Abstract General Movement Assessment (GMA) is a reliable non-invasive method for the early detection of neurodevelopmental disorders in infants, based on the qualitative evaluation of three key parameters: complexity, variability, and fluidity. Current automated approaches primarily use composite indices on two-dimensional data, limiting parameter-specific evaluations and failing to fully exploit three-dimensional kinematic information. This study addresses three critical gaps in automated GMA research: (1) the lack of publicly available datasets for preterm and writhing movements, (2) the need for parameter-specific quantification methods aligned with clinical assessment criteria, and (3) the limited exploration of deep learning approaches for 3D skeletal data analysis. We introduce the AGMA dataset containing 264 three-dimensional movement trajectories from 126 preterm infants (born < 33 weeks gestational age), with expert annotations for complexity, variability, and fluidity. We propose novel handcrafted features for individually quantifying each GMA parameter, achieving area under the curve (AUC) values of 0.75, 0.77, and 0.86 for complexity, variability, and fluidity classification, respectively, using Random Forest classifiers. Notably, spectral entropy emerged as a highly discriminative feature for fluidity assessment (AUC = 0.86, recall = 0.83), representing the first application of this measure in the GMA context. We also evaluate graph convolutional networks (STGCN and DeGCN) for movement classification, though their performance was limited by the dataset size. The publicly released AGMA dataset, containing 264 trajectories from 126 infants, along with our parameter-specific classification methods, establishes a reproducible baseline for future automated GMA research and clinical validation studies. © 2026 The Authors.

Abstract Epigenetic transformations may provide early indicators for cancer and other disease. Specifically, the amount of genomic 5-hydroxymethylcytosine (5-hmC) was shown to be globally reduced in a wide range of cancers. The integration of this global biomarker into diagnostic workflows is hampered by the limitations of current 5-hmC quantification methods. Here we present and validate a fluorescence-based platform for high-throughput and cost-effective quantification of global genomic 5-hmC levels. We utilized the assay to characterize cancerous tissues based on their 5-hmC content, and observed a pronounced reduction in 5-hmC level in various cancer types. We present data for glioblastoma, colorectal cancer, multiple myeloma, chronic lymphocytic leukemia and pancreatic cancer, compared to corresponding controls. Potentially, the technique could also be used to follow response to treatment for personalized treatment selection. We present initial proof-of-concept data for treatment of familial adenomatous polyposis. © 2019 UICC

A Bayesian approach for classification of buried objects using non-parametric prior model

Item Type Conference Paper

Author A. Aliamiri

Author J. Stalnaker

Author E.L. Miller

Abstract We used kernel density estimation to build a-priori probability distributions on the vector of features used to characterize unexploded ordnance from electromagnetic induction sensor data. This priori information is then used in a Bayesian framework to develop a new suite of estimation and classification algorithms. Based on this prior information several classification algorithms are developed in feature and signal space. Results using real field data show more robust estimation and significant improvement in classification performance for signal space classifiers comparing to conventional Gaussian approximation to the density of the features.

A Bayesian approach for maintenance action recommendation

Item Type Journal Article

Author V. Katsouros

Author V. Papavassiliou

Author C. Emmanouilidis

Abstract This paper presents a Bayesian approach for maintenance action recommendation tested on the PHM 2013 Data Challenge dataset. The Challenge focused on maintenance action recommendation based on historical cases and the algorithms were evaluated on their ability to recommend confirmed problem types. The proposed approach is based on a Bayesian inference methodology and deals with recommending an already known problem type for each case. The recommender can be viewed as a classifier among the confirmed problem types. For each such problem type class the a priori probabilities for the events which characterize the problem type from the training data are estimated. When testing cases are presented, the recommender calculates the a posteriori probabilities for each of the confirmed problem types and suggests the type of problem that corresponds to the maximum a posteriori (MAP) probability.

A Bayesian framework for discovering interpretable Lagrangian of dynamical systems from data

Item Type Journal Article

Author T. Tripura

Author S. Chakraborty

Abstract Learning and predicting the dynamics of physical systems requires a profound understanding of the underlying physical laws. Recent works on learning physical

laws involve the extension of the equation discovery frameworks to the discovery of Hamiltonian and Lagrangian of physical systems. While the existing methods parameterize the Lagrangian using neural networks, we propose an alternate framework for learning interpretable Lagrangian descriptions of physical systems from limited data using the sparse Bayesian approach. Unlike existing neural network-based approaches, the proposed approach (a) yields an interpretable description of Lagrangian, (b) exploits Bayesian learning to quantify the epistemic uncertainty due to limited data, (c) automates the distillation of Hamiltonian from the learned Lagrangian using Legendre transformation, and (d) provides ordinary (ODE) and partial differential equation (PDE) based descriptions of the observed systems. Six different examples involving both discrete and continuous systems illustrate the efficacy of the proposed approach. © 2024 Elsevier Ltd

A Bayesian non-parametric Potts model with application to pre-surgical FMRI data

Item Type Conference Paper

Author T.D. Johnson

Author Z. Liu

Author A.J. Bartsch

Author T.E. Nichols

Abstract The Potts model has enjoyed much success as a prior model for image segmentation. Given the individual classes in the model, the data are typically modeled as Gaussian random variates or as random variates from some other parametric distribution. In this article, we present a non-parametric Potts model and apply it to a functional magnetic resonance imaging study for the pre-surgical assessment of peritumoral brain activation. In our model, we assume that the Z-score image from a patient can be segmented into activated, deactivated, and null classes, or states. Conditional on the class, or state, the Z-scores are assumed to come from some generic distribution which we model non-parametrically using a mixture of Dirichlet process priors within the Bayesian framework. The posterior distribution of the model parameters is estimated with a Markov chain Monte Carlo algorithm, and Bayesian decision theory is used to make the final classifications. Our Potts prior model includes two parameters, the standard spatial regularization parameter and a parameter that can be interpreted as the a priori probability that each voxel belongs to the null, or background state, conditional on the lack of spatial regularization. We assume that both of these parameters are unknown, and jointly estimate them along with other model parameters. We show through simulation studies that our model performs on par, in terms of posterior expected loss, with parametric Potts models when the parametric model is correctly specified and outperforms parametric models when the parametric model is misspecified. © The Author(s) 2012 Reprints and permissions: sagepub.co.uk/journalsPermissions.nav.

Abstract Soil organic matter (SOM) is a key metric for assessing soil quality and crop yield potential. It plays a vital role in maintaining the ecological balance environment and promoting sustainable farming practices. This review examines the evolving trends in remote sensing (RS)-based SOM monitoring by analyzing 739 scholarly publications from the Web of Science database from 2003 to 2023 using a bibliometric approach. The study reveals that research on RS-based SOM monitoring has entered a rapid growth phase since 2018, with China and the United States as the main contributors and an extensive international cooperation network. In model construction, high frequency covariates such as soil pH, precipitation, temperature, and topography significantly improved the prediction accuracy. Data preprocessing methods such as Standard Normal Variables (SNV), Principal Component Analysis (PCA), and Multiple Scattering Correction (MSC) enhanced data consistency. Traditional statistical models are gradually being replaced by nonlinear machine learning and deep learning methods (CNN, XGBoost, and Stacking), which are particularly good at handling complex high-dimensional data. Regional spectral libraries (OzSoil and

AfSIS) excel in local accuracy, while global spectral libraries (ISRIC and LUCAS) are more suitable for cross-region modeling, and the migration learning technique effectively improves the model generalization ability in low data regions. Integrated models (CNN-LSTM and GAN) have significant advantages in capturing the spatial and temporal dynamics of SOMs, and uncertainty quantification methods (Bayesian inference, Monte Carlo simulation) enhance the reliability of the models in multi-source data and data-scarce scenarios. Future research should focus on further optimization of multi-source data fusion and uncertainty quantification to promote the development and applicability of RS-based SOM monitoring techniques for precision soil management and sustainable agriculture. © 2025 The Authors

A bottom-up building stock quantification methodology for construction minerals using Earth Observation. The case of Hanoi

Item Type Journal Article**Author** T. Bide**Author** A. Novellino**Author** E. Petavratzi**Author** C.S. Watson

Abstract Increasing demand for significant volumes of construction materials, especially sand for use in concrete, in rapidly developing urban environments is becoming a significant socio-economic and environmental issue. The consumption of concrete (comprised of sand, aggregates and cement) is especially concerning on a city level as vast volumes of materials are extracted within the urban hinterland, causing direct impacts locally and the potential for supply issues directly impacting city level metabolism. Excessive consumption and poor management of these materials make it increasingly hard for society to ensure new urban development and infrastructure projects, essential for maintaining the health of cities, meet sustainable development objectives. However, it is difficult to implement suitable resource management policies without first understanding how materials are produced and consumed at an appropriate spatial level. For many areas, especially on a city level, such data is absent, especially so for sand and aggregates which can further exacerbate these local supply issues and environmental impacts. This study attempts to address this data gap via combining earth observation datasets with estimates of materials contained within urban infrastructure (material intensities) to calculate the rapid increase of construction material stocks in Hanoi. Spatial data on buildings have been gathered using, producing, and collating a variety of spaceborne open-source datasets on built up areas (GlobalMLBuildingFootprint, World Settlement Footprint 3D, Open Street Map) and land use classification maps. Linking this spatial data with estimated quantities of sand, gravel, cement and concrete in typical buildings in Hanoi enables quantification of building stocks for a range of building types over a time series. The results show that for every new km² of urban infrastructure approximately 520,000 tonnes of concrete, or 360,000 tonnes of sand, 580,000 tonnes of gravel and 115,000 tonnes of cement are required. If the Hanoi Masterplan is to be achieved by 2030, then the material demand is likely to be for 106 million tonnes of concrete or 73 million tonnes of sand, 118 million tonnes of gravel and 24 million tonnes of cement. These all exceed historical consumption trends and are far in excess of current extraction rates and therefore careful planning is required to ensure access to sustainable resources into the future. © 2023 The Authors

Abstract Pervasive sensing enables diverse wearable event detection (WED) applications, but deploying machine learning models on resource-constrained microcontrollers (MCUs) poses significant challenges, particularly in ensuring prediction reliability under data shifts or out-of-distribution (OOD) inputs. While Uncertainty quantification methods offer a way to assess this reliability, many are computationally prohibitive for MCUs, and detecting multiple events concurrently further exacerbates resource constraints. Addressing these combined challenges, this paper presents an uncertainty and resource-aware framework designed for reliable and efficient multi-event WED on MCUs, significantly extending our preliminary work. The proposed framework achieves this by integrating Evidential Deep Learning (EDL) for efficient, single-pass uncertainty estimation with a novel cascade learning architecture. This architecture promotes resource efficiency via: (i) intra-event sharing using uncertainty-aware early exits within a staged model (shallow, medium, deep), allowing simpler samples to terminate inference earlier; and (ii) inter-event sharing using a multi-head design where multiple event detectors share a common backbone, minimizing overhead. System efficiency is further enhanced through MCU-specific optimizations, including targeted architecture search, quantization, efficient uncertainty operator implementation using standard TensorFlow Lite Micro (TFLM) operations, and library footprint reduction. We conducted extensive experiments on four distinct wearable datasets (Oesense, KWS, ECG5000, and HHAR) and two MCU platforms (STM32F446ZE, STM32H747XI), comparing the proposed

framework against strong baselines including Deep Ensembles and Vanilla EDL. Results demonstrate the proposed framework's effectiveness, achieving competitive accuracy and uncertainty performance (e.g., up to 22% lower NLL than data augmentation) while drastically reducing resource consumption, offering up to 8.64× faster inference, up to 8.57× lower energy use, and 55% smaller memory footprint compared to ensemble methods. The proposed framework enables the deployment of reliable, uncertainty-aware multi-event detection on a wider range of low-power MCUs. © 2026

A case study of SVM extension techniques on classification of imbalanced data

Item Type Journal Article

Author K.K. Lee

Author C.J. Harris

Author S.R. Gunn

Author P.A.S. Reed

Abstract In many classification problems the data is imbalanced, that is the class priors are different. Here, we consider the classification problem of fatigue crack initiation in automotive camshafts, where this imbalance is significant. The extension techniques

of Support Vector Machine (SVM) - the Control Sensitivity (CSSVM) and Adaptive Margin (AMSVM) - which offer different ways of dealing with imbalanced data was investigated. Geometric mean was used to evaluate the performance of the model. The CSSVM has outperformed the AMSVM. The use of different kernels did not produce significant changes in the results. The ratio between the misclassification cost and the training size for each class is very similar, indicating a strong relationship between them.

A classification and quantitative assessment method for internal and external surface defects in pipelines based on ASTC-Net

Item Type Journal Article

Author J. Yuan

Author M. Qiao

Author C. Hu

Author Y. Cheng

Author Z. Wang

Author D. Zheng

Abstract Classification and size quantification of defects on both the internal and external surfaces of pipelines are critical to pipeline integrity assessment. However, defect

classification is challenging because of the similarities of defect signals on the internal and external surfaces. In addition, most existing size quantification methods are not sufficiently accurate. To solve these problems, this paper proposes a classification and quantitative evaluation method based on an asymmetric student–teacher with a classifier network (ASTC-Net). First, a novel approach for expanding defect magnetic flux leakage (MFL) data is validated through experiments and simulations. Second, ASTC-Net is built to address the problem of defect classification and quantification. Finally, the superiority of the method is verified by experiments. The results show that this approach pioneers the accurate classification of defects on both internal and external surfaces by achieving an accuracy of 99.41%. Furthermore, a high-precision quantitative assessment of defect size is realized, with length, width, and depth errors of only 0.35 mm, 0.34 mm, and 0.41% of the wall thickness, respectively. These experimental results clearly demonstrate that this method has exceptionally high accuracy in defect classification and quantification, offering vast prospects for its application in pipeline MFL evaluation. © 2024 Elsevier Ltd

A classification for macroscopic charcoal morphologies found in Holocene lacustrine sediments

Item Type Journal Article

Author C.J.C. Mustaphi

Author M.F. Pisaric

Abstract Macroscopic charcoal analysis of lake sediment stratigraphies is a widely used approach to reconstruct past biomass burning patterns of ecosystems. The development of fire records often relies on a single quantification method of charcoal in a sediment subsample; however, recent studies have shown that additional paleoecological information can be obtained by classifying charcoal morphologies. The morphologies and diagnostic features of charcoal yields information about fuel sources, fire type, and charcoal taphonomy, and can aid in calibrating sediment records to known historical fires. This additional information enhances paleoecological inferences by providing more paleoenvironmental information than studies of total charcoal as the only metric. Here we present a classification of 27 macroscopic charcoal morphologies observed in Holocene sediments of lakes located in the mixed-conifer forests of southeastern British Columbia, Canada. This classification system builds on other morphological classifications that have been previously utilized, but is more inclusive of the morphological variability observed and is flexible to modification for use when applied to other study settings. The morphological classification presented here was developed following the observation of >100,000 macroscopic charcoal fragments >150 µm. This paper focuses on the observed morphological classes, their identification, potential fuel sources, and the morphotype assemblage stratigraphy from one site as an example. The charcoal assemblages varied throughout the mid-to-late Holocene contemporaneously with known regional scale hydroclimatic changes in British Columbia. Major changes in fire frequency were also concomitant with morphotype assemblage changes. Future work focusing on linking fuel types with charcoal morphotypes, post-fire observations of charcoal taphonomy, and the analysis of multiple attribute charcoal data sets from a variety of ecosystems will improve our understanding of biomass burning and long-term fire ecology. © The Author(s) 2014.

