions into one label per time step. Experiments show our model remains effective on time-series with sparse label shifts, but particularly excels in detecting frequent transitions. This model is ideal for tasks demanding accurate pinpointing of rapid label changes in time-series data, such as gesture recognition, making it ideal for fast-paced human activity recognition.

Mapping the Brazilian savanna's natural vegetation: A SAR-optical uncertainty-aware deep learning approach

Item Type Journal Article

Author P. Silva Filho

Author C. Persello

Author R.V. Mareto

Author R. Machado

Abstract The Brazilian savanna (Cerrado) is considered a hotspot for conservation. Despite its environmental and social importance, the biome has suffered a rapid transformation process due to human activities. Mapping and monitoring the remaining vegetation is essential to guide public policies for biodiversity conservation. However, accurately mapping the Cerrado's vegetation is still an open challenge. Its diverse but spectrally similar physiognomies are a source of confusion for state-of-the-art (SOTA) methods. This study proposes a deep learning model to map the natural vegetation of the Cerrado at the regional to biome level, fusing Synthetic Aperture Radar (SAR) and optical data. The proposed model is designed to deal with uncertainties caused by the different resolutions of the input Sentinel-1/2 images (10 m) and the reference data, derived from Landsat images (30 m). We designed a multi-resolution label-propagation (MRLP) module that infers maps at both resolutions and uses the class scores from the 30 m output as features for the 10 m classification layer. We train the model with the proposed calibrated dual focal loss function in a 2-stage hierarchical manner. Our results reached an overall accuracy of 70.37%, representing an increase of 15.64% compared to a SOTA random forest (RF) model. Moreover, we propose an uncertainty quantification method, which has shown to be useful not only in validating the model, but also in highlighting areas of label noise in the reference. The developed codes and dataset are available on Github. © 2024 The Authors

Mapping the spatial heterogeneity of nitrogen species in road dust through integrated multi-source remote sensing and interpretable machine learning

Item Type Journal Article

Author M.N. Ashraf

Author S. Huang

Author A. Basheer

Abstract Nitrogen accumulation in road dust constitutes a significant yet underexplored threat to environmental quality, particularly in regions where rapid urbanization intersects with intensive agriculture. The spatial distribution patterns and governing factors of individual nitrogen species within this environmental matrix remain poorly characterized. This study presents an integrated framework coupling field-based chemical speciation analysis, multi-source remote sensing, and interpretable machine learning to quantify and map the spatial distribution of total nitrogen (TN), nitrate-nitrogen (NO_3^- -N), ammonium-nitrogen (NH_4^+ -N), and organic nitrogen (Org-N) in road dust across South Tianjin, China. Laboratory analysis of 41 road dust samples collected along urban–rural transects revealed pronounced spatial heterogeneity, with TN concentrations spanning 289–3782 mg/kg; the highest values were consistently associated with agricultural land use. Org-N constituted the dominant nitrogen fraction, accounting for more than 88% of TN across all land-use categories. Predictive models constructed with the Extra Trees algorithm demonstrated strong generalization capability, yielding cross-validated coefficients of determination (R^2) of 0.891 for TN, 0.887 for Org-N, 0.846 for NH_4^+ -N, and 0.806 for NO_3^- -N. Among all predictors, spatial distance from the urban core emerged as the most influential variable, explaining 32–46% of model variance across nitrogen species. Model interpretation via SHapley Additive exPlanations (SHAP) and permutation importance further identified surface runoff, precipitation, and population density as potential drivers of nitrogen variability, while Monte Carlo uncertainty analysis indicated greater predictive uncertainty for Org-N relative to inorganic nitrogen forms. Spatially explicit predictions delineated agricultural districts in eastern and southern South Tianjin as critical nitrogen hotspots. The proposed remote sensing–machine learning framework effectively discriminates between diffuse agricultural nitrogen inputs and localized urban emission sources, offering actionable guidance for source-specific pollution management and sustainable land-use governance in rapidly urbanizing regions. © 2026 Elsevier Inc.

Markov random field based background subtraction method for foreground detection under moving background scene

Item Type Conference Paper
Author T.-H. Tsai
Author C.-Y. Lin

Abstract Detection of moving objects in video streams is the first relevant step of information extraction in many computer vision applications. Aside from the intrinsic usefulness of being able to segment video streams into moving and background components, detecting moving objects provides a focus of attention for recognition, classification, and activity analysis, making these later steps more efficient. In this paper, a background subtraction based on Bayesian estimation is proposed. The basic of our solution is a Bayesian likelihood test which can distinguish between foreground variation and dynamic background variation. The prior knowledge about the likelihood test is brought to bear by appropriately specified a priori probability as Markov random field. Based on this approach, decision thresholds vary depending on context, thus improving detection performance substantially. We compare our method with other modeling techniques and report experimental results, both in term of detection accuracy, for color video sequences that represent typical situations critical for video surveillance systems. Quantitative evaluation and comparison with the existing methods show that the proposed algorithm provides much improved results. © 2010 IEEE.

Abstract Machine learning models deployed in real-world applications are often evaluated with precision-based metrics such as F1-score or AUC-PR (Area Under the Curve of Precision Recall). Heavily dependent on the class prior, such metrics make it difficult to interpret the variation of a model's performance over different subpopulations/subperiods in a dataset. In this paper, we propose a way to calibrate the metrics so that they can be made invariant to the prior. We conduct a large number of experiments on balanced and imbalanced data to assess the behavior of calibrated metrics and show that they improve interpretability and provide a better control over what is really measured. We describe specific real-world use-cases where calibration is beneficial such as, for instance, model monitoring in production, reporting, or fairness evaluation. © 2020, The Author(s).

Masticatory performance in postmaxillectomy patients with edentulous maxillae fitted with obturator prostheses

Item Type Journal Article

Author T. Ono

Author H. Kohda

Author K. Hori

Author T. Nokubi

Abstract Purpose: Oral cancer develops frequently in older populations. In Japan, the incidence of oral and pharyngeal cancer is 9,201 per year, with such tumors accounting for 1.74% of all cancers. Although obturator prostheses play an important role in the rehabilitation of postmaxillectomy patients, clinicians sometimes experience difficulty in placing obturator prostheses in edentulous maxillae, and criteria for the objective evaluation of treatment outcome have yet to be established. The present study aimed to investigate postsurgical factors influencing the masticatory performance of postmaxillectomy patients with edentulous maxillae fitted with obturator prostheses. Materials and Methods: The extent of the hard palate defect, status of the mandibular dentition, mouth-opening distance, and maximum occlusal force were investigated, and masticatory performance was measured using a testing gummy jelly in 27 postmaxillectomy patients with edentulous maxillae fitted with obturator prostheses. The influence of these items was evaluated quantitatively, and theoretical masticatory performance for each subject was calculated using multiple-regression analysis (quantification method type 1). Results: Although average masticatory performance was almost equivalent to that of healthy, independent older patients with occlusal support classified as Eichner C, considerable individual variation was noted among subjects. The order of strength of influence on masticatory performance was identified by category weight: extent of hard palate defect > status of posterior mandibular teeth > maximum occlusal force > mouth-opening distance. A relatively high correlation ($R^2 = 0.78$, $P < .01$, Pearson correlation coefficient) was evident between theoretical and actual values. Conclusion: Masticatory performance could be predicted by evaluating postsurgical factors in patients with edentulous maxillae fitted with obturator prostheses.