A Classification for Synthetic Inertia Quantification Methods with Practical Recommendations

Item Type	Conference Paper
Author	M. Mohammadi
Author	W. Ripley
Author	T. Hsu
Author	M.G. Dozein
Abstract	With ongoing advancements in grid-forming (GFM) technologies and inverter design, future power systems will likely operate with a mix of synthetic inertia, provided by inverter-based resources (IBRs) and large-scale loads, and synchronous inertia from traditional rotating machines such as synchronous condensers and conventional power plants. In this context, there is an essential need to quantify synthetic inertia to ensure its commercial viability as a service, add further certainty to GFM system interconnection and business cases of GFM projects, and their integration into emerging ancillary service market mechanisms. This paper presents a classification for synthetic inertia quantification methods, including large disturbance methods, RoCoF emulation methods, probing signal injection strategies, and conceptual approaches that may become practical in the future. The mathematical and implementation process for these synthetic inertia quantification methods are presented, as well as the issues and requirements. A rigorous comparison between different methods are presented considering accuracy, perturbation type, damping decoupling, as well as the issues with implementation and the complexity involved. Finally, practical recommendations and future research directions are presented along with industry specifications on equipment capable of providing synthetic inertial responses. © 2025 IEEE.

A Cluster-based Regrouping approach for Imbalanced data distributions

Item Type Conference Paper

Author W. Yu

Author S. Jiang

Abstract In real-world applications, it has been observed that class imbalance (significant differences in class prior probabilities) may produce an important deterioration of the classifier performance, in particular with patterns belonging to the less represented classes. In this paper, we propose a Cluster-based Regrouping approach (CR) which divides the whole training data into positive group and negative group by clustering through the outlier factor. As a result, the similar samples will be in the same group while the dissimilar samples will be in the different groups. Then the basic classifier is employed to build the models on both the positive group and the negative group respectively. When classifying the new object, the model used to evaluate will be chosen according to the type of the group which the new object is nearest. The experimental results demonstrate that our approach achieved promising performance in some cases by directly or indirectly reducing the class distribution skewness. © 2012 TSI Press.

Abstract The characterization and evaluation of uncertainties caused by the automated manufacturing procedure are essential for the early structural design and application of 3D woven composites. To account for the inherent uncertainties, numerical simulations must be integrated with statistical uncertainty quantification and propagation methods. However, in some cases, it is very challenging and computationally time consuming. In this paper, a multiscale uncertainty quantification method combining finite element analysis, wide & deep neural network and sensitivity analysis is proposed to probabilistically evaluate the tensile response of 3D angle-interlock woven composites. The required dataset for training and validating the model is created by a two-step numerical simulation. With the present model, a framework of the importance of each uncertainty in determining the macroscopic properties' variance can be established with fewer computational resources. The results indicate that the effect of uncertainties on the material tensile response is significant and the sensitivity information can serve as a guide for reducing uncertainties at the macroscale. © 2022 Elsevier Ltd

A Comfort Quantification Method Based on Semi-Supervised Learning for Automated Vehicle at Lane Change Scenarios

Item Type Journal Article

Author W. Zhu

Author X. Zhang

Author C. Hu

Author B. Zhao

Author S. Peng

Author H. Yang

Abstract This paper systematically investigates a passenger comfort quantification model for automated vehicle by integrating attention mechanism-based bidirectional long short-term memory (AM-Bi-LSTM) network, semi-supervised learning strategy, and passenger heterogeneity. Firstly, a comfort quantification dataset is gathered from a physical vehicle. More than thirty volunteers are recruited. Passenger classification based on volunteer heterogeneity is introduced for label reconstruction. Secondly, this

paper innovatively develops a comfort degree quantification model based on the combination of AM-Bi-LSTM and semi-supervised learning. The semi-supervised learning strategy is developed to generate pseudo-labels and reduce dataset noise caused by individual variances of volunteers. The final model precision increases by 22.7% compared with the model trained on raw dataset. Finally, the deployment of model on physical automated vehicle is accomplished. The outputs of onboard real-time comfort quantification system are consistent with the driving intensity of automated vehicle. The results illustrate that the proposed model can accurately identify different comfort degrees of lane change scenarios, which can enhance the evaluation capacity of automated vehicle and optimize the decision-making and path planning modules of automated driving framework with more personalized driving styles. © 2016 IEEE.

A Comparative Approach to Threshold Optimization for Classifying Imbalanced Data

Item Type Conference Paper

Author J. Hancock

Author J.M. Johnson

Author T.M. Khoshgoftaar

Abstract For the practical application of a classifier, it is necessary to select an optimal output probability threshold to obtain the best classification results. There are many criteria one may employ to select a threshold. However, selecting a threshold will often involve trading off performance in terms of one metric for performance in terms of another metric. In our literature review of studies involving selecting thresholds to optimize classification of imbalanced data, we find there is an opportunity to expand on previous work for an in-depth study of threshold selection. Our contribution is to present a systematic method for selecting the best threshold value for a given classification task and its desired performance constraints. Just as a machine learning algorithm is optimized on some training data set, we demonstrate how a user-defined set of performance metrics can be utilized to optimize the classification threshold. In this study we use four popular metrics to optimize thresholds: precision, Matthews' Correlation Coefficient, f-measure and geometric mean of true positive rate, and true negative rate. Moreover, we compare classification results for thresholds optimized for these metrics with the commonly used default threshold of 0.5, and the prior probability of the positive class (also known as the minority to majority class ratio). Our results show that other thresholds handily outperform the default threshold of 0.5. Moreover, we show that the positive class prior probability is a good benchmark for finding classification thresholds that perform well in terms of multiple metrics. © 2022 IEEE.

A Comparative Evaluation of Quantification Methods

Item Type Journal Article

Author T. Schumacher

Author M. Strohmaier

Author F. Lemmerich

Abstract Quantification represents the problem of estimating the distribution of class labels on unseen data. It also represents a growing research field in supervised machine learning, for which a large variety of different algorithms has been proposed in recent years. However, a comprehensive empirical comparison of quantification methods that supports algorithm selection is not available yet. In this work, we close this research gap by conducting a thorough empirical performance comparison of 24 different quantification methods on in total more than 40 datasets, considering binary as well as multiclass quantification settings. We observe that no single algorithm generally outperforms all competitors, but identify a group of methods that perform best in the binary setting, including the threshold selection-based median sweep and TSMax methods, the DyS framework including the HDy method, Forman's mixture model, and Friedman's method. For the multiclass setting, we observe that a different, broad group of algorithms yields good performance, including the HDx method, the generalized probabilistic adjusted count, the readme method, the energy distance minimization method, the EM algorithm for quantification, and Friedman's method. We also find that tuning the underlying classifiers has in most cases only a limited impact on the quantification performance. More generally, we find that the performance on multiclass quantification is inferior to the results obtained in the binary setting. Our results can guide practitioners who intend to apply quantification algorithms and help researchers identify opportunities for future research. ©2025

A Comparative Study of Landslide Susceptibility Mapping Using Bagging PU Learning in Class-Prior Probability Shift Datasets

Item Type Journal Article

Author L. Zhao

Author H. Ma

Author J. Dong

Author X. Wu

Author H. Xu

Author R. Niu

Abstract Landslide susceptibility mapping is typically based on binary prediction probabilities. However, non-landslide samples in modeling datasets are often unlabeled data, and the phenomenon of class-prior shift, that is, the proportion of landslide samples frequently deviates from real-world scenarios and is spatially heterogeneous. By comparing the classification performance and predicted probability distributions across multiple unbalanced datasets with known and unknown sample proportions, this study assesses the landslide susceptibility model's generalization ability in the context of class-prior shifts. The study investigates the potential of Bagging PU

Learning, a semi-supervised learning approach, in improving the generalization performance of landslide susceptibility models and proposes the Bagging PU-GDBT algorithm. Our findings highlight the effectiveness of Bagging PU Learning in enhancing the recall of landslides and the generalization capabilities of models on unbalanced datasets. This method reduces prediction uncertainties, especially in high and very high susceptibility zones. Furthermore, results emphasize the superiority of models trained on balanced datasets with 1:1 sample ratio for landslide susceptibility mapping over those trained on unbalanced datasets. © 2023 by the authors.

A Comparison of Data-Driven Shape Quantification Methods for 2D Microscopy Images

Item Type Conference Paper

Author A.F. Romero

Author A. Krull

Author V. Uhlmann

Abstract Shape is a fundamental property of cells and nuclei that informs on their function and state, and is one of the key readouts of 2D microscopy image data. Quantifying shape in an unbiased manner however remains challenging, especially in exploratory contexts where discovering phenotypes with as little prior as possible is highly desirable. In this work, we demonstrate the practical value of data-driven shape quantification methods on three publicly available microscopy image datasets of cells and nuclei. We compare the information that can be gathered from shape representations obtained with state-of-the-art self-supervised learning models and contrast it against the performance of the widely-used baseline consisting of describing shape with a collection of summary statistics. Our results identify the recently-published ShapeEmbed model as a powerful option, prompting us to propose a simpler variant, coined ShapeEmbedLite, which reduces the complexity of the approach without sacrificing performance and even achieve gains in some metrics. Through our experiments, we demonstrate that data-driven representations obtained through self-supervised learning can facilitate the visual and quantitative exploration of shape differences in 2D microscopy image data with minimal bias, and that the variations they capture align with true signal originating from different experimental conditions or biological states. These findings outline the promising outlook of such methods to drive biology discovery and to help identify rare or unknown shape phenotypes. © 2025 IEEE.

A comparison of three different methods for the quantification of the in vitro wear of dental materials

Item Type Journal Article

Author S.D. Heintze

Author A. Cavalleri

Author M. Forjanic

Author G. Zellweger

Author V. Rousson

Abstract Objective: Different approaches are utilized to quantify the wear generated on flat specimens with a wear simulator. However, there are no systematic studies comparing different wear quantification methods with a series of materials that exhibit different wear rates. Methods: Sixteen restorative materials, including 14 composites (BelleGlass, Chromasit, Estenia, Esthet-X, Four Seasons, Heliomolar RO, Heliomolar HB, Herculite XRV, InTen-S, Point 4, SureFil, Targis cured at 95 and 130 °C, Tetric Ceram) as well as an amalgam (Amalcap) and a ceramic (Empress) material, were subjected to attrition wear against standardized Empress antagonists in the Willytec wear simulator (120,000 cycles, 5 kg, 1.6 Hz). The volume and maximal vertical loss were quantified directly on the specimens with a profilometry device (Perthometer) and the FRT MicroProf optical sensor. After the fabrication of plaster replicas, the loss was also determined with a 3D laser scanning device. For the statistical analysis, the data were subjected to a logarithmic transformation. Intraclass correlation was calculated to measure the agreement among all three methods, while limits of agreement were used to compare one method against another. Results: There was a very good agreement between all three quantification methods for both volume and vertical loss. The mechanical sensor measured consistently higher values compared to the optical sensors for the volume loss (correction factor 0.95), whereas for the vertical loss, consistently lower values were obtained (correction factor 1.17). However, the ranking of the materials was only marginally influenced by the quantification method. Significance: All three sensors are suitable for the quantification of wear facets. Due to speed and simplicity, the laser sensor has greater advantages over the two other sensors. © 2005 Academy of Dental Materials.

Abstract The adoption of machine learning (ML) technology in real-world settings like medical imaging is currently hampered by a lack of trust in ML models and a lack of labeled data. These two issues are currently addressed in parallel by two subdisciplines of ML: uncertainty quantification (UQ) is concerned with obtaining reliable estimates of a model's confidence in its outputs, and active learning (AL) deals with efficiently training models in low-data regimes. To date, the usefulness of the new methods emerging from the field of UQ for AL remains under-explored. We here take a step to address this by comparing seven different UQ methods on three image classification data sets. Our experiments confirm previous indications in the AL literature that the ranking of sampling strategies can vary greatly across models and data sets. We find that Concrete Dropout, Least Confidence, Smallest Margin, and Entropy sampling consistently outperform Random sampling across data sets, whereas Ensembles, Monte-Carlo Dropout, and Bayes-by-Backprop do not. We also observe that AL training stability is sensitive to data quality. © 2022 IEEE.

A comprehensive strategy using chromatographic profiles combined with chemometric methods: Application to quality control of *Polygonum cuspidatum* Sieb. et Zucc

Item Type Journal Article

Author F. Gao

Author Z. Xu

Author W. Wang

Author G. Lu

Author Y. Vander Heyden

Author T. Zhou

Author G. Fan

Abstract For the strict quality control of herbs, a comprehensive strategy based on chromatographic profiles and chemometric methods which could reliably select quantitative indices, robustly quantitate multi-markers and systematically compare different chemometric methods was proposed and successfully applied to the quality analysis of *P. cuspidatum*. Based on the construction of chromatographic profiles by an efficient accelerated solvent extraction (ASE) and reliable high-performance liquid chromatography-ultraviolet (HPLC-UV) methods, different chemometric methods were employed, namely similarity analyses (SA), hierarchical clustering analysis (HCA) and linear discriminant analysis (LDA). The differences in classification of herb samples were studied for the first time. To reasonably determine the quality of herbs and evaluate different chemometric methods, a comprehensive strategy containing three key steps was performed including selection of quantitative indices, development of a reliable quantification method and adoption of an easily calculated and visible parameter. The quantitative method which was acceptable with good linearity with correlation coefficients >0.9995 and satisfactory repeatability ($\text{RSD} < 1.5\%$), precision ($\text{RSD} < 2.84\%$), reproducibility ($\text{RSD} < 2.88\%$), stability ($\text{RSD} < 2.85\%$) and recoveries (91.5%–105.6%, $\text{RSD} < 2.83\%$) was applied to quality evaluation of fourteen batches of the *P. cuspidatum* samples through simultaneous quantitative determination of fifteen marker compounds. The limits of quantitation of fifteen compounds ranged from 1 to 60 $\mu\text{g}/\text{ml}$. From the results of the quality evaluation, it was found that the different calculation theories of the chemometric methods resulted in the variation of classifiers of samples: SA classified samples through the mean values and HCA & LDA classified similar objects. © 2016 Elsevier B.V.

Editor Su Z.

Abstract SHM and NDE/NDT are developed to evaluate the amount of damage to a structure. Since human inspections are prone to misdiagnosis and/or misinterpretations, the damage assessment and identification methods are shifting from human-based to computer-based. In this article, a computer vision method is used to detect and quantify the cracks on a concrete surface. After processing the

crack images, cracks are modeled as graphs for feature extraction. To study the proposed method, concrete surface crack images from a reinforced concrete shell under quasi-linear load at each load step are used. Pearson Correlation Analysis is implemented to evaluate the relationship between graph measures at the north and south faces of the wall. All correlation values are above 50%, and 8 out of 10 graph measures demonstrated a correlation above 85%. The average correlation value between both sides of the wall reports 84% compatibility. High correlation values between the two sides of the wall attribute to the fidelity of graph features to the crack patterns on the two sides of the wall. Moreover, the monotonic increases in different graph measures and damage indexes indicate that the extracted features from the converted crack patterns to graph are meaningful information. Results of this study reveal that the proposed crack quantification method has the potential of translating crack patterns for further machine learning applications. This novel idea of using different graph measures introduces more features and can act as a base to study the fundamental and mathematical relation between crack patterns and graph theory. © 2022 SPIE.

A Conceptual Model to Estimate Microplastics (MPs) Mass Flux Discharged from Urban Areas: Identification of Relevant Pathways and Uncertainties

Item Type Journal Article

Author T. Nasrabadi

Author D. Renner

Author H. Ruegner

Author P. Grathwohl

Abstract Many studies concerning the occurrence of MPs in urban areas so far are prone to a variety of uncertainties due to significant deficiencies in temporal/spatial resolution of sampling, representativeness of samples, sampled volume/mass adequacy, size classification, and characterization. Even more important, a remarkable lack exists in assessing the suitability of methods/concepts needed for quantification of MP fluxes. In this study, quantification methods based on mass loadings (flux) analysis rather than details on number and size/shape are suggested for the estimation of MPs occurrence and release from urban areas, which is considered one of the most significant sources of MPs in the environment. MP sources are categorized in different classes e.g.: houses/offices/workshops (textile washing, kitchen work, bathroom activities, municipal waste management, carwash) and traffic, which is mainly responsible for the generation of tire and road wear particles. Release of MPs considers various pathways such as compost/sludge, (un)treated wastewater/surface runoffs/baseflows and wind-driven transport. A conceptual model is proposed to allow quantification of total discharged MP mass flux in relevant pathways normalized by population density. This has the advantage of comparing MP fluxes with other relevant fluxes, such as particulate organic carbon or ubiquitous pollutants. A detailed classification of existing urban wastewater and solid waste collection and disposal networks is presented, which is a prerequisite for the potential implementation of improved waste management strategies. Finally, to achieve an unbiased/ fair share of different cities to global MPs generation, a scheme including factors of tourism intensity, economic well-being, and plastic waste trade is suggested. © University of Tehran 2026.

Abstract LeQua 2022 is a new lab for the evaluation of methods for “learning to quantify” in textual datasets, i.e., for training predictors of the relative frequencies of the classes of interest $Y = \{y_1, \dots, y_n\}$ in sets of unlabelled textual documents. While these predictions could be easily achieved by first classifying all documents via a text classifier and then counting the numbers of documents assigned to the classes, a growing body of literature has shown this approach to be suboptimal, and has proposed better methods. The goal of this lab is to provide a setting for the comparative evaluation of methods for learning to quantify, both in the binary setting and in the single-label multiclass setting; this is the first time that an evaluation exercise solely dedicated to quantification is organized. For both the binary setting and the single-label multiclass setting, data were provided to participants both in ready-made vector form and in raw document form. In this overview article we describe the structure of the lab, we report the results obtained by the participants in the four proposed tasks and subtasks, and we comment on the lessons that can be learned from these results. © 2022, The Author(s), under exclusive license to Springer Nature Switzerland AG.

A continual test-time domain adaptation method for online machinery fault diagnosis under dynamic operating conditions

Item Type Journal Article

Author J. Tian

Author Y. Yu

Author H.R. Karimi

Author F. Gao

Author J. Lin

Abstract In practical industrial scenarios, monitoring data is collected in a streaming fashion under dynamic changes in operating conditions of mechanical systems, with continual covariate shift and label shift occurring in the collected data. Traditional transfer learning-based fault diagnosis methods typically involve pre-collecting substantial monitoring data for offline training and testing under static conditions. These approaches cannot adjust the model in real-time to continuous data shifts caused by dynamically changing conditions, resulting in a lack of adaptability and generalization. To overcome this practical challenge, a continual test-time domain

adaptation (CTDA) approach with a teacher-student framework is developed for online machinery fault diagnosis under dynamic operating conditions in this study. Firstly, a class-balanced sampling mechanism is proposed to eliminate the impact of continual condition label shift by enforcing the model to learn from a uniform label distribution. Secondly, a joint positive-negative learning strategy is employed to guide model optimization and reduce the interference from pseudo-label noise. Lastly, the continual covariate shift is mitigated by performing the knowledge alignment between the teacher and student models. Comprehensive experiments on four rotating machinery datasets demonstrate that the proposed method improves average diagnosis accuracy by 3.78% in handling dynamic industrial streaming data compared to existing fault diagnosis methods. © 2025

Abstract Cross-lingual document classification aims at training a document classifier on resources in one language and transferring it to a different language without any additional resources. Several approaches have been proposed in the literature and the current best practice is to evaluate them on a subset of the Reuters Corpus Volume 2. However, this subset covers only few languages (English, German, French and Spanish) and almost all published works focus on the the transfer between English and German. In addition, we have observed that the class prior distributions differ significantly between the languages. We argue that this complicates the evaluation of the multilinguality. In this paper, we propose a new subset of the Reuters corpus with balanced class priors for eight languages. By adding Italian, Russian, Japanese and Chinese, we cover languages which are very different with respect to syntax, morphology, etc. We provide strong baselines for all language transfer directions using multilingual word and sentence embeddings respectively. Our goal is to offer a freely available framework to evaluate cross-lingual document classification, and we hope to foster by these means, research in this important area. © LREC 2018 - 11th International Conference on Language Resources and Evaluation. A Critical Reassessment of the Saerens-Latinne-Decaestecker Algorithm for Posterior Probability Adjustment

Item Type Journal Article

Author A. Esuli

Author A. Molinari

Author F. Sebastiani

Abstract We critically re-examine the Saerens-Latinne-Decaestecker (SLD) algorithm, a well-known method for estimating class prior probabilities ("priors") and adjusting posterior probabilities ("posteriors") in scenarios characterized by distribution shift, i.e., difference in the distribution of the priors between the training and the unlabelled documents. Given a machine learned classifier and a set of unlabelled documents for which the classifier has returned posterior probabilities and estimates of the prior probabilities, SLD updates them both in an iterative, mutually recursive way, with the goal of making both more accurate; this is of key importance in downstream tasks such as single-label multiclass classification and cost-sensitive text classification. Since its publication, SLD has become the standard algorithm for improving the quality of the posteriors in the presence of distribution shift, and SLD is still considered a top contender when we need to estimate the priors (a task that has become known as "quantification"). However, its real effectiveness in improving the quality of the posteriors has been questioned. We here present the results of systematic experiments conducted on a large, publicly available dataset, across multiple amounts of distribution shift and multiple learners. Our experiments show that SLD improves the quality of the posterior probabilities and of the estimates of the prior probabilities, but only when the number of classes in the classification scheme is very small and the classifier is calibrated. As the number of classes grows, or as we use non-calibrated classifiers, SLD converges more slowly (and often does not converge at all), performance degrades rapidly, and the impact of SLD on the quality of the prior estimates and of the posteriors becomes negative rather than

positive. © 2020 ACM.

A cumulative, pipeline-oriented framework for extreme imbalanced classification: Large-scale benchmarking of 4,100 rare-event models

Item Type Journal Article

Author J. Villanueva-García

Author I. Moral-Arce

Author L.J. García Villalba

Abstract Extreme class imbalance remains a long-standing challenge in supervised learning, particularly when the minority class corresponds to rare but high-impact events such as fraud, equipment failure, or retirement transitions. Although a wide range of imbalance-handling techniques has been proposed-including penalization, resampling, loss shaping, threshold calibration, optimization, and ensemble strategies-the field largely lacks an operational understanding of how these

components should be combined, calibrated, and consolidated within end-to-end pipelines. This paper introduces a cumulative, pipeline-oriented framework for imbalanced classification under extreme skew. Rather than categorizing learning algorithms or paradigms, the framework reorganizes the design space of imbalanced learning around where and how imbalance-aware interventions act within the modeling pipeline. By progressively integrating data-level adjustments, objective and decision-rule shaping, and higher-level consolidation mechanisms, the framework exposes the structural logic underlying effective rare-event classifiers. We validate this framework through a large-scale benchmark comprising 4109 pipeline configurations applied to administrative microdata from the Spanish Social Security system, where monthly retirement detection exhibits a positive-class prevalence of 2.34%. The results reveal clear and interpretable performance regimes as pipeline complexity increases. Explicit pipeline-level ensemble architectures achieve the strongest recall and balance-sensitive metrics, while well-calibrated and optimized intermediate pipelines frequently attain comparable or superior performance in selected metrics—such as F1-score and Matthews correlation coefficient—relative to ensemble baselines, at substantially lower computational cost and with improved interpretability. Distributional and robustness analyses further show that consolidation mechanisms act primarily by stabilizing the upper tail of the performance distribution rather than by improving isolated best-case outcomes. Beyond this application, the proposed framework provides a reproducible benchmarking protocol and a unifying operational lens for understanding when additional methodological sophistication yields robust, stable, and practically meaningful performance gains under extreme class imbalance. © 2026 The Authors. A deep learning framework for non-invasive quantification of wing and foot phenotypes in live broiler chickens

Item Type Journal Article

Author L. Li

Abstract Accurate phenotypic quantification in poultry is essential for precision breeding and genetic improvement. Recent advances in deep learning have substantially improved the automation and accuracy of phenotyping. However, non-invasive and precise measurement of specific anatomical traits, particularly wings and feet, remains challenging. To address this challenge, we propose a CT imaging-based framework combined with deep learning to quantify wing and foot characteristics in live chickens. Specifically, we develop the DGCUNet for estimating the volumes of eight phenotypic targets associated with wings and feet. The encoder incorporates dilation transformer modules and stage-specific learning strategies to capture hierarchical representations, while the decoder employs a multi-scale fusion architecture to enhance feature integration. Four CT datasets covering multiple chicken breeds are constructed to validate the proposed framework. On the WB2024 dataset, five-fold cross-validation results demonstrate that DGCUNet achieves a Dice similarity coefficient of 86.41%, a 95th percentile Hausdorff distance of 3.28 mm, and an average symmetric surface distance of 0.69 mm. Furthermore, regression models establish relationships between segmented volumes and ground truth weights, and Bland-Altman analysis illustrates the agreement between estimated and actual weights. Overall, our framework enables fine-grained quantification of individual phenotypic traits rather than coarse whole-body measurements, demonstrating the potential of CT imaging and deep learning for advancing poultry phenotyping. © 2026 Elsevier B.V.

A deep learning method for extensible microstructural quantification of DP steel enhanced by physical metallurgy-guided data augmentation

Item Type Journal Article

Author C. Shen

Author X. Wei

Author C. Wang

Author W. Xu

Abstract The small sample problem caused by time-consuming annotation has greatly restricted the development of deep learning (DL) methods with high generality and extensibility, hindering the wide application of DL-based microstructural analysis. To address this problem, an extensible microstructural quantification method is proposed by combining physical metallurgy (PM)-guided data augmentation and DL. In this method, PM-guided data augmentation, which combines key PM information highly related to microstructural evaluation and random image transformation, is used to generate microstructures with other processes and therefore construct a comprehensive dataset. The proposed method is successfully applied and validated to dual-phase (DP) steels to classify martensite/ferrite phases and quantify their fractions and grain sizes at various temperatures based on only two SEM images of

annealing temperatures of 750 and 780 °C, in which a comprehensive dataset covering the entire dual phase regime is constructed with guidance from the content and morphology of the phase and dissolved carbide during annealing. Moreover, the good extensibility and data independency of the present method is demonstrated by various DP steels with different compositions and processes collected from the literature. © 2021 Elsevier Inc.

Author T. Danino

Abstract The motility mechanisms of microorganisms are critical virulence factors, enabling their spread and survival during infection. Motility is frequently characterized by qualitative analysis of macroscopic colonies, yet the standard quantification method has mainly been limited to manual measurement. Recent studies have applied deep learning for classification and segmentation of specific microbial species in microscopic images, but less work has focused on macroscopic colony analysis. Here, we advance computational tools for analyzing colonies of *Proteus mirabilis*, a bacterium that produces a macroscopic bullseye-like pattern via periodic swarming, a process implicated in its virulence. We present a dual-task pipeline for segmenting (1) the macroscopic colony including faint outer swarm rings, and (2) internal ring boundaries, unique features of oscillatory swarming. Our convolutional neural network for patch-based colony segmentation and U-Net with a VGG-11 encoder for ring boundary segmentation achieved test Dice scores of 93.28% and 83.24%, respectively. The predicted masks at times improved on the ground truths from our automated annotation algorithms. We demonstrate how application of our pipeline to a typical swarming assay enables ease of colony analysis and precise measurements of more complex pattern features than those which have been historically quantified. An implementation of our work can be found on <https://github.com/daninolab/proteus-mirabilis>. © 2022 IEEE.

A Deep Learning-Based Assessment of the Synergy Between New Energy Policies and New Quality Productive Forces: An Integrated Goal-Instrument-Value Framework for Sustainable Development

Item Type Journal Article

Author J. Cao

Author R. Pan

Abstract China has shifted from a stage of rapid growth to a stage of high-quality development. This highlights the critical need for policy frameworks that synergistically align technological innovation with sustainable development. To address the research gap in systematically assessing the collaboration between New Energy Industry (NEI) policies and New Quality Productive Forces (NQPF), this study proposes a three-dimensional “Goal-Instrument-Value” framework. Methodologically, we employ a combination of deep learning models (including LDA topic modeling, LSTM networks, and the Soft EDA algorithm) and policy quantification methods, analyzing 135 NQPF policies and nearly 800 NEI policies. The findings reveal a significant and strengthening synergy between the two policy domains. Notably, a misalignment exists in the goal dimension, where the weight of science and technology in NEI policies remains modest at 20%, indicating substantial potential for enhancement. In the instrument dimension, there is a predominant reliance on economically driven instruments, along with a notable underutilization of environmental instruments. Nevertheless, the overall synergy in policy value, as measured by a specialized New-Force Dictionary and the BM25 model, exhibits a consistent upward trend. Based on these findings, we recommend strengthening investment in NEI technology R&D, increasing the deployment of environment-oriented policy instruments, and establishing a cross-departmental policy synergy mechanism. These measures are crucial to fully harness the synergistic potential of NEI and NQPF policies for accelerating China’s green industrial transformation and achieving its sustainable development goals. © 2025 by the authors.

Author T. Zhou

Author Z. Huang

Author F. Li

Author H. Wang

Abstract This paper proposes a classification and recognition method for Distributed Acoustic Sensing (DAS) signals based on a two-dimensional attention-enhanced YOLOv9 network, aimed at intelligent monitoring and identification of downhole flow in wells. Addressing the issues of low accuracy and poor real-time performance of traditional flow monitoring technologies in complex downhole environments, this invention transforms the one-dimensional time-series vibration signals collected by DAS into two-dimensional time-frequency spectra through Short-Time Fourier Transform (STFT). It then combines the YOLOv9 network with its advanced detection capabilities to adaptively extract temporal, frequency, and spatial features of the signals, achieving precise classification of low, medium, and high flow rate vibration patterns. Experimental results demonstrate that this method significantly enhances the accuracy and robustness of signal recognition, resolving the issues of low precision and poor real-time performance encountered by traditional methods in complex downhole environments. The application of this study can provide reliable technical support for monitoring liquid profiles during fracturing processes and interpreting production profiles in the production phase, thereby facilitating real-time control and efficiency improvement in unconventional oil and gas development. A deep learning-based pipeline for mosquito detection and classification from wingbeat sounds

Item Type Journal Article**Author** M.S. Yin**Author** P. Haddawy**Author** T. Ziemer**Author** F. Wetjen**Author** A. Supratak**Author** K. Chiamsakul**Author** W. Siritanakorn**Author** T. Chantanalertvilai**Author** P. Sriwichai**Author** C. Sa-ngamuang**Abstract** Mosquito vector-borne diseases such as malaria and dengue constitute some of the most serious public health burdens in tropical and sub-tropical countries. Effective

targeting of disease control efforts requires accurate estimates of mosquito vector population density. The traditional, and still most common, approach to this involves the use of traps along with manual counting and classification of mosquito species. This process is costly and labor-intensive, which hinders its widespread use. In this paper we present a software pipeline for detection and classification of mosquito wingbeat sounds. Since our target platform is low-cost IoT devices, we explore the tradeoff between accuracy and efficiency. When a fast binary mosquito detector precedes the classifier, we can reduce the computational demand compared with use of the classifier alone by a factor of 10. While the accuracy of traditional machine learning model drops from 90% to 64% when reducing the sample rate from 96 kHz to 8 kHz, our deep-learning models maintain an accuracy of almost 83%, even when additionally reducing the bit depth from 24 to 16 bits. We conclude that the combination of an efficient mosquito detector with a convolutional neural network provides for an excellent trade-off between accuracy and efficiency to detect, classify and count mosquitoes. © 2022, The Author(s), under exclusive licence to Springer Science+Business Media, LLC, part of Springer Nature.