Match: A Maximum-Likelihood Approach for Classification under Label Shift

Item Type Conference Paper

Author Z. Donyavi

Author F. Li

Author Y. Zhang

Author D.F. Silva

Author G.E. Batista

Abstract Machine learning models often suffer from performance degradation when dealing with class distributions that differ from the training distribution, a scenario commonly referred to as label shift. Addressing this challenge, this paper introduces Match, a novel adjustment approach that maximizes the likelihood of predicted probabilities under class prevalence constraints. Unlike existing methods such as retraining with instance re-weighting and the Bayes update rule, Match ensures that the adjusted class distribution aligns precisely with the prevalence estimates from quantifiers. By formulating the adjustment process as a

binary integer linear optimization problem, Match benefits from efficient mixed-integer solvers. Extensive experiments demonstrate that Match outperforms the state-of-the-art in classifier adjustment with statistical significance, particularly in handling scenarios with imbalanced distributions. © 2025 ACM.

Matching Distributions Algorithms Based on the Earth Mover's Distance for Ordinal Quantification

Item Type Journal Article

Author A. Castaño

Author P. González

Author J.A. González

Author J.J. Del Coz

Abstract The goal of quantification learning is to induce models capable of accurately predicting the class distribution for new bags of unseen examples. These models only return the prevalence of each class in the bag because prediction of individual examples is irrelevant in these tasks. A prototypical application of ordinal quantification is to predict the proportion of opinions that fall into each category from one to five stars. Ordinal quantification has hardly been studied in the literature, and in fact, only one approach has been proposed so far. This article presents a comprehensive study of ordinal quantification, analyzing the applicability of the most important algorithms devised for multiclass quantification and proposing three new methods that are based on matching distributions using Earth mover's distance (EMD). Empirical experiments compare 14 algorithms on synthetic and benchmark data. To statistically analyze the obtained results, we further introduce an EMD-based scoring function. The main conclusion is that methods using a criterion somehow related to EMD, including two of our proposals, obtain significantly better results. © 2012 IEEE.

Abstract Transposable elements (TEs) are crucial for genetic diversity and gene regulation. Current single-cell quantification methods often align multi-mapping reads to either ‘best-mapped’ or ‘random-mapped’ locations and categorize them at the subfamily levels, overlooking the biological necessity for accurate, locus-specific TE quantification. Moreover, these existing methods are primarily designed for and focused on transcriptomics data, which restricts their adaptability to single-cell data of other modalities. To address these challenges, here we introduce MATES, a deep-learning approach that accurately allocates multi-mapping reads to specific loci of TEs, utilizing context from adjacent read alignments flanking the TE locus. When applied to diverse single-cell omics datasets, MATES shows improved performance over existing methods, enhancing the accuracy of TE quantification and aiding in the identification of marker TEs for identified cell populations. This development facilitates the exploration of single-cell heterogeneity and gene regulation through the lens of TEs, offering an effective transposon quantification tool for the single-cell genomics community. © The Author(s) 2024.

Matt Finish- Emerging Trend in Automotive Sector for Visual Application

Item Type	Conference Paper
Author	V. Kumar
Author	R. Lalwani
Author	B. Jayanthan
Abstract	Exterior paint look is one the important tie braker on vehicle aesthetic appeal when compared with equal contenders. Time to time, globally new trend emerges to make the vehicle look attractive, one of the technologies is matt finish. To adapt with changing trends, current Indian market trend is moving from glossy finish paint to Matte finish paint by low gloss and attractive texture characteristics, which can provide soft light and pleasant feel. Matt finish helps to enhance the shape and features of the painted surface, feature lines clarity and enhanced visual appeal with absorption of light rather than reflection by glossy finish. Any new technology comes with challenges and limitations compared to traditional approach of vehicle painting and handling in field. In this paper, we have discussed on development of matt finish paint for automotive sector as per OEM manufacturing setup, definition of gloss for matt finish, quantification method, classification of gloss, mechanism, method, as well as the factors that affect the gloss of films. Finally, acceptance criteria for all the tests are defined as per Automotive standards. Also, explicitly defines the technical requirements and Robust technical evaluation methodologies of various automotive short- and long-term tests. All the performance results were compared for screening of product and to meet the first-time right implementation target. © 2025 Mahindra & Mahindra Ltd.

Maximizing model generalization under feature and label shifts for structural damage detection via Bayesian theory

Item Type Journal Article**Author** X. Wang**Author** J. Jiao**Author** X. Zhou**Author** Y. Xia

Abstract Machine learning models face performance degradation when migrating to datasets with different distributions from training data. This challenge limits their applications because recollecting labeled data to retrain models is expensive and time-consuming. Domain generalization (DG) aims to learn a predictive model that can extract invariant features across source domains and then generalize to related but unseen target domains. However, most existing feature-invariant DG methods rely on unrealistic assumptions (e.g., stable feature distribution or no label shift) and simplify the problem to learn either invariant feature marginal or conditional distributions. In practice, both feature and label shifts may exist, rendering these assumptions invalid. This study develops a novel DG method to simultaneously consider conditional, marginal, and label shifts. With Bayes' theorem, DG is interpreted as a posterior distribution alignment problem, which is derived by the likelihood function, evidence, and prior. The likelihood function and evidence correspond to feature conditional and marginal distributions, respectively, which are estimated by exploiting variational Bayesian inference. The conditional distributions across domains are aligned by minimizing the Kullback–Leibler divergence, and the marginal distributions across domains are aligned through moment minimization. The label prior shift is estimated by the label smoothing mechanism and class-wise

prototype learning. Consequently, DG is achieved by aligning the label posterior distribution according to the Bayesian equation. Numerical and experimental examples demonstrate that the developed method outperforms state-of-the-art DG methods in damage detection of both mechanical and civil structures. The method can be extended to DG tasks in other fields. © 2024

Maximum likelihood in cost-sensitive learning: Model specification, approximations, and upper bounds

Item Type Journal Article

Author J.P. Dmochowski

Author P. Sajda

Author L.C. Parra

Abstract The presence of asymmetry in the misclassification costs or class prevalences is a common occurrence in the pattern classification domain. While much interest has been devoted to the study of cost-sensitive learning techniques, the relationship between cost-sensitive learning and the specification of the model set in a parametric estimation framework remains somewhat unclear. To that end, we differentiate

between the case of the model including the true posterior, and that in which the model is misspecified. In the former case, it is shown that thresholding the maximum likelihood (ML) estimate is an asymptotically optimal solution to the risk minimization problem. On the other hand, under model misspecification, it is demonstrated that thresholded ML is suboptimal and that the risk-minimizing solution varies with the misclassification cost ratio. Moreover, we analytically show that the negative weighted log likelihood (Elkan, 2001) is a tight, convex upper bound of the empirical loss. Coupled with empirical results on several real-world data sets, we argue that weighted ML is the preferred cost-sensitive technique. © 2010 Shyam Visweswaran and Gregory F. Cooper.

Maximum likelihood with bias-corrected calibration is hard-To-beat at label shift adaptation

Item Type Conference Paper

Author A.M. Alexandari

Author A. Kundaje

Author A. Shrikumar

Editor Daume H.

Editor Singh A.

Abstract Label shift refers to the phenomenon where the prior class probability $p(y)$ changes between the training and test distributions, while the conditional probability $p(x|y)$ stays fixed. Label shift arises in settings like medical diagnosis, where a classifier trained to predict disease given symptoms must be adapted to scenarios where the baseline prevalence of the disease is different. Given estimates of $p(y|x)$ from a predictive model, Saerens et al. proposed an efficient maximum likelihood algorithm to correct for label shift that does not require model retraining, but a limiting assumption of this algorithm is that $p(y|x)$ is calibrated, which is not true of modern neural networks. Recently, Black Box Shift Learning (BBSL) and Regularized Learning under Label Shifts (RLLS) have emerged as state-of-the-art techniques to cope with label shift when a classifier does not output calibrated probabilities, but both methods require model retraining with importance weights and neither has been benchmarked against maximum likelihood. Here we (1) show that combining maximum likelihood with a type of calibration we call bias-corrected calibration outperforms both BBSL and RLLS across diverse datasets and distribution shifts, (2) prove that the maximum likelihood objective is concave, and (3) introduce a principled strategy for estimating source-domain priors that improves robustness to poor calibration. This work demonstrates that the maximum likelihood with appropriate calibration is a formidable and efficient baseline for label shift adaptation. Maximum Likelihood with Bias-Corrected Calibration is Hard-To-Beat at Label Shift Adaptation

Item Type Conference Paper

Author A.M. Alexandari

Author A. Kundaje

Author A. Shrikumar

Editor Daumé III H.