A Deep-Learning Phase Picker with Calibrated Bayesian-Derived Uncertainties for Earthquakes in the Yellowstone Volcanic Region

Item Type Journal Article

Author A.D. Armstrong

Author Z. Claerhout

Author B. Baker

Author K.D. Koper

Abstract Traditional seismic phase pickers perform poorly during periods of elevated seismicity due to inherent weakness when detecting overlapping earthquake waveforms. This weakness results in incomplete seismic catalogs, particularly deficient in earthquakes that are close in space and time. Supervised deep-learning (DL) pickers allow for improved detection performance and better handle the overlapping waveforms. Here, we present a DL phasepicking procedure specifically trained on Yellowstone seismicity and designed to fit within the University of Utah Seismograph Stations (UUSS) real-time system. We modify and combine existing DL models to label the seismic phases in continuous data and produce better phase arrival times. We use transfer learning to achieve consistency with UUSS analysts while maintaining robust models. To improve the performance during periods of enhanced seismicity, we develop a data augmentation strategy to synthesize waveforms with two nearly coincident P arrivals. We also incorporate a model uncertainty quantification method, Multiple Stochastic Weight Averaging-Gaussian (MultiSWAG), for arrival-time estimates and compare it to dropout—a more standard approach. We use an efficient, model-agnostic method of empirically calibrating the uncertainties to produce meaningful 90% credible intervals. The credible intervals are used downstream in association, location, and quality assessment. For an in-depth evaluation of our automated method, we apply it to continuous data recorded from 25 March to 3 April 2014, on 20 three-component stations and 14 vertical-component stations. This 10-day period contains an Mw 4.8 event, the largest earthquake in the Yellowstone region since 1980. A seismic analyst manually examined more than 1000 located events, including ~ 855 previously unidentified, and concluded that only two were incorrect. Finally, we present an analyst-created, high-resolution arrival-time data set, including 651 new arrival times, for one hour of data from station WY.YNR for robust evaluation of missed detections before association. Our method identified 60% of the analyst P picks and 81% of the S picks. © Seismological Society of America.

A design-centered review of in-situ tracer tests for HLW repositories: an overview of radioactive tracer cases, comparison with non-radioactive tracers, and a Korea-tailored strategy

Item Type Journal Article

Author Y. Lee

Author J.-S. Kim

Author J.-D. Kim

Abstract This review is organized around a design-centered framework that links experimental objectives to design premises, test configurations, tracer selection, and interpretation strategies. On this basis, a strategy tailored to the Korean context is proposed. The contents are as follows: (1) An overview of in-situ tracer tests is presented, including testing methodologies, design strategies, and prerequisites to ensure the reliability of safety assessments. (2) The classification criteria for tracers and the significance of radioactive tracer use are clarified. Tracers are categorized according to sorption properties and quantification methods, and the advantages of radioactive tracers—in terms of feasibility, cost-effectiveness, and improved reliability of safety assessments—are described. (3) Case studies of in-situ radioactive tracer injections conducted in Sweden (two sites), Switzerland, Finland, and Belgium (one site each) are introduced and compared with non-radioactive tracer cases to characterize the comparative advantages of radioactive tracers. (4) The results of non-radioactive in-situ tracer tests in Korea are reviewed. Considering the utility of radioactive tracers alongside the social climate in Korea—where in-situ injection of radioactive materials is virtually impossible—a strategic direction based on a dual approach is proposed, combining in-situ non-radioactive field tests with laboratory radioactive tracer experiments as the most feasible pathway. © 2026 Korean Nuclear Society, Published by Elsevier Korea LLC. Abstract LeQua 2022 is a new lab for the evaluation of methods for “learning to quantify” in textual datasets, i.e., for training predictors of the relative frequencies of the classes of interest $Y = \{y_1, \dots, y_n\}$ in sets of unlabelled textual documents. While these predictions could be easily achieved by first classifying all documents via a text classifier and then counting the numbers of documents assigned to the classes, a growing body of literature has shown this approach to be suboptimal, and has proposed better methods. The goal of this lab is to provide a setting for the comparative evaluation of methods for learning to quantify, both in the binary setting and in the single-label multiclass setting; this is the first time that an evaluation exercise solely dedicated to quantification is organized. For both the binary setting and the single-label multiclass setting, data were provided to participants both in ready-made vector form and in raw document form. In this overview article we describe the structure of the lab, we report the results obtained by the participants in the four proposed tasks and subtasks, and we comment on the lessons that can be learned from these results. © 2022 Copyright for this paper by its authors.

A Diffusion-Based Uncertainty Quantification Method to Advance E3SM Land Model Calibration

Item Type Journal Article

Author D. Lu

Author Y. Liu

Author Z. Zhang

Author F. Bao

Author G. Zhang

Abstract Calibrating land surface models and accurately quantifying their uncertainty are crucial for improving the reliability of simulations of complex environmental processes. This, in turn, advances our predictive understanding of ecosystems and supports climate-resilient decision-making. Traditional calibration methods, however, face challenges of high computational costs and difficulties in accurately quantifying parameter uncertainties. To address these issues, we develop a diffusion-based uncertainty quantification (DBUQ) method. Unlike conventional generative diffusion methods, which are computationally expensive and memory-intensive, DBUQ innovates by formulating a parameterized generative model and approximates this model through supervised learning, which enables quick generation of parameter posterior samples to quantify its uncertainty. DBUQ is effective, efficient, and general-purpose, making it suitable for site-specific ecosystem model calibration and broadly applicable for parameter uncertainty quantification across various earth system models. In this study, we applied DBUQ to calibrate the Energy Exascale Earth System Model land model at the Missouri Ozark AmeriFlux forest site. Results indicated that DBUQ produced accurate parameter posterior distributions similar to those from Markov Chain Monte Carlo sampling but with 30 times less computing time. This significant improvement in efficiency suggests that DBUQ can enable rapid, site-level model calibration at a global scale, enhancing our predictive understanding of climate impacts on terrestrial ecosystems. © 2024 Oak Ridge National Laboratory, managed by UT–Battelle, LLC and The Author(s). A discrete fracture network approach to study the variability of the geological strength index

Item Type Conference Paper

Author T. Miyoshi

Author D. Elmo

Author S. Rogers

Abstract One of the important applications of DFN models is the quantification of rock mass quality through rock mass classification systems such as Geological Strength Index (GSI, Hoek et al., 1995). For instance, Cai et al. (2004) presented a quantitative method to assist in the use of the GSI system for rock mass classification, introducing the concept of equivalent block volume and considering the impact of fracture persistence. However, the analysis was limited to a simple conceptual rock mass and did not account for the complex configurations in term of fracture intersections and connectivity that would arise when considering natural fracture networks. In this context, DFN models allow more realistic representation of 3D network of fractures and better prediction of block fragmentation of rock mass. This paper discusses an alternative method of quantifying the variation of GSI by using the quantification method of Cai et al. (2004) in combination with the block volume cumulative density function (CDF) plots obtained from DFN models. Since DFN approaches exploits the use of fracture data collected from mapping of exposed surfaces and boreholes, including direct physical mapping and indirect mapping by remote sensing techniques, the authors believe the proposed method would provide a better and more objective quantification of GSI variability. A fast in situ non-invasive approach to classify mortars from a construction of high historical value

Item Type Journal Article

Author C. García-Florentino

Author M. Maguregui

Author H. Morillas

Author I. Marcaida

Author J.M. Madariaga

Abstract The use of hand-held X-ray fluorescence (HH-XRF) spectrometers has increased in the last years due to its easily portable capacity and its rapid and non-destructive analysis. In this work, HH-XRF is proposed as a fast in situ non-invasive technique to classify mortars from a construction of high historical value. The current HH-XRF devices are able to provide large amounts of information almost instantaneously based on Fundamental Parameters quantification methodology that especially for the analyses of samples with very complex matrixes such as building materials is not very reliable. The accuracy of the semi-quantitative information provided by the HH-XRF spectrometer was compared with a previously optimized WD-XRF quantification method and a complete spectral data treatment followed by Principal Component Analysis is also proposed to classify easily and quickly the mortars used in this construction, without a previous sampling procedure, according to the similarities/differences in their elemental composition. © 2017 Elsevier B.V.

A fast method for simultaneous reconstruction and segmentation in X-ray CT application

Item Type Journal Article**Author** Y. Dong**Author** C. Wu**Author** S. Yan

Abstract In this paper, we propose a new method to solve the minimization problem in a simultaneous reconstruction and segmentation (SRS) model for X-ray computed tomography (CT). The SRS model uses Bayes' rule and the maximum a posteriori (MAP) estimate on the hidden Markov measure field model (HMMFM). The original method [Romanov M, Dahl AB, Dong Y, Hansen PC. Simultaneous tomographic reconstruction and segmentation with class priors. *Inverse Problems Sci Eng.* 2016;24(8):1432–1453] includes a subproblem with logarithmic-summation (log-sum) term, which is non-separable to the classification index. This subproblem was solved by Frank–Wolfe algorithm, which is very time consuming especially when dealing with large-scale CT problems. The starting point of this paper is the commutativity of log-sum operations, where the log-sum problem could be transformed into a sum-log problem by introducing an auxiliary variable. The corresponding sum-log problem for the SRS model is separable. By applying the primal-dual algorithm, the sum-log problem turns into several easy-to-solve convex subproblems. In addition, we introduce an improved model by adding Tikhonov regularization on the SRS model, and give some convergence results for the proposed methods. Experimental results demonstrate that the proposed methods produce comparable results compared with the original SRS method with much less CPU time. © 2021 Informa UK Limited, trading as Taylor & Francis Group.

A Feature Quantification method based on Binary Tree Oriented for Constructional Frameset of Heterogeneous Models

Item Type Conference Paper

Author N. Shen

Author C. Zhao

Author W. Liu

Author Y. Liu

Author H. Yang

Editor Pei Z.

Abstract To meet the more demanding requirements of the modeling and simulation technology in various fields, more diverse modeling languages and methods are emerging, which in turn makes it more challenging to integrate and reuse heterogeneous models for field applications. Therefore, it is necessary to extract a

constructional frameset of heterogeneous models based on a unified modeling language. This paper presents a method of constructional frameset extraction and feature quantization to address the issues of matching, classification, and composition of multi-domain heterogeneous models. Firstly, heterogeneous models are converted into unified models, which are described by X language. Then, the structural features of each X model are extracted to be incorporated into a predefined template. Then the template can be quantified in the form of a binary tree. The sequence obtained by inorder transversal of the binary tree can be a quantified feature of the template. All the model templates make up the constructional frameset of multi-domain heterogeneous models. The results show that the proposed method can abstract the features of multi-domain heterogeneous models and support a constructional frameset library to rapid modeling, integration, and reuse. © 2022 SPIE.

Author C. Xu

Abstract Background/Objectives: Non-invasive prenatal testing (NIPT) for fetal aneuploidy requires accurate trisomy detection together with reliable fetal fraction assessment. This study evaluated the clinical feasibility of a 106-plex digital PCR (dPCR) NIPT assay for trisomies 13, 18, and 21 with internal fetal fraction quantification. Methods: We consecutively recruited 470 women with high-risk singleton pregnancies. Fetal trisomies were detected using dPCR-NIPT and confirmed by invasive prenatal diagnosis. Pregnancies with negative prenatal diagnostic results were followed to birth. Analytical performance and quality control were assessed using trisomic DNA. The euploid cut-off and diagnostic performance were evaluated in two independent maternal plasma sample sets, using invasive diagnosis and clinical outcome as the reference standard. Results: dPCR-NIPT measured fetal fraction irrespective of fetal sex and detected trisomies at fetal fractions $\geq 3\%$ using 5 ng DNA. A total of 12 of 470 plasma samples failed cell-free DNA quality control and were excluded before dPCR testing. Of the remaining 458 samples, 5 had fetal fractions below 3% and were classified as failed tests, yielding a nonreportable rate of 1.1%. Using a cut-off of 6.9 established in 103 training samples, no false-positive or false-negative trisomy calls were observed in the 350-sample testing set, corresponding to 100% sensitivity (95% confidence interval [CI], 85.18–100%) and 100% specificity (95% CI, 98.88–100%) for 23 confirmed trisomies. Conclusions: This proof-of-principle study supports the feasibility of fetal fraction-informed dPCR-NIPT for trisomy detection in high-risk singleton pregnancies. Larger prospective studies in average-risk and earlier-gestation populations are required. © 2026 by the authors.

A fixed-point algorithm to minimax learning with neural networks

Item Type Journal Article

Author A. Guerrero-Curieses

Author R. Alaiz-Rodríguez

Author J. Cid-Sueiro

Abstract In some real applications, such as medical diagnosis or remote sensing, available training data do not often reflect the true a priori probabilities of the underlying data distribution. The classifier designed from these data may be suboptimal. Building classifiers that are robust against changes in prior probabilities is possible by applying a minimax learning strategy. In this paper, we propose a simple fixed-point algorithm that is able to train a neural minimax classifier [i.e., a classifier minimizing the worst (maximum) possible risk]. Moreover, we present a new parametric family of loss functions that is able to provide the most accurate estimates for the posterior class probabilities near the decision regions, and we also discuss the application of these functions together with a minimax learning strategy. The results of the experiments carried out on different real databases point out the ability of the proposed algorithm to find the minimax solution and produce a robust classifier when the real a priori

probabilities differ from the estimated ones. © 2004 IEEE.

Abstract A quantification learning task estimates class ratios or class distribution given a test set. Quantification learning is useful for a variety of application domains such as commerce, public health, and politics. For instance, it is desirable to automatically estimate the proportion of customer satisfaction in different aspects from product reviews to improve customer relationships. We formulate the quantification learning problem as a maximum likelihood problem and propose the first end-to-end Deep Quantification Network (DQN) framework. DQN

jointly learns quantification feature representations and directly predicts the class distribution. Compared to classification-based quantification methods, DQN avoids three separate steps: classification of individual instances, calculation of the predicted class ratios, and class ratio adjustment to account for classification errors. We evaluated DQN on four public datasets, ranging from movie and product reviews to multi-class news. We compared DQN against six existing quantification methods and conducted a sensitivity analysis of DQN performance. Compared to the best existing method in our study, (1) DQN reduces Mean Absolute Error (MAE) by about 35%. (2) DQN uses around 40% less training samples to achieve a comparable MAE. © 2021, Springer Nature Switzerland AG.