Editor Singh A.

Abstract Label shift refers to the phenomenon where the prior class probability $p(y)$ changes between the training and test distributions, while the conditional probability $p(x|y)$ stays fixed. Label shift arises in settings like medical diagnosis, where a classifier trained to predict disease given symptoms must be adapted to scenarios where the baseline prevalence of the disease is different. Given estimates of $p(y|x)$ from a predictive model, Saerens et al. proposed an efficient maximum likelihood algorithm to correct for label shift that does not require model retraining, but a limiting assumption of this algorithm is that $p(y|x)$ is calibrated, which is not true of modern neural networks. Recently, Black Box Shift Learning (BBSL) and Regularized Learning under Label Shifts (RLLS) have emerged as state-of-the-art techniques to cope with label shift when a classifier does not output calibrated probabilities, but both methods require model retraining with importance weights and neither has been benchmarked against maximum likelihood. Here we (1) show that combining maximum likelihood with a type of calibration we call bias-corrected calibration outperforms both BBSL and RLLS across diverse datasets and distribution shifts, (2) prove that the maximum likelihood objective is concave, and (3) introduce a principled strategy for estimating source-domain priors that improves robustness to poor calibration. This work demonstrates that the maximum likelihood with appropriate calibration is a formidable and efficient baseline for label shift adaptation. See sec. 6 for links to code, video, and blogpost. © 2020 by the author(s).

MC-SQ and MC-MQ: Ensembles for Multi-Class Quantification

Item Type Journal Article

Author Z. Donyavi

Author A.B.S. Serapiao

Author G. Batista

Abstract Quantification research proposes methods to estimate the class distribution in an independent sample. Quantification methods find applications in areas that rely on estimated aggregated quantities, such as epidemiology, sentiment analysis, political research, and ecological surveillance. For instance, epidemiologists are often concerned with the dynamics of the number of disease cases across space and time. Thus, while classification predicts individual subjects, quantifiers are the methods that directly estimate the number of cases. Although quantification is a thriving area of research, with numerous approaches proposed in the last decade, most focus has been on binary-class quantifiers. One common approach for multi-class quantification is the one-versus-all (OVA) approach, but empirical evidence suggests its performance is suboptimal. This paper's first contribution is to elucidate why OVA quantifiers struggle to perform well in multi-class settings due to a distribution shift. To circumvent this problem, our second proposal is two new multi-class quantifiers based on ensemble learning that significantly improve performance for binary and multi-class settings. Our comprehensive experimental setup with 37 state-of-the-art (single and ensemble) quantifiers shows that our ensembles are the best-performing quantifiers and rank first in a recent quantification competition. © 1989-2012 IEEE.

MC-SQ: A Highly Accurate Ensemble for Multi-class Quantification

Item Type Conference Paper

Author Z. Donyavi

Author A. Serapio

Author G. Batista

Abstract Quantification research proposes methods to estimate the class distribution in an independent sample. Many areas, such as epidemiology, sentiment analysis, political research and ecological surveillance, rely on quantification methods to estimate aggregated quantities. For instance, epidemiologists are often concerned with the dynamics of the number of disease cases across space and time. Thus, while classification predicts individual subjects, quantification is the class of methods that directly estimate the number of cases. Quantification is a thriving research area, and the community has proposed several approaches in the last decade. Nevertheless, most quantification research has focused on binary-class quantifiers, expecting these approaches to extend to multi-class using the one-

versus-all (OVA) approach. However, there is enough empirical evidence indicating the performance of OVA multi-class quantifiers is subpar. This paper has two main contributions. First, we demonstrate why OVA quantifiers are doomed to underperform in multi-class settings due to a distribution shift they cannot handle. Second, we propose a new class of quantifiers based on ensemble learning that boosts the performance of the base quantifiers in the binary and, more importantly, multi-class settings. In one of the most comprehensive experimental setups ever attempted in quantification research, we show that our ensembles are the best-performing quantifiers compared with 33 state-of-the-art (single and ensemble) quantifiers and rank first in a recent quantification competition. McGET: A rapid image-based method to determine the morphological characteristics of gravels on the Gobi desert surface

Item Type Journal Article

Author Y. Mu

Author F. Wang

Author B. Zheng

Author W. Guo

Author Y. Feng

Abstract The relationship between morphological characteristics (e.g. gravel size, coverage, angularity and orientation) and local geomorphic features (e.g. slope gradient and aspect) of desert has been used to explore the evolution process of Gobi desert. Conventional quantification methods are time-consuming, inefficient and even prove impossible to determine the characteristics of large numbers of gravels. We propose a rapid image-based method to obtain the morphological characteristics of gravels on the Gobi desert surface, which is called the “morphological characteristics gained effectively technique” (McGET). The image of the Gobi desert surface was classified into gravel clusters and background by a machine-learning “classification and regression tree” (CART) algorithm. Then gravel clusters were segmented into individual gravel clasts by separating objects in images using a “watershed segmentation” algorithm. Thirdly, gravel coverage, diameter, aspect ratio and orientation were calculated based on the basic principles of 2D computer graphics. We validated this method with two independent datasets in which the gravel morphological characteristics were obtained from 2728 gravels measured in the field and 7422 gravels measured by manual digitization. Finally, we applied McGET to derive the spatial variation of gravel morphology on the Gobi desert along an alluvial-proluvial fan located in Hami, Xinjiang, China. The validated results show that the mean gravel diameter measured in the field agreed well with that calculated by McGET for large gravels ($R^2 = 0.89$, $P < 0.001$). Compared to manual digitization, the McGET accuracies for gravel coverage, gravel diameter and aspect ratio were 97%, 83% and 96%, respectively. The orientation distributions calculated were consistent across two different methods. More importantly, McGET significantly shortens the time cost in obtaining gravel morphological characteristics in the field and laboratory. The spatial variation results show that the gravel coverage ranged from 88% to 65%, the gravel diameter was unimodally distributed and ranged from 19 mm to 13 mm. Most gravels were bladed or rod-like, with a mean aspect ratio of 1.57, and had no preferred orientation on the surveyed Gobi desert. From the center to the edge of the fan, gravel coverage decreased 2.2% per 100 m elevation decrease ($R^2 = 0.69$, $P < 0.001$), mean gravel diameter decreased 0.5 mm per 100 m elevation decrease ($R^2 = 0.52$, $P < 0.001$), and mean aspect ratio slightly increased 0.004 per 100 m elevation decrease ($R^2 = 0.26$, $P < 0.05$). These results imply that surface washing was the main process on the investigated Gobi desert. This study demonstrates that the new method can quickly and accurately calculate the gravel coverage, diameter, aspect ratio and orientation from the images of Gobi desert. © 2017 Elsevier B.V.