A framework for monitoring classifiers' performance: When and why failure occurs?

Item Type Journal Article

Author D.A. Cieslak

Author N.V. Chawla

Abstract Classifier error is the product of model bias and data variance. While understanding the bias involved when selecting a given learning algorithm, it is similarly important to understand the variability in data over time, since even the One True Model might perform poorly when training and evaluation samples diverge. Thus, it becomes the ability to identify distributional divergence is critical towards pinpointing when fracture points in classifier performance will occur, particularly since contemporary methods such as tenfolds and hold-out are poor predictors in divergent circumstances. This article implement a comprehensive evaluation framework to proactively detect breakpoints in classifiers' predictions and shifts in data distributions through a series of statistical tests. We outline and utilize three scenarios under which data changes: sample selection bias, covariate shift, and shifting class priors. We evaluate the framework with a variety of classifiers and datasets. © Springer-Verlag London Limited 2008.

A Fuzzy Neural Network-Based System for Alleviating Students' Boredom in English Learning

Item Type Journal Article**Author** L. Yang**Author** X. Wu

Abstract In order to explore students' boredom in English learning, a recognition algorithm based on fuzzy neural network is proposed. The algorithm selects Gaussian membership function and initializes the clustering center obtained by fuzzy c-means algorithm to the center of Gaussian function, and the width of Gaussian function is obtained by the membership and center of fuzzy c-means clustering algorithm. In the construction of base classifier, diversity strategy is adopted to increase its diversity and complementarity. In the selection of base classifiers, the combination of contour coefficient and clustering algorithm is used to determine the number of classifiers to be fused, and the inconsistency measurement method is used to evaluate their differences. In the combination strategy, we learn from the Bayesian thought and dynamically adapt the weight of learning base classifier based on its a priori probability and class conditional probability. The experimental results show that 10 times of cross-validation are carried out, respectively, and the accuracy of each algorithm is given. The algorithm based on tree structure obviously has better performance, followed by the rule-based algorithm, and finally the fuzzy neural network algorithm based on neural network, while the accuracy of SVM and logistic regression algorithm LR is lower. It is proved that the fuzzy neural network can effectively identify students' boredom in English learning. © 2022 Liuhui Yang and Xiuying Wu.

A Gaussian adaptive resonance theory neural network classification algorithm applied to supervised land cover mapping using multitemporal vegetation index data

Item Type Journal Article

Author D. Muchoney

Author J. Williamson

Abstract Neural network classifiers have been shown to provide supervised classification results that significantly improve on traditional classification algorithms such as the Bayesian (maximum likelihood [ML]) classifier. While the predominant neural network architecture has been the feedforward multilayer perceptron known as backpropagation, Adaptive resonance theory (ART) neural networks offer advantages to the classification of optical remote sensing data for vegetation and land cover mapping. A significant advantage is that it does not require prior specification of the neural net structure, creating as many internal nodes as are needed to represent the calibration (training) data. The Gaussian ARTMAP classification algorithm bases the probability that input training samples belong to specific classes on the parameters of its Gaussian distributions: the means, standard deviations, and a priori probabilities. The performance of the Gaussian ARTMAP classification algorithm in terms of classification accuracy using independent validation data indicated was over 70% accurate when applied to an annual series of monthly 1-km advanced very high resolution radiometer (AVHRR) satellite normalized difference vegetation index (NDVI) data. The accuracies were comparable to those of fuzzy ARTMAP and a univariate decision tree, and significantly higher than a Bayesian classification algorithm. Algorithm testing is based on calibration and validation data developed and applied to Central America to map the International Geosphere-Biosphere Programmed (IGBP) land cover classification system. Thus, it provides a realistic test of the algorithms for operational classification of a regional remote sensing and site dataset.

Abstract In many practical applications of machine learning, a discrepancy often arises between a source distribution from which labeled training examples are drawn and a target distribution for which only unlabeled data is observed. Traditionally, two main scenarios have been considered to address this issue: covariate shift (CS), where only the marginal distribution of features changes, and label shift (LS), which involves a change in the class variable's prior distribution. However, these frameworks do not encompass all forms of distributional shift. This paper introduces a new setting, Conditional Probability Shift (CPS), which captures the case when the conditional distribution of the class variable given some specific features changes while the distribution of remaining features given the specific features and the class is preserved. For this scenario we present the Conditional Probability Shift Model (CPSM) based on modeling the class variable's conditional probabilities using multinomial regression. Since the class variable is

not observed for the target data, the parameters of the multinomial model for its distribution are estimated using the Expectation-Maximization algorithm. The proposed method is generic and can be combined with any probabilistic classifier. The effectiveness of CPSM is demonstrated through experiments on synthetic datasets and a case study using the MIMIC medical database, revealing its superior balanced classification accuracy on the target data compared to existing methods, particularly in situations of conditional distribution shift and no prior distribution shift, which are not detected by LS-based methods. © 2025 The Authors.

A generalized shapelet-based method for analysis of nanostructured surface imaging

Item Type Journal Article

Author T.J. Akdeniz

Author D.J. Lizotte

Author N.M. Abukhdeir

Abstract The determination of quantitative structure-property relations is a vital but challenging task for nanostructured materials research due to the presence of large-scale spatially varying patterns resulting from nanoscale processes such as self-assembly and nano-lithography. Focusing on nanostructured surfaces, recent advances have been made in automated quantification methods for orientational and translational order using shapelet functions, originally developed for analysis of images of galaxies, as a reduced-basis for surface pattern structure. In this work, a method combining shapelet functions and machine learning is developed and applied to a representative set of images of self-assembled surfaces from experimental characterization techniques including scanning electron microscopy, atomic force microscopy and transmission electron microscopy. The method is shown to be computationally efficient and able to quantify salient pattern features including deformation, defects, and grain boundaries from a broad range of patterns typical of self-assembly processes. © 2018 IOP Publishing Ltd.

A generalized spatially adaptive sparse grid combination technique with dimension-wise refinement

Item Type Journal Article

Author M. Obersteiner

Author H.-J. Bungartz

Abstract Today, high-dimensional calculations can be found in almost all scientific disciplines. The application of machine learning and uncertainty quantification methods are common examples where high-dimensional problems appear. Typically, these problems are computationally expensive or even infeasible on current machines due to the curse of dimensionality. The sparse grid combination technique is one method to mitigate this effect, but it still does not generate optimal grids for many application scenarios. In such cases, adaptivity strategies are applied to further optimize the grid generation. Generally, adaptive grid generation strategies can be classified as spatially or dimensionally adaptive. One of the most prominent examples is the dimension-adaptive combination technique, which is easy to implement and suitable for cases where dimensions contribute in different magnitudes to the accuracy of the solution. Unfortunately, spatial adaptivity is not possible in the standard combination technique due to the required regular structure of the grids. We therefore propose a new algorithmic variant of the combination technique that is based on the combination of rectilinear grids which can adapt themselves locally to the target function using 1-dimensional refinements. We further increase the efficiency by adjusting point levels with tree rebalancing. Results for numerical quadrature and interpolation show that we can significantly improve upon the standard combination technique and compete with or even surpass common spatially adaptive implementations with sparse grids. At the same time our method keeps the black-box property of the combination technique which makes it possible to apply it to black-box solvers. © 2021 Michael Obersteiner and Hans-Joachim Bungartz

A generic high-throughput microstructure classification and quantification method for regular SEM images of complex steel microstructures combining EBSD labeling and deep learning

Item Type Journal Article**Author** C. Shen**Author** C. Wang**Author** M. Huang**Author** N. Xu**Author** S. van der Zwaag**Author** W. Xu

Abstract We present an electron backscattered diffraction (EBSD)-trained deep learning (DL) method integrating traditional material characterization informatics and artificial intelligence for a more accurate classification and quantification of complex microstructures using only regular scanning electron microscope (SEM) images. In this method, EBSD analysis is applied to produce accurate ground truth data for guiding the DL model training. An U-Net architecture is used to establish the correlation between SEM input images and EBSD ground truth data using only small experimental datasets. The proposed method is successfully applied to two engineering steels with complex microstructures, i.e., a dual-phase (DP) steel and a quenching and partitioning (Q&P) steel, to segment different phases and quantify phase content and grain size. Alternatively, once properly trained the method can also produce quasi-EBSD maps by inputting regular SEM images. The good generality of the trained models is demonstrated by using DP and Q&P steels not associated with the model training. Finally, the method is applied to SEM images with various states, i.e., different imaging modes, image qualities and magnifications, demonstrating its good robustness and strong application ability. Furthermore, the visualization of feature maps during the segmenting process is utilised to explain the mechanism of this method's good performance. © 2021

A highly sensitive and quantitative telomerase activity assay with pancreatic juice is useful for diagnosis of pancreatic carcinoma without problems due to polymerase chain reaction inhibitors: Analysis of 100 samples of pancreatic juice from consecutive patients

Item Type Journal Article

Abstract BACKGROUND. Early detection of pancreatic carcinoma is difficult even with current diagnostic tools. Novel biomarkers and detection techniques are urgently needed. Telomerase activity is a promising diagnostic marker. However, the conventional telomeric repeat amplification protocol (TRAP) assay is not suitable for clinical application because of its complexity, time-consuming nature, and the effects of polymerase chain reaction (PCR) inhibitors in samples leading to difficulties in quantification. METHODS. The authors used a hybridization protection assay in combination with TRAP (TRAP/HPA) to investigate the effects of PCR inhibitors in

pancreatic juice on quantification of telomerase activity. They analyzed 117 consecutive samples of pancreatic juice to determine the feasibility of TRAP/HPA for diagnosis of pancreatic carcinoma. RESULTS. The authors found that TRAP/HPA was 1000-fold more sensitive than the conventional TRAP assay, and that the effects of PCR inhibitors could be avoided by diluting samples. In a large analysis of pancreatic juice samples with TRAP/HPA, 17 samples were excluded from the final analysis because of insufficient follow-up periods or inadequate treatment of the samples. Relative telomerase activity (RTA) in samples from patients with pancreatic carcinoma was significantly higher in comparison to samples from patients with pancreatitis and 13 (61.9%) of 21 samples from patients with pancreatic carcinoma showed high RTA (> 4 U). Meanwhile, high RTAs were observed in 4 of 35 (11.4%) samples from patients with intraductal papillary mucinous tumor and in 1 of 40 samples (2.5%) from patients without malignant disease. CONCLUSIONS. TRAP/HPA accurately evaluated weak telomerase activity in pancreatic juice samples without the problem due to PCR inhibitors. This large analysis of nonselected pancreatic juice samples suggested that TRAP/HPA is a promising approach for the diagnosis of pancreatic carcinoma. © 2004 American Cancer Society.

A hippocampal-based biosensor for neurotoxins detection and classification using a novel short-term plasticity quantification method

Item Type Journal Article

Author G. Gholmieh

Author S. Courellis

Author V. Marmarelis

Author M. Baudry

Author T.W. Berger

Abstract Current sensors such as the handheld chemical agent monitor (CAM by Graseby Dynamics) and the M90-D1-C (EnviroNics, Finland) are capable of detecting and identifying nerve agents but come short of identifying unknown chemical compounds. Hence, there is a need to develop a new type of sensor that can detect newly uncharacterized chemical compounds. In this chapter, we present a newly developed biosensor for rapid neurotoxins screening based on the quantification of short-term plasticity (STP) of CA1 hippocampal system in vitro using a newly developed analytical approach. The hippocampal slice with its preserved trisynaptic pathway (Andersen et al., 1971) has been a very popular experimental preparation for investigating memory mechanisms and drug effects using long-term potentiation (LTP) and short-term plasticity (Bliss and Lomo, 1973; Fountain and Teyler, 1995; Xie et al., 1997; Buonomano, 1999, 2000). Short-term plasticity (STP)-based methods are typically chosen to assess drug effects of rapidly acting chemical compounds inasmuch as they require less experimental time. Current experimental methods for measuring STP are mostly based on the analysis of paired pulse (Dobrunz et al., 1997; Leung et al., 1994; Creager et al., 1980) or fixed frequency train stimulation (Papatheodoropoulos et al., 2000; Buonomano 1999; Pananceau et al., 1998; Castro-Alamancos et al., 1997). These methods lack the ability to test all the possible time intervals in a time-efficient manner. Based on a variant of the Volterra approach, we have developed and implemented an efficient method to characterize and quantify STP using Poisson distributed random train (RIT) stimulation (Gholmieh et al., 2002). It can be viewed as a hybrid between the paired pulse and the fixed frequency train approaches. It is, however, more time efficient than both of them. Responses to a large variety of interimpulse intervals can be evaluated in three minutes in contrast to several hours when using the paired pulse approach (Gholmieh et al., 2001, 2002). The computed STP descriptors of the underlying nonlinear dynamics are the first- and second-order Volterra kernels that describe the state of the system. The second-order kernel can be further linearly decomposed into nine Laguerre functions. The first-order kernel and the Laguerre coefficients of the second-order kernel expansion can be viewed as the characteristics of the system. These characteristics are speculated to change under different chemical environments, giving each drug a unique signature. The proposed biosensor is comprised of a multi-electrode array, a hippocampal slice, and MATLAB software for data acquisition and online nonlinear STP analysis. It was tested using chemical

compounds belonging to six different classes: DNQX and CNQX (AMPA receptor antagonists), DAP5 (an NMDA receptor antagonist), carbachol (a cholinergic agonist), trimethylopropane phosphate (TMPP) and picrotoxin (GABAA antagonists), tetraethylammonium (a potassium channel blocker), and valproate (an antiepileptic medication). The current chapter summarizes our successful efforts for the last four years to build a hippocampal-based biosensor for neurotoxin detection and classification. Section 12.2 describes the novel modeling approach in detail. Section 12.3 presents the nonlinear characteristics of the CA1 region obtained through the described nonlinear modeling approach. Section 12.4 proves that the novel method can detect changes in STP. Section 12.5 tests our hypothesis that each drug can have a unique signature, and Section 12.6 presents a proof of principle solution for long-term monitoring. © 2006 Springer Science+Business Media, Inc. A hybrid ensemble learning method for tourist route recommendations based on geo-tagged social networks

Item Type Journal Article

Author L. Wan

Author Y. Hong

Author Z. Huang

Author X. Peng

Author R. Li

Abstract Geo-tagged travel photos on social networks often contain location data such as points of interest (POIs), and also users' travel preferences. In this paper, we propose a hybrid ensemble learning method, BAYes-Knn, that predicts personalized tourist routes for travelers by mining their geographical preferences from these location-tagged data. Our method trains two types of base classifiers to jointly predict the next travel destination: (1) The K-nearest neighbor (KNN) classifier quantifies users'

location history, weather condition, temperature and seasonality and uses a feature-weighted distance model to predict a user's personalized interests in an unvisited location. (2) A Bayes classifier introduces a smooth kernel function to estimate a-priori probabilities of features and then combines these probabilities to predict a user's latent interests in a location. All the outcomes from these subclassifiers are merged into one final prediction result by using the Borda count voting method. We evaluated our method on geo-tagged Flickr photos and Beijing weather data collected from 1 January 2005 to 1 July 2016. The results demonstrated that our ensemble approach outperformed 12 other baseline models. In addition, the results showed that our framework has better prediction accuracy than do context-aware significant travel-sequence-patterns recommendations and frequent travel-sequence patterns. © 2018, © 2018 Informa UK Limited, trading as Taylor & Francis Group.