Measurement of Adolescent Drug Use

Item Type Journal Article

Author A.R. Morral

Author D.F. McCaffrey

Author S. Chien

Abstract There is widespread agreement that estimates of adolescent drug use prevalence from the National Household Survey of Drug Abuse (NHSDA) and Monitoring the Future (MTF) are subject to considerable measurement error. Nevertheless, some have suggested that trends over time in these prevalence estimates probably reflect true trends in drug use, since underreporting may be assumed to be constant over time. A recent National Research Council report criticizes this assumption on logical grounds. The present study examines adolescent drug use responses on the NHSDA and MTF for evidence of “drug omission,” “jargon confusion” and “conceptual confusion,” three types of misreporting expected to vary in magnitude with changes in drug use practices and changes in survey items. Results demonstrate that adolescent drug users are significantly more likely than adults to report use of drugs not listed in the NHSDA. Among adolescents who wrote in the “other” drugs they used, 66% and 86% of hallucinogen and inhalant responses showed confusion over the meaning of the pharmacological terms used in the NHSDA. Almost 20% of MTF respondents who report lifetime use of Rohypnol or ecstasy, when specifically queried about these drugs, deny lifetime use of any substances in the drug classes intended to assess use of Rohypnol and ecstasy. MTF respondents reporting lifetime use of PCP underreport use of hallucinogens at rates that vary substantially over time, from a high of 45% (in 1986), to a low of just 8% (in 1998). The implications of these findings for adolescent drug use prevalence estimation and survey design are discussed. © 2003 Taylor and Francis Group, LLC.

Measurement of Drivers' Confidence Levels in Left-Turn Decisions Using Machine Learning

Item Type Conference Paper

Author Y. Liu

Author J. Liu

Author H. Li

Author L.-Z. Yang

Abstract Decision confidence in driving, especially in complex operations such as left turns, is crucial for understanding human cognitive behavior and improving driving safety. At present, the lack of confidence quantification methods for dynamic real-time driving tasks limits the development of intelligent driving systems. This study proposes a method based on machine learning, which for the first time utilizes driving performance data (such as speed, acceleration, steering wheel angle) to measure driver confidence levels in left turn decisions. In a simulated driving environment, data from 33 participants were used to train seven machine learning models. Among them, the stacked classifier performed the best within the 0-5 second time window after stepping on the accelerator, with an accuracy of 90.97% and an F1 score of 90.91%, better than the 5 - 10 second

time window. The study identifies the standard deviation of forward direction position, maximum speed and mean speed as key features for confidence measurement. These findings provide the possibility for real-time assessment of driver confidence and have significant potential for improving human-machine interaction in intelligent driving systems and enhancing road safety. © 2025 IEEE.

Measuring Cross-National Variations in Religiosity and Attitudes Toward Science and Technology Using Machine Learning

Item Type Journal Article

Author J.J. Lee

Abstract This study uses resampling methods and machine learning to measure how religio-scientific groups are distributed across regions, countries/territories, and religious groups. Across 76 societies (N = 143,092), the distribution of class membership is as follows: traditional (31.9 percent), modern (23.7 percent), post-secular (30.3 percent), and postmodern (14.1 percent). Although most societies are dominated by a single class, there is evidence of significant heterogeneity within societies in class prevalence. Those with post-secular views are both religious and feel favorably toward science; however, when faced with a conflict between religion and science they tend to support religion. Ultimately, societies with large traditional and post-secular classes are significantly more likely to support religion given a conflict with science; in contrast, the reverse is true for societies with large modern and postmodern classes. © 2023 MSS.

Measuring daytime and nighttime variations in leisure service efficiency of community green spaces for older adults

Item Type Journal Article

Author C. Chen

Author H. Li

Author X. Wen

Author W. Zhang

Author J. Zhang

Author E.H.K. Yung

Author L. Meng

Abstract Community green spaces (CGSs) offer a range of leisure services (LSs) for older adults. However, the relationship between LS resources and their effectiveness, particularly regarding efficiency, across day and night scenarios and different geographical contexts remains underexplored. Using Guangzhou, China, as a case study, this research integrates human-perspective CGS imagery, crowdsourced data, and deep learning to quantify LS resources, effectiveness, and efficiency in both daytime and nighttime contexts. The results show that areas with abundant resources or high effectiveness do not necessarily exhibit high efficiency. High-efficiency areas during the day are primarily community parks and high-quality residential green spaces, but shift at night to roadside green spaces and residential green spaces in older urban areas. Conversely, roadside green spaces and residential green spaces within urban villages show low efficiency during the day, whereas at night, community parks and high-quality residential areas exhibit lower efficiency. The study recommends increasing daytime LS resources in urban villages and older neighborhoods and enhancing nighttime resources in community parks and high-quality residential areas. In addition, the findings highlight the nonlinear impact of LS resources on efficiency, with brightness identified as the most influential factor. This study proposes a theoretical model for assessing LS efficiency for older adults and provides practical recommendations for optimizing CGS resource allocation to support creation of age-friendly environments. © 2025 Elsevier Inc.

Measuring predictive reliability under temporal class-prior drift: A forward cohort-based evaluation framework with application to student retention prediction

Item Type Journal Article

Author A.P. Utomo

Author P. Purwanto

Author B. Surarso

Abstract Evaluating predictive reliability under temporally evolving data distributions remains a critical measurement challenge in real-world machine learning systems. In educational contexts, student populations change over time, introducing temporal class-prior drift and generalization instability that are often overlooked by conventional evaluation protocols based on random data splitting or cross-validation. This study proposes a measurement-oriented evaluation framework for assessing predictive reliability under forward cohort-based temporal conditions. The framework integrates discrimination performance, validation–test generalization gaps, and probability calibration to provide a deployment-aligned assessment of model robustness. The approach is demonstrated through sequential student retention prediction across thirteen semester-level stages using longitudinal academic data, comparing a sequential deep learning model (Long Short-Term Memory, LSTM) with non-sequential ensemble baselines (Random Forest and XGBoost). Empirical results reveal substantial temporal variability in predictive reliability. Intermediate prediction stages exhibit the largest generalization gaps, indicating reduced temporal generalization stability under forward cohort evaluation, while temporal class-prior evolution contributes to instability across cohorts. Calibration analysis further shows that probability reliability follows a stage-dependent pattern, deteriorating in intermediate stages and partially recovering in later stages, even when discrimination performance remains competitive. These findings demonstrate that predictive reliability in non-stationary environments cannot be adequately assessed using discrimination metrics alone. Instead, a multi-dimensional measurement framework is required to capture temporal generalization stability and calibration behavior, providing a more realistic evaluation of predictive models under deployment conditions. © 2026 Elsevier Ltd

MEDIC - a method for predicting residual service life and refurbishment investment budgets

Item Type Journal Article

Author F. Flourentzou

Author E. Brandt

Author C. Wetzel

Abstract In the European project, EPIQR deterioration of building materials and components is described by the use of a classification system with four classes for the qualitative condition of, e.g., a facade or window. The prediction of the probable period of passing into the next (worse) deterioration state is of high interest as this is directly connected to higher refurbishment costs. MEDIC, which stands for 'Methode d'Evaluation de scenarios de Degradation probables d'Investissements Correspondants' is a proposal for a new method to predict the future degradation state of the building. It calculates for each element regarded in EPIQR the probability to pass from one class to another during time. The prediction is based on the combination of the a priori probability based on experience from a large number of previous investigations/refurbishments and the current state of the object under study.

Meta-analytic connectivity modeling revisited: Controlling for activation base rates

Item Type Journal Article

Author R. Langner

Author C. Rottschy

Author A.R. Laird

Author P.T. Fox

Author S.B. Eickhoff

Abstract Co-activation of distinct brain regions is a measure of functional interaction, or connectivity, between those regions. The co-activation pattern of a given region can be investigated using seed-based activation likelihood estimation meta-analysis of functional neuroimaging data stored in databases such as BrainMap. This method reveals inter-regional functional connectivity by determining brain regions that are consistently co-activated with a given region of interest (the "seed") across a broad range of experiments. In current implementations of this meta-analytic connectivity modeling (MACM), significant spatial convergence (i.e. consistent co-activation) is distinguished from noise by comparing it against an unbiased null-distribution of random spatial associations between experiments according to which all gray-matter voxels have the same chance of convergence. As the a priori probability of finding activation in different voxels markedly differs across the brain, computing such a quasi-rectangular null-distribution renders the detection of significant convergence more likely in those voxels that are frequently activated. Here, we propose and test a modified MACM approach that takes this activation frequency bias into account. In this new specific co-activation likelihood estimation (SCALE) algorithm, a null-

distribution is generated that reflects the base rate of reporting activation in any given voxel and thus equalizes the a priori chance of finding across-study convergence in each voxel of the brain. Using four exemplary seed regions (right visual area V4, left anterior insula, right intraparietal sulcus, and subgenual cingulum), our tests corroborated the enhanced specificity of the modified algorithm, indicating that SCALE may be especially useful for delineating distinct core networks of co-activation. © 2014 Elsevier Inc.