A Hybrid Time-Series Simulation Framework for Provincial Carbon Emissions Using Multi-Factor Decomposition and Deep Learning

Item Type Journal Article

Author L. Zhang

Author Y. Ye

Author X. Ren

Author X. Qiu

Author Z. Sun

Author W. Zhou

Author D. Han

Abstract Accurate time-series simulation of carbon emissions for both the whole society and the electricity industry is pivotal for realizing China's "Dual Carbon" goals. This research constructs a hybrid simulation architecture integrating factor decomposition with deep learning to quantify emission trajectories for both the whole society and the electricity industry in Anhui Province. First, the extended Kaya identity and Logarithmic Mean Divisia Index (LMDI) are employed to analyze socioeconomic drivers. The decomposition analysis indicates that per capita income is the primary driver of carbon emissions, whereas energy intensity exerts the strongest inhibitory effect. Subsequently, Variational Mode Decomposition (VMD) is applied to the nonstationary emission series to produce multi-scale sub-signals, which are then fed into a predictive model comprising a Bayesian-optimized (BO) Transformer coupled with Long Short-Term Memory (LSTM) networks. The study establishes three distinct evolution scenarios: Moderate Sustainability (MS), Business as Usual (BAU), and Strong Economic Growth (SEG). Simulation results indicate that under MS, carbon emissions from the whole society and the electricity industry peak in 2029 at 435.2 Mt and 2030 at 281.2 Mt, respectively. Conversely, the SEG scenario delays the peak of the whole society to 2034, while the electricity industry fails to peak before 2035. These findings reveal significant risks of temporal asynchrony between the whole society and the electricity industry peaks, providing robust methodological support for regional decarbonization planning. © 2026 by the authors.

A Joint Training-Calibration Framework for Test-Time Personalization with Label Shift in Federated Learning

Item Type Conference Paper

Author J. Xu

Author S.-L. Huang

Abstract The data heterogeneity has been a challenging issue in federated learning in both training and inference stages, which motivates a variety of approaches to learn either personalized models for participating clients or test-time adaptations for unseen clients. One such approach is employing a shared feature representation and a customized classifier head for each client. However, previous works either neglect the global head with rich knowledge or assume the new clients have enough labeled data, which significantly limit their broader practicality. In this work, we propose a lightweight framework to tackle with the label shift issue during the model deployment by test priors estimation and model prediction calibration. We also demonstrate the importance of training a balanced global model in FL so as to guarantee the general effectiveness of prior estimation approaches. Evaluation results on benchmark datasets demonstrate the superiority of our framework for model adaptation in unseen clients with unknown label shifts. © 2023 Copyright held by the owner/author(s). A learning-based automatic segmentation and quantification method on left ventricle in gated myocardial perfusion SPECT imaging: A feasibility study

Item Type Journal Article**Author** T. Wang**Author** Y. Lei**Author** H. Tang**Author** Z. He**Author** R. Castillo**Author** C. Wang**Author** D. Li**Author** K. Higgins**Author** T. Liu**Author** W.J. Curran**Author** W. Zhou**Author** X. Yang

Abstract Background: The performance of left ventricular (LV) functional assessment using gated myocardial perfusion SPECT (MPS) relies on the accuracy of segmentation. Current methods require manual adjustments that are tedious and subjective. We propose a novel machine-learning-based method to automatically segment LV myocardium and measure its volume in gated MPS imaging without human intervention. Methods: We used an end-to-end fully convolutional neural network to segment LV myocardium by delineating its endocardial and epicardial surface. A novel compound loss function, which encourages similarity and penalizes discrepancy between prediction and training dataset, is utilized in training stage to

achieve excellent performance. We retrospectively investigated 32 normal patients and 24 abnormal patients, whose LV myocardial contours automatically segmented by our method were compared with those delineated by physicians as the ground truth. Results: The results of our method demonstrated very good agreement with the ground truth. The average DSC metrics and Hausdorff distance of the contours delineated by our method are larger than 0.900 and less than 1 cm, respectively, among all 32 + 24 patients of all phases. The correlation coefficient of the LV myocardium volume between ground truth and our results is 0.910 ± 0.061 ($P < 0.001$), and the mean relative error of LV myocardium volume is $-1.09 \pm 3.66\%$. Conclusion: These results strongly indicate the feasibility of our method in accurately quantifying LV myocardium volume change over the cardiac cycle. The learning-based segmentation method in gated MPS imaging has great promise for clinical use. © 2019, American Society of Nuclear Cardiology.

A learning-based optimal uncertainty quantification method and its application to ballistic impact problems

Item Type Journal Article

Author X. Sun

Author B. Liu

Abstract This paper concerns the study of optimal (supremum and infimum) uncertainty bounds for systems where the input (or prior) probability measure is only partially/imperfectly known (e.g., with only statistical moments and/or on a coarse topology) rather than fully specified. Such partial knowledge provides constraints on the input probability measures. The theory of Optimal Uncertainty Quantification allows us to convert the task into a constraint optimization problem where one seeks to compute the least upper/greatest lower bound of the system's output uncertainties by finding the extremal probability measure of the input. Such optimization requires repeated evaluation of the system's performance indicator (input to performance map) and is high-dimensional and non-convex by nature. Therefore, it is difficult to find the optimal uncertainty bounds in practice. In this paper, we examine the use of machine learning, especially deep neural networks, to address the challenge. We achieve this by introducing a neural network classifier to approximate the performance indicator combined with the stochastic gradient descent method to solve the optimization problem. We demonstrate the learning-based framework on the uncertainty quantification of the impact of magnesium alloys, which are promising light-weight structural and protective materials. Finally, we show that the approach can be used to construct maps for the performance certificate and safety design in engineering practice. © 2023

A Machine Learning based uncertainty quantification for compressive strength of high-performance concrete

Item Type Journal Article

Author N. Vu-Bac

Author T. Le-Anh

Author T. Rabczuk

Abstract High performance concrete (HPC) properties depend on both its constituent materials and their interaction. This study presents a machine learning framework to quantify the effects of constituents on HPC compressive strength. We first develop a stochastic constitutive model using experimental data and subsequently employ an uncertainty quantification method to identify key parameters in relation to the compressive strength of HPC. The resultant sensitivity indices indicate that fly ash content has the strongest influence on compressive strength, followed by concrete age at test and blast surface slag content. © Higher Education Press 2025.

Abstract Quantification of in vitro osteoclast cultures (e.g. cell number) often relies on manual counting methods. These approaches are labour intensive, time consuming and result in substantial inter- and intra-user variability. This study aimed to develop and validate an automated workflow to robustly quantify in vitro osteoclast cultures. Using ilastik, a machine learning-based image analysis software, images of tartrate resistant acid phosphatase-stained mouse osteoclasts cultured on dentine discs were used to train the ilastik-based algorithm. Assessment of algorithm training showed that osteoclast numbers strongly correlated between manual- and automatically quantified values ($r = 0.87$). Osteoclasts were consistently faithfully segmented by the model when visually compared to the original reflective light images. The ability of this method to detect changes in osteoclast number in response to different treatments was validated using zoledronate, ticagrelor, and co-culture with MCF7 breast cancer cells. Manual and automated counting methods detected a 70% reduction ($p < 0.05$) in osteoclast number, when cultured with 10 nM zoledronate and a dose-dependent decrease with 1–10 μM ticagrelor ($p < 0.05$). Co-culture with MCF7 cells increased osteoclast number by $\geq 50\%$ irrespective of quantification method. Overall, an automated image segmentation and analysis workflow, which consistently and sensitively identified in vitro osteoclasts, was developed. Advantages of this

workflow are (1) significantly reduction in user variability of endpoint measurements (93%) and analysis time (80%); (2) detection of osteoclasts cultured on different substrates from different species; and (3) easy to use and freely available to use along with tutorial resources. © 2023, The Author(s).

Abstract Background: Thalassaemia is one of the most common inherited monogenic diseases worldwide with a heavy global health burden. Considering its high prevalence in low and middle-income countries, a cheap, accurate and high-throughput screening test of thalassaemia prior to a more expensive confirmatory diagnostic test is urgently needed. Methods: In this study, we constructed a machine learning model based on MALDI-TOF mass spectrometry quantification of haemoglobin chains in blood, and for the first time, evaluated its diagnostic efficacy in 674 thalassaemia (including both asymptomatic carriers and symptomatic patients) and control samples collected in three hospitals. Parameters related to haemoglobin imbalance (α -globin, β -globin, γ -globin, α/β and $\alpha-\beta$) were used for feature selection before classification model construction with 8 machine learning methods in cohort 1 and further model efficiency validation in cohort 2. Results: The logistic regression model with 5 haemoglobin peak features achieved good classification performance in validation cohort 2 (AUC 0.99, 95% CI 0.98–1, sensitivity 98.7%, specificity 95.5%). Furthermore, the logistic regression model with 6 haemoglobin peak features was also constructed to specifically identify β -thalassaemia (AUC 0.94, 95% CI 0.91–0.97, sensitivity 96.5%, specificity 87.8% in validation cohort 2). Conclusions: For the first time, we constructed an inexpensive, accurate and high-throughput classification model based on MALDI-TOF mass spectrometry quantification of haemoglobin chains and demonstrated its great potential in rapid screening of thalassaemia in large populations. Key messages Thalassaemia is one of the most common inherited monogenic diseases worldwide with a heavy global health burden. We constructed a machine learning model based on MALDI-TOF mass spectrometry quantification of haemoglobin chains to screen for thalassaemia. © 2022 The Author(s). A Markov random field approach for sidescan sonar change detection

Item Type Journal Article

Author S. Wei

Author H. Leung

Abstract One of the main challenges in mine detection using sidescan sonar images is the high density of mine-like objects (MLOs) in a clutter environment. This paper proposes an image change detection technique for bitemporal images which suppresses false alarms efficiently without involving large training data sets. The proposed approach uses the spatial dependence of a stationary object between bitemporal images to eliminate the differences caused by a position error. Bayes theory is then employed to classify the changed and unchanged objects. In particular, the a priori probabilities are formulated by the Markov random field (MRF). The likelihood functions are modeled using the coarseness difference of objects as the test statistics, and the parameters are estimated using the expectation-maximization (EM) method. Real sidescan sonar data are used to validate the proposed method. Results show that the proposed MRF change detection method is robust to the poor quality of object boundaries due to speckle noise, and outperforms the conventional pixel-level change detection methods. © 1976-2012 IEEE.

Abstract Early detection is critical for minimizing mortality from cancer. Plasma cell-free DNA (cfDNA) contains the signatures of tumor DNA, allowing us to quantify the signature and diagnose early-stage tumors. Here, we report a novel tumor fragment quantification method, TOF (Tumor Originated Fragment) for the diagnosis of lung cancer by quantifying and analyzing both the plasma cfDNA methylation patterns and fragmentomic signatures. TOF utilizes the amount of ctDNA predicted from the methylation density information of each cfDNA read mapped on 6243 lung-tumor-specific CpG markers. The 6243 tumor-specific markers were derived from lung tumor tissues by comparing them with corresponding normal tissues and healthy blood from public methylation data. TOF also utilizes two cfDNA fragmentomic signatures: 1) the short fragment ratio, and 2) the 5' end-motif profile. We used 298 plasma samples to analyze cfDNA signatures using enzymatic methyl-sequencing data from 201 lung cancer patients and 97 healthy controls. The TOF score showed 0.98 of the area under the curve in correctly classifying lung cancer from normal samples. The TOF score resolution was high enough to clearly differentiate even the early-stage non-small cell lung cancer patients from the healthy controls. The same was true for small cell lung cancer patients. © 2022 Elsevier Ltd

A method of evidence association mining on target identification

Item Type Conference Paper

Author X. Wang

Author H. Wang

Abstract in the target identification system, it is difficult to get the target identification result because of massive and heterogeneous data obtaining from various information sensors. In this paper, a probability statistical method is used to analyze the quantification method through the association analysis of support evidences and the fact of the evidence. Using this novel algorithm, a large number of evidences which are not related to the facts could be filtered out quickly, and the evidences of different aspects which reflect the comprehensive identification of targets could be extracted. Meanwhile, the evidence history information classification model and the evidence-related intensity matrix are established, and the model is updated iteratively according to the new evidences contained in multiple information sources in the target identification system. Based on this method, this paper carries out a simulation experiment of evidence correlation of target identification, which verifies the feasibility and validity of the method. © 2017 IEEE.

A Methodology for Disaster Construction &Demolition Debris Quantification

Item Type Journal Article

Author E. Mansour

Author I. Srouf

Author S. Nassar

Abstract Post disaster Construction and Demolition (C&D) waste quantification is critical in contexts where recurrent conflicts and natural disasters have led to significant infrastructure damage and large-scale debris accumulation. Debris quantification is a natural first step for efficient recovery planning, removal and management, and circular economy strategies. However, existing quantification methodologies lack national or regional standardization and fail to combine both rapid assessment as well as material characterization. Therefore, this study proposes a structured six-step debris quantification framework in post-disaster settings that integrates field data collection, material classification, density-based calculations, and demographic normalization to estimate per capita C&D waste generation. The framework was integrated in an automated decision-making tool using Visual Basic for Applications

(VBA) macros in Microsoft Excel. The tool was applied to fully collapsed buildings, amid the 2023–2024 war in Lebanon. Based on an average household size of 4 to 5 persons and two apartments per floor in these regions, results indicated that the calculated C&D waste generation rate was approximately 55–69 tons per capita—an order of magnitude higher than typical demolition or municipal solid waste figures reported globally. Additionally, the study showed the tool's effectiveness in producing rapid, replicable, and verifiable estimates, enabling faster operational decision-making compared to traditional, resource-intensive post-conflict assessments. Findings highlight the importance of standardized debris quantification protocols in enhancing disaster waste management readiness, with implications for contingency planning, resource allocation, and integration of remote sensing in damage assessment. © 2026 The Author(s)

A microfluidic approach to study variations in *Chlamydomonas reinhardtii* alkaline phosphatase activity in response to phosphate availability

Abstract Algal growth depends strongly on phosphorus (P) as a key nutrient, underscoring the significance of monitoring P levels. Algal species display a sensitive response to fluctuations in P availability, notably through the expression of alkaline phosphatase (AP) when challenged with P-depletion. As such, alkaline phosphatase activity (APA) serves as a valuable metric for P availability, offering insights into how algae utilize and fix available P resources. However, current APA quantification methods lack single cell resolution, while also being time- and reagent consuming. Microfluidics offers a promising cost-effective solution to these limitations, providing a platform for precise single-cell analysis. In this study, a trap-based microfluidic device was integrated with a commercially available AP live stain to study the single cell APA response of a model algae strain, *Chlamydomonas reinhardtii*, when exposed to different exogenous P levels. A three-step culture-starve-spike process was used to induce APA in cells cultured under two different basal P levels (1 and 21 mM). When challenged with different spiked P levels (ranging from 0.1-41 mM), *C. reinhardtii* cells demonstrated a highly heterogeneous APA response. Two-way ANOVA confirmed that this response is influenced by both spiked and basal P levels. Utilizing an unsupervised machine learning approach (HDBSCAN), distinct subpopulations of *C. reinhardtii* cells were identified exhibiting varying levels of APA at the single-cell level. These subpopulations encompass significant groups of individual cells with either notably high or low APA, contributing to the overall behavior of the cohorts. Considerable intrapopulation differences in APA were observed across cohorts with similar average behavior. For instance, while some cohorts exhibited a concentrated distribution around the overall average APA, others displayed subpopulations dispersed across a wider range of APA levels. This underscores the potential bias introduced by analyzing a small number of cells in bulk, which may skew results by overrepresenting extreme behavioral subpopulations. The findings of this study highlight the need for analytical approaches that account for single cell heterogeneity in APA and demonstrate the utility of microfluidics as a well-suited means for such investigations. This study illuminates the complexities of APA regulation at the single cell level, providing crucial insights that advance our understanding of algal phosphorus metabolism and environmental responses. © 2024 The Royal Society of Chemistry.

Abstract Gliomas represent a disparate group of tumours for which there are to date no cure. Thus, there is a recognized need for new diagnostic and therapeutic approaches based on increased understanding of their molecular nature. We performed the comparison of the microRNA (miRNA) profile of 8 WHO grade II gliomas and 24 higher grade tumours (2 WHO grade III and 22 glioblastomas) by using the Affymetrix GeneChip miRNA Array v. 1.0. A relative quantification method (RT-qPCR) with standard curve was used to confirm the 22 miRNA signature resulted by array analysis. The prognostic performances of the confirmed miRNAs were estimated on the Tumor

Cancer Genome Atlas (TCGA) datasets. We identified 22 miRNAs distinguishing grade II gliomas from higher grade tumours. RT-qPCR confirmed the differential expression in the two patients' groups for 13 out of the 22 miRNAs. The analysis of the Glioblastoma Multiforme (GBM) and Lower Grade Glioma (LGG) datasets from TCGA demonstrated the association with prognosis for 6 of those miRNAs. Moreover, in the GBM dataset miR-21 and miR-210 were predictors of worse prognosis in both univariable and multivariable Cox regression analyses (HR 1.19, $p = 0.04$, and HR 1.18, $p = 0.029$ respectively). Our results support a direct contribution of miRNAs to glioma cancerogenesis and suggest that miR-21 and miR-210 may play a role in the aggressive clinical behaviour of glioblastomas. © 2014 Barbano et al. A Mobile Application for Electronic Parts Counting and Identification in Physics Laboratory

Item Type Conference Paper

Author T. Leelawattananon

Author S. Chittayasothorn

Abstract Counting of small objects such as resistors, capacitors, and inductors in physics laboratories are tedious and challenging tasks because of their numbers and small size. In this paper we present the development of a mobile application for counting and identifying small electronics parts. The system employs object edges detection using the difference of gaussian operator and classify the objects using template matching. Pictures taken using mobile phone camera are used as the input to the mobile application which correctly classify and count the objects. Electronics objects used in the counting and classification include resistors, mylar capacitors, and ceramic capacitors. The mobile application helps reduce the work required by laboratory personnel for intermediate physics laboratory management and is now deployed in the physics laboratory of the School of Science, King Mongkut's Institute of Technology Ladkrabang. © 2025 IEEE.

A model-free Bayesian classifier

Item Type Journal Article

Author Z. Geng

Author Q. Meng

Author J. Bai

Author J. Chen

Author Y. Han

Author Q. Wei

Author Z. Ouyang

Abstract When using the naïve Bayesian classifier (NBC), it is necessary to assume that the attributes are independent. Although the relationship between the attributes can be analyzed by the Bayesian network (BN), the network structure and parameters need to be trained. Meanwhile, each continuous attribute is given a priori probability distribution for both the NBC and the BN. If the actual probability distribution of the samples is inconsistent with the priori probability distribution, the classification result is poor. In this paper, a model-free Bayesian classifier (MFBC) is proposed to cope with the drawbacks of the NBC and the BN. The information of the sample space and the joint probability density can be obtained based on the nearest neighbor (NN) strategy. The proposed MFBC is able to cope with discrete or continuous attributes even if there is no a priori probability distribution of the attributes. It is also not necessary to build a network structure to obtain a unitive calculation framework for the attributes. Moreover, the probability distribution for limited amounts of samples is approximated using the NN method. Then, the classification label of a sample can be predicted by the MFBC. The sensitivity analysis of the MFBC is obtained using the UCI data sets. Compared with some classical and ensemble classifiers, the analysis results verify the effectiveness and convergence performance of the MFBC. © 2019 Elsevier Inc.

Editor Liu H.

Abstract Image noise seriously affects the accuracy of brain magnetic resonance (MR) image classification. The traditional Gaussian mixture model (GMM) is widely applied in image segmentation, which uses only image intensity information thus is susceptible to image noise. Markov random field (MRF) model overcome the problem by using a priori probability for local smoothing and denoising, which depends on the pixel class labelling with the Gibbs distribution. However, the MRF model still lacks accurate classification of brain tissue. To improve the segmentation of brain MR image, the paper proposes a joint segmentation scheme based on combination of GMM and MRF model to classify the brain tissue into three parts: white matter (WM), grey matter (GM) and cerebrospinal fluid (CSF). During the implementation, both image intensity and local neighbouring voxels are considered. The main steps are as follows: 1) we use K-means estimation to acquire the initial distribution parameters of the three brain tissues; then use Expectation maximization (EM) estimation to obtain GMM parameters. 2) For the spatial voxels, the energy function of joint probability is change in terms of their corresponding GMM class information; then the intensity-related energy

function's component is controlled. Therefore, the parameter of the joint model is estimated adaptively according to the local intensity and spatial information. The proposed method performs well in the experiments, for example, it is not sensitive to image noise, and has good robustness and segmentation accuracy as well as high computational efficiency. © 2017 IEEE.

Abstract Environmental context: Tunnel wash water contains high concentrations of tyre-road wear particles, tyre-derived chemicals, and metals, which can threaten aquatic ecosystems if untreated. This study applies a multi-analytical approach to assess pollutant retention and transformation during sedimentation, revealing treatment limitations and emphasising the need for advanced strategies to reduce pollution from enclosed road infrastructures. Rationale: Tunnel wash water (TWW) accumulates tyre-road wear particles (TRWPs), tyre-derived chemicals (TDCs) and metals at high concentrations, posing risks to aquatic ecosystems if untreated. Understanding pollutant retention and transformation during treatment is essential for effective mitigation. Methodology: We investigated TWW from the Vålereng tunnel (Oslo, Norway) using a multi-analytical approach. TRWPs were quantified by pyrolysis–gas chromatography–mass spectrometry (PYR-GC/MS) with a marker mix (M4), a single marker (4-vinylcyclohexene, 4-VCH), and automated scanning electron microscopy–energy dispersive X-ray spectroscopy (SEM-EDX) single particle analysis with machine-learning classification (automated single particle analysis, ASPA, MC2). Metals were analysed by inductively coupled plasma–mass spectrometry (ICP-MS) and TDCs by ultraperformance liquid chromatography–tandem mass spectrometry (UPLC-MS/MS). Samples were collected before, during and after sedimentation treatment over 21 days. Results: Zinc (Zn) was the most abundant metal (274–2300 µg L⁻¹), reduced by up to 93% post-treatment. TRWP concentrations ranged from 15–160 mg L⁻¹ (M4), 13–122 mg L⁻¹ (4-VCH) and 13–240 mg L⁻¹ (ASPA MC2), with treatment efficiencies of 95–99.7%. Despite reductions, fine particles (<20 µm) dominated both untreated and treated water (up to 85%). For TDCs, N-(1,3-dimethylbutyl)-N-phenyl-p-phenylenediamine (6PPD) showed 85% reduction, whereas 6PPD-quinone (6PPD-Q) (–26%) and N,N-diphenylguanidine (DPG) (–3.7%) exhibited negative retention, likely due to leaching and transformation. 1-hydroxybenzotriazole hydrate (OHBT) increased by up to 167% during sedimentation. Discussion: Sedimentation effectively removed particles and metals but was insufficient for several dissolved TDCs, releasing them at ecotoxicologically relevant concentrations (e.g. 6PPD-Q exceeded Environment Protection Authority freshwater limits). This first cross-validation of three TRWP quantification methods highlights the need for advanced treatment technologies and regulatory thresholds for tyre-derived pollutants. © 2026 The Author(s) (or their employer(s)). A multi-resolution hidden markov model for optimal detection, tracking, separation, and classification of marine mammal vocalizations

Item Type Conference Paper

Author B.F. Harrison

Author P.M. Baggenstoss

Abstract We employ the multi-resolution hidden Markov model (MRHMM) to develop an improved algorithm for modeling marine mammal wandering tone vocalizations (whistles). A vocalization is modeled by a series of time segments in which the signal has a constant frequency rate (chirps). Rather than using chirps of uniform length, the segments are allowed to be of variable size, thus adapting to both short rapid changes in frequency rate as well as long segments of constant rate. The method supports the goals of finding the single best segmentation or the average joint probability density function of the data over all possible segmentations, weighted by the a priori probability of each segmentation. The probability density function (PDF) projection theorem is used to allow likelihood comparisons in the raw data domain. Simulated data and recorded marine mammal vocalizations are used to demonstrate the technique.

A multi-source comprehensive risk quantification method for cascade reservoirs based on Monte Carlo simulation, HEC-RAS and Bayesian networks: Development and application in the Dadu river Basin

Item Type Journal Article

Author T. Wang

Author H. Yuan

Author Y. Li

Author T. Zhang

Author Y. Zhang

Author Y. Liu

Abstract The failure of cascade dams is prone to triggering the superposition, transmission, and amplification of risks in the reservoir group of a river basin. Accurate assessment of the comprehensive risks of cascade reservoirs is of decisive significance for the safe operation of water conservancy systems and the protection of people's lives and property. At present, the traditional comprehensive risk analysis methods based on flood disaster risk transmission have obvious limitations. They only focus on single risk factors like flooding, and the flood routing analysis mostly adopts empirical formulas, resulting in insufficient assessment accuracy. To address this issue, we propose a novel multi-source comprehensive risk quantification method for cascade dams integrating Monte Carlo simulation, the hydrodynamic model and Bayesian networks. Firstly, Monte Carlo simulations are applied to the hydrodynamic model simulated in HEC-RAS by combining with self-developed programs using Visual Basic for Applications. This application enables automated analysis of actual river flood routing, considering random flood frequencies and random initial reservoir

water levels. Meanwhile, machine learning algorithms including N-M, Adam, and DE are employed to conduct inverse analysis of river roughness, which is determined as 0.0833. Then, based on the analysis of overtopping damage from flood evolution after dam failures in cascade reservoirs, we quantitatively analyze the inter-dam transmission risks by applying the theory of comprehensive influence coefficients. Further, we combine the risk analysis results of floods, earthquakes and landslides for each dam in the system, and use Bayesian networks to assess the failure risk of each individual dam. Finally, by integrating the transmission risk analysis, we develop a multi-source comprehensive risk analysis method for cascade reservoir systems. This method is applied to four cascade dams in the Dadu River Basin of Sichuan Province, China. The results show that the main cause of the single dam failure is the rare high-energy floods, and earthquakes have a significant impact on dam losses. The Changheba Dam has the highest reliability and can block risks, while the Huangjinping Dam and the Luding Dam require focused attention due to their relatively high comprehensive risks. We recommend prioritizing enhanced monitoring and structural reinforcement for the critical dams including Huangjinping and Luding. This method is expected to accurately quantify the risk transmission between dams in cascade reservoir groups under multi-disaster scenarios, thereby contributing to risk management and plan formulation for the water conservancy system. © 2026 Elsevier B.V. A Multivariate Drought Index for Seasonal Agriculture Drought Classification in Semiarid Regions

Item Type Journal Article

Author K. Bageshree

Author T. Kinouchi

Abstract Drought assessment in any region primarily hinges on precipitation deficiency, which is subsequently propagated to various components and sectors, leading to different drought types. In countries such as India, an intricate relationship between various governing factors, drought types, and their quantification methodologies make it elusive to timely initiate government relief measures. This also prevents comprehensive inclusion of the integrated effect of the principal drivers of drought, resulting in ambiguous categorization of severity, where groundwater storage variability is often neglected despite its significant role in irrigation. Here, we developed a multivariate Joint Drought Index (JDI) combining satellite and model-based standardized indices of precipitation and evapotranspiration (SPEI), soil moisture (SSI), groundwater (SGI), and surface runoff (SRI) with different temporal scales by employing two robust methods, principal component analysis (PCA) and Gaussian copula, and applied the index to highly drought-prone Marathwada region from central India. Our novel approach of using different scale combinations of integrated indices for two primary seasons (Kharif and Rabi) provides more realistic drought intensities than multiple univariate indices, by incorporating the response from each index, representing the seasonal drought conditions corroborating with the seasonal crop yields. JDI, with both methods, successfully identified two major drought events in 2015 and 2018, while effectively capturing the groundwater drought. Moreover, despite the high correlation between JDI using PCA and copula, we observed a significant difference in the intensities reported by these methods, where copula detected exceptional drought conditions more frequently than PCA. JDI effectively detected the onset, duration, and termination of drought, where the improved accuracy of drought detection can play a critical role in policy formation and socioeconomic security of the related stakeholders. Seasonal agriculture drought categorization for holistic quantification of drought conditions as presented in this study should provide broad methodological implications on drought monitoring and mitigation measures, especially for agriculture-dominated regions in semiarid climates. © 2022 by the authors.

A neuro-fuzzy approach to virtual screening in molecular bioinformatics

Item Type Journal Article

Author J. Paetz

Author G. Schneider

Abstract Molecular bioinformatics is a transdisciplinary working area. One hot topic is the design of drugs using computers and intelligent algorithms. This is known as in silico approach. We use a new in silico approach for separating active ligand molecules from inactive ones for different drug targets. This kind of retrospective virtual screening is performed by using encoded molecule data and a neuro-fuzzy methodology for classification, feature selection, and rule generation. We generate rules in a retrospective screening process that identify regions, where clearly more active compounds can be found compared to their a priori probability. We show that our approach is superior to a common descriptor-based standard technique. © 2004 Elsevier B.V. All rights reserved.