Meta-DermDiagnosis: Few-shot skin disease identification using meta-learning

Item Type Conference Paper

Author K. Mahajan

Author M. Sharma

Author L. Vig

Abstract Annotated images for diagnosis of rare or novel diseases are likely to remain scarce due to small affected patient population and limited clinical expertise to annotate images. Deep networks employed for image based diagnosis need to be robust enough to quickly adapt to novel diseases with few annotated images. Further, in case of the frequently occurring long-tailed class distributions in skin lesion and other disease classification datasets, conventional training approaches lead to poor generalization on classes at the tail end of the distribution due to biased class priors. This paper focuses on the problems of disease identification and quick model adaptation in such data-scarce and long-tailed class distribution scenarios by exploiting recent advances in meta-learning. This involves training a neural network on few-shot image classification tasks based on an initial set of class labels / head classes of the distribution, prior to adapting the model for classification on a set of unseen / tail classes. We named the proposed method Meta-DermDiagnosis because it utilizes meta-learning based few-shot learning techniques such as the gradient based Reptile and distance metric based Prototypical networks for identification of diseases in skin lesion datasets. We evaluate the effectiveness of our approach on publicly available skin lesion datasets, namely the ISIC 2018, Derm7pt and SD-198 datasets and obtain significant performance improvement over pretrained models with just a few annotated examples. Further, we incorporate Group Equivariant convolutions (G-convolutions) for the Meta-DermDiagnosis network to improve disease identification performance as these images generally do not have any prevailing global orientation / canonical structure and G-convolutions make the network equivariant to any discrete transformations like rotation, reflection and translation. © 2020 IEEE.

Meta-learning for few-shot land cover classification

Item Type Conference Paper

Author M. Ruswurm

Author S. Wang

Author M. Korner

Author D. Lobell

Abstract The representations of the Earth's surface vary from one geographic region to another. For instance, the appearance of urban areas differs between continents, and seasonality influences the appearance of vegetation. To capture the diversity within a single category, such as urban or vegetation, requires a large model capacity and, consequently, large datasets. In this work, we propose a different perspective and view this diversity as an inductive transfer learning problem where few data samples from one region allow a model to adapt to an unseen region. We evaluate the modelagnostic meta-learning (MAML) algorithm on classification and segmentation tasks using globally and regionally distributed datasets. We find that few-shot model adaptation outperforms pre-training with regular gradient descent and fine-tuning on the (1) Sen12MS dataset and (2) DeepGlobe dataset when the source domain and target domain differ. This indicates that model optimization with meta-learning may benefit tasks in the Earth sciences whose data show a high degree of diversity from region to region, while traditional gradient-based supervised learning remains suitable in the absence of a feature or label shift. © 2020 IEEE.

Meta-Learning Without Data via Unconditional Diffusion Models

Item Type Journal Article**Author** Y. Wei**Author** Z. Hu**Author** L. Shen**Author** Z. Wang**Author** L. Li**Author** Y. Li**Author** C. Yuan

Abstract Although few-shot learning aims to address data scarcity, it still requires large, annotated datasets for training, which are often unavailable due to cost and privacy concerns. Previous studies have utilized pre-trained diffusion models, either to synthesize auxiliary data besides limited labeled samples, or to employ diffusion models as zero-shot classifiers. However, they are limited to conditional diffusion models needing class prior information (e.g., carefully crafted text prompts) about unseen tasks. To overcome this, we leverage unconditional diffusion models without needs for class information to train a meta-model capable of generalizing to unseen tasks. The framework contains (1) a meta-learning without data approach that uses synthetic data during training; and (2) a diffusion model-based data augmentation to calibrate the distribution shift during testing. During meta-training, we implement a self-taught class-learner to gradually capture class concepts, guiding unconditional diffusion models to generate a labeled pseudo dataset. This pseudo dataset is then used to jointly train the class-learner and the meta-model, allowing for iterative refinement and clear differentiation between classes. During meta-testing, we

introduce a data augmentation that employs the diffusion models used in meta-training, to narrow the gap between meta-training and meta-testing task distribution. This enables the meta-model trained on synthetic images to effectively classify real images in unseen tasks. Comprehensive experiments showcase the superiority and adaptability of our approach in four real-world scenarios. Code available at <https://github.com/WalkerWorldPeace/MLWDUDM>. © 1991-2012 IEEE.

Abstract Background: Most malignant brain gliomas (MBGs) are associated with dismal outcomes, mainly due to their late diagnosis. Current diagnostic methods for MBGs are based on imaging and histological examination, which limits their early detection. Here, we aimed to identify reliable plasma lipid biomarkers for non-invasive diagnosis for MBGs. Methods: Untargeted lipidomic analysis was firstly performed using a discovery cohort (n=107). The data were processed by a support vector machine (SVM)-based discriminating model to retrieve a panel of candidate biomarkers. Then, a targeted quantification method was developed, and the SVM-based diagnostic model was constructed using a training cohort (n=750) and tested using a test cohort (n=225). Finally, the performance of the diagnostic model was further evaluated in an independent validation cohort (n=920) enrolled from multiple medical centers. Findings: A panel of 11 plasma lipids was identified as candidate biomarkers with an accuracy of 0.999. The diagnostic model developed achieved a high performance in distinguishing MBGs patients from normal controls with an area under the receiver-operating characteristic curve (AUC) of 0.9877 and 0.9869 in the training and test cohorts, respectively. In the validation cohort, the 11 lipid panel still achieved an accuracy of 0.9641 and an AUC of 0.9866. Interpretation: The present study demonstrates the applicability and robustness of utilizing a machine learning algorithm to analyze lipidomic data for efficient and reliable biomarker screening. The 11 lipid biomarkers show great potential for the non-invasive diagnosis of MBGs with high throughput. Abstract

Objectives: Positron emission tomography (PET) and volume of interest (VOI) analysis have recently shown in amyotrophic lateral sclerosis (ALS) an accuracy of 93% in differentiating patients from controls. The aim of this study was to disclose by spatial independent component analysis (ICA) the brain networks involved in ALS pathological processes and evaluate their discriminative value in separating patients from controls. Experimental design: Two hundred fifty-nine ALS patients and 40 age-

and sex-matched control subjects underwent brain 18F-2-fluoro-2-deoxy-D-glucose PET (FDG-PET). Spatial ICA of the preprocessed FDG-PET images was performed. Intensity values were converted to z-scores and binary masks were used as data-driven VOIs. The accuracy of this classifier was tested versus a validated system processing intensity signals in 27 brain meta-VOIs. A support vector machine was independently applied to both datasets and the 'leave-one-out' technique verified the general validity of results. Principal observations: The 8 components selected as pathophysiologically meaningful discriminated patients from controls with 99.0% accuracy, the discriminating value of bilateral cerebellum/midbrain alone representing 96.3%. Among the meta-VOIs, right temporal lobe alone reached an accuracy of 93.7%. Conclusions: Spatial ICA identified in a very large cohort of ALS patients distinct spatial networks showing a high discriminatory value, improving substantially on the previously obtained accuracy. The cerebellar/midbrain component accounted for the highest accuracy in separating ALS patients from controls. Spatial ICA and multivariate analysis perform better than univariate semi-quantification methods in identifying the neurodegenerative features of ALS and pave the way for inclusion of PET in clinical trials and early diagnosis. *Hum Brain Mapp* 37:942-953, 2016. © 2015 Wiley Periodicals, Inc.

MetaQuant: A framework for metaheuristic based quantification

Item Type Journal Article

Author A.B.S. Serapião

Author Z. Donyavi

Author G. Batista

Abstract Metaheuristics are widely employed in various domains; however, their application in quantification learning remains largely unexplored. This study introduces a pioneering approach where the quantification task is treated as a global optimization problem and formulated as a linear regression model solvable by any metaheuristic algorithm. This novel methodology addresses the limitations of traditional quantifiers solved using deterministic methods, such as being trapped in local optima, encountering the curse of dimensionality, and necessitating non-convex cost functions. The paper presents MetaQuant, a novel framework for metaheuristic-based quantification algorithms, and conducts an extensive evaluation comparing 48 nature-inspired metaheuristic algorithms implementing quantifiers with 20 traditional quantifiers. The evaluation encompasses 31 multi-class datasets and reveals compelling results. The findings demonstrate the robustness and exceptional performance of metaheuristic quantifiers, with all 48 MetaQuantifiers outperforming 19 state-of-the-art quantifiers and 18 MetaQuantifiers surpassing the best traditional quantifier. This study contributes towards a promising new line of research in quantification learning. © 2025 Elsevier B.V.

Methane Retrieval Algorithms Based on Satellite: A Review

Item Type Journal Article

Author Y. Jiang

Author L. Zhang

Author X. Zhang

Author X. Cao

Abstract As the second most predominant greenhouse gas, methane-targeted emission mitigation holds the potential to decelerate the pace of global warming. Satellite remote sensing is an important monitoring tool, and we review developments in the satellite detection of methane. This paper provides an overview of the various types of satellites, including the various instrument parameters, and describes the different types of satellite retrieval algorithms. In addition, the currently popular methane point source quantification method is presented. Based on existing research, we delineate the classification of methane remote sensing satellites into two overarching categories: area flux mappers and point source imagers. Area flux mappers primarily concentrate on the assessment of global or large-scale methane concentrations, with a

further subclassification into active remote sensing satellites (e.g., MERLIN) and passive remote sensing satellites (e.g., TROPOMI, GOSAT), contingent upon the remote sensing methodology employed. Such satellites are mainly based on physical models and the carbon dioxide proxy method for the retrieval of methane. Point source imagers, in contrast, can detect methane point source plumes using their ultra-high spatial resolution. Subcategories within this classification include multispectral imagers (e.g., Sentinel-2, Landsat-8) and hyperspectral imagers (e.g., PRISMA, GF-5), contingent upon their spectral resolution disparities. Area flux mappers are mostly distinguished by their use of physical algorithms, while point source imagers are dominated by data-driven methods. Furthermore, methane plume emissions can be accurately quantified through the utilization of an integrated mass enhancement model. Finally, a prediction of the future trajectory of methane remote sensing satellites is presented, in consideration of the current landscape. This paper aims to provide basic theoretical support for subsequent scientific research. © 2024 by the authors.

Methodological issues in international comparison of interval breast cancers

Item Type Journal Article

Author J.-L. Bulliard

Author P. Sasieni

Author C. Klabunde

Author J.-P. De Landtsheer

Author B.C. Yankaskas

Author J. Fracheboud

Abstract International comparisons of interval cancers (IC) are important to better understand the relationship between programmes' performance and screening practices. In this respect, differences in (i) definition, (ii) identification and (iii) quantification of IC have received little attention. To examine these 3 comparability issues and activities involving IC, an assessment was conducted among member countries of the International Breast Cancer Screening Network, and the impact of accuracy of identification and quantification practices was estimated using 1996-98 data from the Dutch breast cancer screening programme. Information was obtained from 19 screening programmes in 18 countries, 16 of which acknowledged the coexistence of opportunistic screening. IC data were collected to evaluate performance of the screening programme (100% of programmes) and the radiologists (89%); 53% of programmes had a designated review process for IC. Most programmes (84%) agreed with the European Guidelines definition of IC, but a case situation exercise evidenced substantial discrepancy in classification of cancers that occurred after a positive screen. Completeness of identification of IC appears to contribute most to international variation, and cannot be easily controlled for in methodologically rigorous comparisons. Statistically significant differences of about 4% were measured between quantification methods for IC. An operational definition of IC is proposed to enhance international comparability. Valid comparisons of IC are possible with careful attention to the definition but true differences in IC frequency across screening programmes should exceed 10% to be possibly indicative of real differences between programmes. © 2006 Wiley-Liss, Inc.

Methodology for quantifying groundwater abstractions for agriculture via remote sensing and GIS

Item Type Journal Article

Author S. Castaño

Author D. Sanz

Author J.J. Gómez-Alday

Abstract Among the difficulties and uncertainties that arise when determining water balance is the calculation of groundwater abstraction. This factor is particularly important in aquifers whose extension and heavy agricultural use make direct quantification methods unfeasible (i.e. flow meters and power consumption data). This study presents a method of quantifying groundwater abstractions for irrigation based on the analysis of multitemporal and multispectral satellite images. The process begins with a highly detailed classification of irrigated crops; these data are entered in a Geographic Information System, overlain with a correct estimate of the irrigation requirements of the crop, and corrected in accordance with the agricultural practices of the area. The results reveal the spatial and temporal distribution of the groundwater volume abstracted and used for agriculture. This methodology has been applied in the Mancha Oriental Hydrogeological System (Spain, 7,260 km²), where abstractions for agriculture comprise more than 90% of the hydrological resources consumed. In this context, accuracies of over 95% have been obtained with a cost sixty times lower than that of traditional methods. © Springer Science+Business Media B.V. 2009.

Methodology to Estimate Low Grade Enhanced Geothermal System (EGS) Reserves Using Heat Extracted from Depleted Wells in High Temperature Shale Gas Formations

Item Type Conference Paper**Author** C. Ehlig-Economides**Author** M. Nikolaou**Author** M.A. Khan

Abstract Eventually there will be low-production gas wells in the Haynesville and Eagle Ford shale formations that are no longer monetized. The objective of this study is to assess the potential for repurposing multiple transverse fracture horizontal wells (MTFHWs) in these formations as low-grade enhanced/engineered geothermal systems. We use DrillingInfo and other available data, including formation temperature, to categorize existing gas wells as active, depleted, and still on production or abandoned, and to estimate an abandonment time for those still on production. Once the categorization is done, further study applies machine learning to quantify the current and future EGS potential of these wells. Finally, the results from the preceding studies are used to evaluate how best to distribute power plants for effective use of these resources, and to estimate how much power generation is possible. The result of this research is a methodology for

forecast of EGS power generation potential of low-grade EGS reserves in the Eagle Ford and Haynesville shale gas formations. This forecast addresses both technical and economic aspects. In effect, this work also provides a methodology for assessing the economic potential of EGS from existing MTFHWs in other formations having sufficiently high temperature for low-grade geothermal heat extraction. This research provides input to support potential EGS development in Texas that could provide clean and affordable continuous (unfluctuating) power for small municipalities or industrial applications and/or as a contribution to the regional grid power supply. Methods for Predicting Multichannel Images Classification Efficiency

Item Type Conference Paper

Author I. Vasilyeva

Author V. Lukin

Editor Ageyev D.

Abstract A method for predicting probability characteristics for algorithms of supervised classification of multichannel images is proposed. Implementation of quasi-Bayesian image recognition strategy in conditions of incomplete a priori information about a satellite image is considered. Total weighted probability of correct class recognition is taken as a criterion of effectiveness of decision rule. Weights are interpreted as estimates of a priori probability for occurrence of precedents of the corresponding classes. The procedure for estimating a priori probabilities of classes by Monte Carlo method based on the results of fuzzy classification of samples with fixed size is described; the empirical dependence of the relative error of estimates on the sample size is given. © 2020 IEEE.

Abstract The chemical diversity of natural antioxidants (AOXs) makes it difficult to separate, detect, and quantify individual antioxidants from a complex food/biological matrix. Moreover, the total antioxidant power is often more meaningful to evaluate health beneficial effects because of the cooperative action of individual antioxidant species. Currently, there is no single antioxidant assay for food labeling because of the lack of standard quantification methods. Antioxidant assays may be broadly classified as the electron transfer (ET)- and hydrogen atom transfer (HAT)-based assays. The results obtained are hardly comparable because of the different mechanisms, redox potentials, pH and solvent dependencies, etc. of various assays. This project will aid the identification and quantification of properties and mutual effects of antioxidants, bring a more rational basis to the classification of antioxidant assays with their constraints and challenges, and make the results more comparable and understandable. In this regard, the task group members convey their own experiences in various methods of antioxidants measurement. © 2013 IUPAC.

MHFNet: Multimodal hybrid fusion framework for misaligned SAR-Optical ship detection

Item Type Journal Article

Author W. Zhang

Author X. Zhang

Author X. Xu

Author S. Wei

Author J. Shi

Author Y. Wang

Author T. Zeng

Abstract Multimodal ship detection using optical and synthetic aperture radar (SAR) imagery is highly desirable for robust maritime monitoring. However, most existing fusion-based methods assume spatially aligned optical–SAR pairs, an assumption that rarely holds in practice due to differences in sensor geometry, acquisition timing, and registration errors. Such misalignment severely undermines the effectiveness of conventional fusion strategies. To address this challenge, we propose MHFNet, an alignment-aware hybrid fusion framework that systematically integrates improvements at the feature, loss, and decision levels. First, we introduce a Feature Alignment and Fusion Module (FAFM) that leverages deformable convolution and content-guided attention to achieve robust cross-modal feature alignment. Second, we design an Uncertainty-Aware Shape IoU Loss (US-Loss) that downweights unreliable training samples caused by cross-modal label shift while enhancing bounding box regression with shape-aware constraints. Third, we develop a Distance Matching Probabilistic Fusion (DMP-Fusion) algorithm that resolves inconsistencies in multimodal detection outputs through distance-based matching and Bayesian inference. Extensive experiments conducted on two benchmark datasets (QXS and Suez) show that MHFNet consistently outperforms state-of-the-art methods, improving average precision by up to + 4.77 % and F1-score by + 4.93 %. These results demonstrate that MHFNet offers a robust and generalizable solution to multimodal ship detection under realistic cross-modal misalignment conditions. The code and datasets are released on <https://github.com/wsdmw1/MHFNet>. © 2025 International Society for Photogrammetry and Remote Sensing, Inc. (ISPRS)

Micro-flow imaging for in-situ and real-time enumeration and identification of microplastics in water

Item Type Journal Article

Author N. Chorán

Author B. Örmeci

Abstract Microplastics (MPs) are emerging contaminants that have recently gained global attention. Current identification and quantification methods are known to be time-consuming, labor-intensive, and lack consensus on protocol standardization. This study explored the potential of micro-flow imaging (MFI) technology for rapid and in-situ identification and enumeration of MPs in water using two (2) MFI-based particle counters. Advantages, limitations, and recommendations for using MFI for MPs analysis were discussed. MPs with diverse physical (i.e., microbeads, fragments, fibers, and films) and surface (i.e., reflectivity, microporosity, color) characteristics were analyzed to understand the detection capabilities and limitations of MFI technology. Results demonstrated that MFI effectively automates most manually obtained particle features, such as size, color, object intensity and shape descriptors. It imparts consistency and reduces the subjective nature of results, thus enabling reliable comparison of the generated data. The particles can be further categorized

based on their circularity and aspect ratio providing further insight into the shape and potential erosion of MPs in the environment. Transparent particles, often missed with other techniques such as microscopy, were detected by the MFI technology. The ability to assign particle IDs to MPs was an important advantage of the MFI technology that enabled the further investigation of selected MPs of interest. The limitations of the MFI technology were apparent in samples with high particle concentrations, with reflective MPs, and in the presence of bubbles. The color of the background against which the image was captured also influenced the detection accuracy. Procedural modifications during sample analysis and improvements in image analysis can assist in overcoming these challenges. MFI requires minimal sample preparation and gives real-time imaging data, making it a prime candidate for field monitoring in surface water systems in addition to laboratory analysis. With the potential application of machine learning and similar developments in the future, MFI-based particle counters are well-positioned to meet an important need in in-flow and real-time identification and enumeration of MPs. Abstract Agricultural mulch films are widely applied to increase crop productivity but are a significant source of microplastics (MPs) in the environment. We investigated the incorporation of conventional and biodegradable MPs into soil aggregates from agricultural fields in Finland, Germany and Spain, hypothesising that (i) MPs become increasingly occluded within soil aggregates over time, (ii) the extent of occlusion differs between conventional and biodegradable MPs, and (iii) occluded MPs differ in morphology and surface characteristics from free MPs. Arable fields were spiked with MPs derived from either a biodegradable polybutylene adipate terephthalate-starch blend (PBAT/starch) or conventional linear low-density polyethylene (LLDPE) mulch films. Soil samples were collected after two barley-growing seasons, separated into free and occluded fractions, and analysed using digital microscopy and deep learning to quantify MP abundance, size and shape. Surface properties were assessed using scanning electron microscopy. Total MP abundance declined between cropping seasons for both polymer types, while the proportion of aggregate-occluded MPs increased, reaching 76% for PBAT/starch and 65% for LLDPE. Soil exposure altered the size, shape and surface properties of MPs in a polymer-specific manner. Occluded PBAT/starch MPs were larger and more solid than their free counterparts, consistent with protection against weathering and fragmentation within aggregates. Occluded LLDPE MPs were smaller than free particles but also exhibited higher solidity, likely reflecting preferential incorporation of particles with smoother, more uniform edges. We conclude that soil aggregate occlusion is a key mechanism governing MP fate in agricultural soils, promoting particle stability while simultaneously reducing mobility and bioavailability. © 2026 The Authors. Microplastics in Different Environmental Matrices: Co-Contaminants and its Monitoring Techniques

Item Type Journal Article

Author A. Kumar

Author K. Ram

Abstract Microplastics (MPs) are tiny plastic particles ranging from 1 to 5000 µm in size and are of particular concern nowadays because of their ecological risk & health concerns. MPs are prevalent environmental contaminants and have been reported in various ecosystems such as soil, air, water, and road dust. However, a thorough understanding of their distribution across various environmental matrices remains elusive. Therefore, this review aims to fill this knowledge gap by examining the abundance of MPs and different techniques utilized for their identification and characterization including sampling, extraction, identification, characterization, and quantification methods. MPs possess a large surface area and exhibit hydrophobic properties, providing a substrate for environmental pollutants such as Polyaromatic hydrocarbons (PAHs) and organochlorine pesticides (OCPs). The primary mechanisms through which pollutants attached to MPs are hydrophobic interactions,

electrostatic attraction, hydrogen bonding, halogen bonding, and π - π interactions. Therefore, a better understanding of these interactions is crucial for determining the fate and transport of MPs and co-contaminants in the environment. Researchers commonly deploy techniques such as stereomicroscopy and spectroscopy for the characterization and quantification of MPs. However, size and chemical properties of MPs pose a challenge in their quantification, thereby necessitating the development of standardized analytical methods. Use of bio-indicators for MPs biomonitoring has gained popularity in recent years as an affordable option over conventional techniques however research in this area is limited. With this intention, the present review is designed to provide information about the status of the field and advance our knowledge of MPs in various environmental matrices. © The Author(s), under exclusive licence to Springer Nature Switzerland AG 2024.

Microplastics in terrestrial ecosystems: Soil contamination and its implications for pedology

Item Type Journal Article**Author** C.B. Andrade**Author** M.R. Francelino**Author** A. Ten Caten

Abstract The environmental persistence of plastics, their slow degradation and constant fragmentation pose risks to soil health. Microplastic (MP) contamination is already a real global environmental issue, with increasing evidence of its widespread presence in all terrestrial ecosystems, affecting physical and chemical properties, microbial communities, and pedogenetic processes. Soil serves as a significant sink for MPs, primarily through agricultural practices, landfills, waste mismanagement, wastewater treatment and atmospheric deposition. Furthermore, plastics can contribute to the formation of "rocks" (e.g., plastiglomerates and antropoquinas) that could redefine soil classification systems. Existing classification frameworks, including the World Reference Base for Soil Resources, Australian Soil Classification, U.S. Soil Taxonomy, and Brazilian Soil Classification System (SiBCS), differ in how they address the presence of plastics, highlighting a lack of consensus in recognizing anthropogenic artifacts within soils. Despite its increasing prevalence, plastics are often overlooked in soil classification systems, prompting the need for new qualifiers. Furthermore, advancements in detection and quantification methods, such as Soil Spectroscopy and Digital Soil Mapping, are essential to improve our understanding of MP behavior in soil matrices. Pedologists play a crucial role in quantifying MP impacts, developing soil management strategies, and contributing to global environmental policy. Addressing soil MP pollution requires international cooperation, transdisciplinary research, and robust methodological approaches to safeguard soil ecosystems and human health. Research on soil MP pollution has the potential to alter our understanding of human influence on soil properties and functions, with implications for the genesis and classification of Anthrosols. This review highlights important aspects of this phenomenon, with a greater focus on the Brazilian context. Soil scientists are encouraged to pay attention to this matter and contribute to filling current knowledge gaps. © 2026, Revista Brasileira de Ciencia do Solo. All rights reserved.

Abstract Background & objectives: In gastrointestinal stromal tumour (GIST), not only genetic abnormalities are responsible for adverse clinical events, but epigenetic modifications also play a crucial role. MicroRNA (miRNA) dysregulation plays a significant role in carcinogenesis as miRNAs serve as natural silencer for their targets. Our study aimed to explore the miRNAs expression and its association with molecular and histopathological characteristics of GIST. Methods: Fifty GIST samples, including 45 formalin fixed paraffin embedded (FFPE) and fresh tissues were included. Peripheral non-tumour tissues were used as controls. All the cases were confirmed using immunohistochemistry. RNA was extracted using miRNA-specific kit, and the expression was performed using RT-qPCR. The data were evaluated using AriaMx software version 1.5 (Agilent, US). MiRNAs expression was analyzed by using the relative quantification method ($\Delta\Delta CT$). Results: miR-221, miR-222, miR-494 and miR-34a showed significant down-regulation in tumours relative to non-tumour tissues. The expression levels of these miRNAs were significantly down-regulated in c-KIT (proto-oncogene encoding the tyrosine kinase transmembrane receptor)-positive tumours compared to c-KIT-negative. Further analysis revealed that reduced expression was associated with spindle subtypes and gastric localization. However,

there was no significant correlation with other histological features. Additionally, miR-221/222, and miR-494 were down-regulated in most of the KIT exon 11 mutant subtypes, while miRNA-34a was associated with platelet derived growth factor receptor alpha (PDGFRA) mutations. Interpretation & conclusions: The present study showed that the down-regulation of these miRNAs may help better molecular classification and characterization of GISTs. Our results offer new insight into the association between miRNAs and histological features, enabling a more thorough understanding of GISTs at the molecular level. © 2024, Indian Journal of Medical Research.

Microvascular Metrics on Diabetic Retinopathy Severity: Analysis of Diabetic Eye Images from Real-World Data

Item Type Journal Article

Author C. Cuscó

Abstract Objective: To quantify microvascular lesions in a large real-world data (RWD) set, based on single central retinal fundus images of diabetic eyes from different origins, with the aim of validating its use as a precision tool for classifying diabetic retinopathy (DR) severity. Design: Retrospective meta-analysis across multiple fundus image datasets. Sample size: The study analyzed 2445 retinal fundus images from diabetic patients across four diverse RWD international datasets, including populations from Spain, India, China and the US. Intervention: The quantification of specific microvascular lesions: microaneurysms (MAs), hemorrhages (Hmas) and hard exudates (HEs) using advanced automated image analysis techniques on central retinal images to validate reliable metrics for DR severity assessment. The images were pre-classified in the DR severity levels as defined by the International Clinical Diabetic Retinopathy (ICDR) scale. Main Outcome Measures: The primary variables measured were the number of MAs, Hmas, red lesions (RLs) and HEs. These counts were related with DR severity levels using statistical methods to validate the relationship between lesion counts and disease severity. Results: The analysis revealed a robust and statistically significant increase ($p < 0.001$) in the number of microvascular lesions and the DR severity across all datasets. Tight data distributions were reported for MAs, Hmas and RLs, supporting the reliability of lesion quantification for accurately assessing DR severity. HEs also followed a similar pattern, but with a broader dispersion of data. Data used in this study are consistent with the definition of the DR severity levels established by the ICDR guidelines. Conclusions: The statistically significant increase in the number of microvascular lesions across DR severity validate the use of lesion quantification in a single central retinal field as a key biomarker for disease classification and assessment. This quantification method demonstrates an improvement over traditional assessment scales, providing a quantitative microvascular metric that enhances the precision of disease classification and patient monitoring. The inclusion of a numerical component allows for the detection of subtle variations within the same severity level, offering a deeper understanding of disease progression. The consistency of results across diverse datasets not only confirms the method's reliability but also its applicability in a global healthcare setting. © 2024 by the authors.

Mid-infrared spectra of dried and roasted cocoa (*Theobroma cacao* L.): A dataset for machine learning-based classification of cocoa varieties and prediction of theobromine and caffeine content

Item Type Journal Article**Author** G.A. Collazos-Escobar**Author** A.F. Bahamón-Monje**Author** N. Gutiérrez-Guzmán

Abstract This paper presents a comprehensive dataset of mid-infrared spectra for dried and roasted cocoa beans (*Theobroma cacao* L.), along with their corresponding theobromine and caffeine content. Infrared data were acquired using Attenuated Total Reflectance-Fourier Transform Infrared (ATR-FTIR) spectroscopy, while High-Performance Liquid Chromatography (HPLC) was employed to accurately quantify theobromine and caffeine in the dried cocoa beans. The theobromine/caffeine relationship served as a robust chemical marker for distinguishing between different cocoa varieties. This dataset provides a basis for further research, enabling the integration of mid-infrared spectral data with HPLC (as a standard) to fine-tune machine learning and deep learning models that could be used to simultaneously predict the theobromine and caffeine content, as well as cocoa variety in both dried and roasted cocoa samples using a non-destructive approach based on spectral data. The tools developed from this dataset could significantly advance automated processes in the cocoa industry and support decision-making on an industrial scale, facilitating real-time quality control of cocoa-based products, improving cocoa variety classification, and optimizing bean selection, blending strategies, and product formulation, while reducing the need for labor-intensive and costly quantification methods. The dataset is organized into Excel sheets and structured according to experimental conditions and replicates, providing a valuable framework for further analysis, model development, and calibration of multivariate statistical models. © 2024 The Author(s)