Abstract Adsorbate interactions with substrates (e.g. surfaces and nanoparticles) are fundamental for several technologies, such as functional materials, supramolecular chemistry, and solvent interactions. However, modeling these kinds of systems in silico, such as finding the optimum adsorption geometry and energy, is challenging, due to the huge number of possibilities of assembling the adsorbate on the surface. In the current work, we have developed an artificial intelligence (AI) approach based on an active learning (AL) method for adsorption optimization on the surface of materials. AL uses machine learning (ML) regression algorithms and their uncertainties to make a decision (based on a policy) for the next unexplored structures to be computed, increasing, though, the probability of finding the global minimum with a small number of calculations. The methodology allows an accurate and automated structural elucidation of the adsorbate on the surface, based on the

minimization of the total electronic energy. The new AL method for adsorption optimization was developed and implemented in the quantum machine learning software/agent for material design and discovery (QMLMaterial) program and was applied for C60@TiO₂ anatase (101). It marks another software extension with a new feature in addition to the automatic structural elucidation of defects in materials and of nanoparticles as well. SCC-DFTB calculations were used to build the complex search surfaces with a reasonably low computational cost. An artificial neural network (NN) was employed in the AL framework evaluated together with two uncertainty quantification methods: K-fold cross-validation and non-parametric bootstrap (BS) resampling. Also, two different acquisition functions for decision-making were used: expected improvement (EI) and the lower confidence bound (LCB). Author M.X. Silva

Author D.R. Salahub

Abstract In catalysis, an accurate structural elucidation of molecules, atomic clusters, nanoparticles and solid surfaces is required to understand chemical processes. Therefore, an efficient and automatic structure determination for these systems is of great benefit since it requires a global search within huge chemical spaces. In this work, we propose a new active learning (AL) method intended for atomic clusters that uses different supervised machine learning techniques and their uncertainties to decide the promising non-observed (virtual) structures to be evaluated from quantum calculations. The method was developed for structural elucidation of (I) clusters where all atomic coordinates are allowed to change in a continuous chemical space and (II) doped ones where the atoms exchange in a sufficiently rigid structure, thus, a discrete search space where all cluster descriptors are known. Particularly for case I, a genetic algorithm operator was used to create the unknown virtual structures (and then their descriptors) from the observed ones to improve the performance of the AL search. The proposed AL was applied to the global optimization of heteronuclear (Al_4Si_7 and $4\text{Al}@ \text{Si}_{11}$) and homonuclear (Na_{20}) clusters using self-consistent charge density-functional tight-binding (SCC-DFTB), where a new repulsion parameter was developed to reproduce isomers evaluated from high-level calculations. The performance of the Gaussian process and artificial neural network algorithms was evaluated together with several uncertainty quantification methods: from Gaussian process, K-fold cross-validation and nonparametric bootstrap (BS) resampling. The efficiency of the AL was compared to conventional global optimization methods, such as random search and a genetic algorithm. The results show that the AL can find efficiently the global minimum of atomic clusters. © 2021, The Author(s), under exclusive licence to Springer-Verlag GmbH Germany, part of Springer Nature.

A new approach for EEG feature extraction for detecting error-related potentials

Item Type Conference Paper

Author Z. Pang

Author J. Li

Author H. Ji

Author M. Li

Abstract Error-related negativity (ERN) is one of the electroencephalographical (EEG) traces related to the subject perception of erroneous responses. Methods for detecting the ERN from EEG signals have been widely investigated. Many known techniques use the ERN component of event-related potentials (ERP) by extracting relevant features and feeding those features to a classifier. In these approaches, feature extraction becomes the key point. In this paper, we used the t-CWT method which was based on the continuous wavelet transform (CWT) and Student's t-test for extracting ERN features. In the experiment, EEG was recorded from 5 electrode sites (Fz, FC1, Cz, FCz and FC2) during a sustained attention experiment in 10 subjects. We used a support vector machine for classification. In

addition, the algorithm provides fully automated detection and quantification methods for extracting the most discriminative ERP components between two cognitive states and are particular suitable for classifying single-trial ERPs. The features extracted by the algorithm can be interpreted in terms of signal characteristics that are contributing to the efficiency of classification, giving a new method for brain activity investigation. © 2016 IEEE.

A new approach to estimate a priori probabilities in remote sensing digital image classification

Item Type Journal Article

Author C. Liczbinski

Author V. Haertel

Abstract An adaptive classifier designed for high-dimensional image data classification has recently been proposed. The main feature in this proposed classifier consists of a novel method to acquire semilabeled samples in an iterative way during the

classification process itself. The semilabeled samples are then added to the set of available labeled samples, thus increasing the total number of training samples and consequently the reliability of the estimated values for the parameters in a parametric classifier. In this study we propose the insertion of an additional step into the iterative procedure implemented in the adaptive classifier to produce more realistic estimates of the a priori probability of the classes. The proposed procedure to estimate the a priori probability of the classes makes use of the same weighted approach used by the adaptive classifier, is computationally efficient, and can be easily implemented. Tests using hyperspectral image data have shown that the proposed approach can contribute to increased accuracies in the classification process. © 2008, Taylor & Francis Group, LLC. Abstract Aims: The incidence of clinical events related to medication errors and/or adverse drug reactions reported in the literature varies by a degree that cannot solely be explained by the clinical setting, the varying scrutiny of investigators or varying definitions of drug-related events. Our hypothesis was that the individual complexity of many clinical cases may pose relevant limitations for current definitions and algorithms used to identify, classify and count adverse drug-related events. Methods: Based on clinical cases derived from an observational study we identified and classified common clinical problems that cannot be adequately characterized by the currently used definitions and algorithms. Results: It appears that some key models currently used to describe the relation of medication errors (MEs), adverse drug reactions (ADRs) and adverse drug events (ADEs) can easily be misinterpreted or contain logical inconsistencies that limit their accurate use to all but the simplest clinical cases. A key limitation of current models is the inability to deal with complex interactions such as one drug causing two clinically distinct side effects or multiple drugs contributing to a single clinical event. Using a large set of clinical cases we developed a revised model of the interdependence between MEs, ADEs and ADRs and extended current event definitions when multiple medications cause multiple types of problems. We propose algorithms that may help to improve the identification, classification and counting of drug-related events. Conclusions: The new model may help to overcome some of the limitations that complex clinical cases pose to current paper- or software-based drug therapy safety. © 2013 The British Pharmacological Society.

A new approach to robustness-based optimization using uncertainty set constructed through machine learning

Item Type Journal Article

Author R.M. Shahbab

Author K. Zaman

Abstract This paper proposes three machine learning-based uncertainty set construction methods and a novel uncertainty quantification method for robustness-based optimization. The proposed methods are capable of capturing all possible types of uncertainties in the form of sparse point and/or interval data and efficiently quantify uncertainty in robustness-based optimization. In contrast to traditional approaches that rely on expert opinion or assumptions to construct uncertainty sets, our methods leverage machine learning algorithms to extract uncertainty patterns from historical data and effectively capture epistemic uncertainty in input variables. Another challenge in existing robustness-based optimization under epistemic uncertainty is the high computational cost associated with the iterative method of epistemic analysis. Moreover, these methods struggle with uncertainty sets containing a mixture of point and interval data. To overcome these limitations, we propose a unified probabilistic approach that utilizes maximum likelihood estimation to efficiently quantify uncertainty, regardless of the data form. Using the proposed methods, we introduce new approaches for robustness-based portfolio optimization (RPO) and multidisciplinary design optimization (RO/MDO), namely the worst-case maximum likelihood estimation (WMLE)-based single-loop RPO and WMLE-based RO/MDO approach, respectively. Illustrated through applications to minimum variance portfolios, our methods consistently demonstrate significant improvements over established formulations in terms of both return and risk. Additionally, when applied to a complex multidisciplinary engineering design, the WMLE-based RO/MDO approach showcases a computationally efficient solving technique, yielding more realistic results than the existing methodologies. © The Author(s), under exclusive licence to Springer-Verlag GmbH Germany, part of Springer Nature 2024.

A New Classifier by Remixing Features and Adjusting Logits for Long-Tailed Visual Data

Item Type Conference Paper

Author X. Deng

Author Y. Wang

Author M. Li

Abstract The natural visual recognition for long-tailed distribution data is a difficult problem because the classifier is more biased towards the head classes, which often results in incorrect prediction. To solve this problem, we propose a simple one-stage network by remixing features and adjusting logits (RFAL) to handle long-tailed recognition. Our method enhances the expression ability of the tail class through the effective re-organization of deep features, and reassigns the label in favor of the tail class by providing a higher weight to the tail class. Extensive experiments on three long-tailed visual recognition datasets are conducted and the comparison of the proposed network with the existing state-of-the-art networks is made. The results show the better performance of the proposed network in long-tailed data recognition. © 2021 IEEE.

Abstract Vugular porosity, per this work is defined as a set of secondary porosity development in carbonate rocks that could have developed through alteration of rock-fabric, commonly by processes such as dolomitization and dissolution (including mouldic porosity). It is one of the important secondary porosity types and its characterization can influence rock model petro-physical behavior. Traditionally vugular porosity can be quantified on water-based mud (WBM) high resolution electrical imaging logs by counting the image pixels that has electrical resistivity lower than the rock background. With the popularity of non-conductive drilling fluid (OBM) and improvement of electrical image logging technology, it is possible nowadays to acquire similar high resolution electrical images in OBM environment. Vugs can be identified visually on these new types of electrical images. However open vugs filled with OBM can appear resistive on those images and invalidate the basic assumptions of secondary porosity quantification software that open vugs should have lower electrical resistivity. At the same time, the new generation of electrical imaging tools uses megahertz logging frequencies to decrease the capacitance of the OBM to acquire formation images. With this frequency range, both electrical conductivity and dielectric permittivity impact the image log acquired. This challenges our understanding of the tool response in terms of image color contrast and opens the question of how to integrate such OBM electrical images into current geologic interpretation software that commonly uses the image resistivity value thresholds. In this case, a new laboratory device that features the same logging frequency has been developed and presented in this paper. The device was used to investigate images of secondary porosity features acquired in OBM in controlled laboratory conditions. It is demonstrated that by integrating both resistivity image and dielectric permittivity image, it is possible to overcome the OBM filled resistive vug limitation and account for all fluid-filled effective vugs. A new post processing method is introduced by combining the effects of resistivity and dielectric permittivity and generating a new image called the rock Hayman factor image. On the Hayman factor image, it is possible to differentiate fluid-filled vugs from cemented vugs. Vug density quantification in WBM is based on resistivity threshold values to characterize conductive and resistive heterogeneity patches and can be highly user dependent. In OBM environment, mud filled features will appear resistive and may decrease the contrast with rock resistive matrix. This can make current vug quantification software miss parts of open vugs. Two popular vug separation and quantification methods (Gray-scale reconstruction transform plus watershed transform method and Sobel gradient edge detection plus Otsu's image thresholding method) are investigated first on a vuggy limestone outcrop and then on a downhole log as a case study to derive a vug density quantification workflow. The new Hayman factor image has proven on the laboratory data its ability to quantify both vugs beneath the rock surface and on the rock surface filled with OBM. Integrating the Hayman factor image, the procedure to set heterogeneity patches can be well-defined and not rely on user settings. The two image class separation methods can give very similar vug density quantified. Best practices of parameter adjustments on these two image classification methods are provided that can achieve the best results based on both laboratory data and downhole data. In this paper investigation results including both laboratory measurements and downhole logging data analysis of the OBM electrical image vug density quantification are presented. A new post-processing Hayman factor image is designed to quantify rock resistivity and the dielectric permittivity relationship and help vug density quantification. Application of this new image and best practices of how to set processing parameters using this image are investigated and summarized. Using the new vug characterization workflow involving Hayman image can improve OBM well vug quantification

A new method for acquiring images of meiobenthic images using the FlowCAM

Item Type Journal Article

Author T. Kitahashi

Author H.K. Watanabe

Author M. Tsuchiya

Author H. Yamamoto

Author H. Yamamoto

Abstract The purpose of this study was to develop a new method for investigating sediment-inhabiting meiobenthos using the Flow Cytometer And Microscope (FlowCAM). Meiobenthos are widely recognized as a useful indicator for assessing the effects of anthropogenic and natural disturbances in both shallow and deep ocean ecosystems. These small benthic invertebrates are traditionally investigated by individually

counting and identifying specimens under a microscope, which is labor intensive and time consuming. However, FlowCAM, which was originally developed to semiautomatically analyze microplankton, has the potential to resolve these challenges. Meiobenthic specimens were extracted from sediment using the centrifugal separation method and were then pipetted into the FlowCAM system and imaged. The images were then used to classify and count the specimens at high taxonomic levels to verify the effectiveness of this method compared with traditional methods. We found that FlowCAM system: • Enabled sufficient meiobenthic images to be obtained to allow the identification and classification of specimens at high taxonomic levels. • Obtained comparable numbers of individuals to traditional methods. • Has the potential to rapidly process large the volumes of meiobenthos samples that are required when monitoring seasonal and spatial variation in ocean ecosystems and conducting long-term environmental impact assessments. © 2018 The Author(s)

A new method for assessment of regional drought risk: information diffusion and interval mapping adjustment based on k-means cluster points

Item Type Journal Article

Author W. Xu

Author M. Tang

Author Y. Li

Abstract Aiming at the defect that there is no ability for the conventional weighted comprehensive assessment method (WCA) to grade drought risk directly, a method based on k-means cluster points to realize the classification of drought risk is proposed in this paper. On the basis of calculating the drought risk value of cluster points, the inverse distance weight interpolation method (IDWI) and multidimensional normal diffusion method (MND) were used to quantify the drought risk value, and the discrimination between the risk value and grade was improved by interval mapping adjustment (IMA). In this paper, the drought risk of Anhui Province from 2000 to 2020 was calculated to verify the above method. The results show that: (1) The drought risk quantification method based on information redistribution of k-means cluster point can not only realize automatic risk classification, but also re-quantify the risk value of the assessment object in the same risk grade, which makes up for the defects that the conventional WCA cannot carry out grade division and the conventional clustering method cannot assign the risk value of the assessment object. (2) The result of information redistribution based on MND is closer to the actual drought situation and more reasonable than IDWI. (3) The dispersion effect of risk value obtained by information redistribution based on k-means cluster point can be improved by the IMA of drought risk. It improves the discrimination degree of risk value, so that the grades can be displayed more intuitively. The defect of the WCA is overcome by the new method proposed in this paper, the follow-up utilization space is widened, and the thinking of risk quantification in drought risk assessment is broadened. © 2022 The Authors.

Abstract Introduction Gap and step-off measurements are generally used in the surgical decision-making process of distal radius fractures. Unfortunately, there is no consensus on treatment choice as these measurements are prone to inter- and intraobserver variability. In this study, we aim to introduce a new 3D fracture quantification method and compare it to conventional fracture analysis. Methods Forty patients with a minimally displaced intra-articular distal radius fracture that was treated nonoperatively between 2008–2015 were included. 2D-CT images were reassessed by three orthopedic trauma surgeons who performed gap and step-off measurements. Subsequently, 3D models were created and a 3D measurement method for fracture displacement was developed. For each fracture, the ‘3D gap area’ (3D surface between all fracture fragments) was determined by three observers. Interobserver agreements were calculated for all measurements, and the intraobserver agreement was calculated for the new 3D measurement. All patients completed two questionnaires in order to link our measurements to functional outcome. Results The interobserver agreement of the 2D measurements was fair (ICC = 0.54) for the gap and poor (ICC = 0.21) for the step-off. The median gap was 2.8 (IQR: 1.9–3.5) mm

and step-off was 0.9 (IQR: 0.0–1.6) mm. Interobserver agreement on 3D gap area measurements was excellent (ICC = 0.81), with a median difference between measurements of 6.0 (IQR: 2.0–19.0) mm², which indicates reliable assessment of 3D fracture displacement. Intraobserver agreement was also excellent (ICC = 0.98), with a median difference of 4.0 (IQR: 1.5–5.5) mm². No significant differences in clinical outcome were found between the above and below 2mm displacement groups. The score of the DASH was 3.4 (IQR: 0.4–8.8) versus 4.2 (IQR: 0.0–11.6) respectively. Results from the PRWE questionnaire shows a similar result of 3.5 (IQR: 0.0–12.6) versus 5.0 (IQR: 0.0–25.5). Conclusion 3D gap area is a more objective measurement method compared to the conventional gap and step-off measurements to quantify the level of fracture displacement of distal radius fractures. 3D fracture assessment can be used in addition to the currently used classification systems of distal radius fractures. A new quantitative method for pivot shift grading

Item Type Journal Article

Author S. Kopf

Author R. Kauert

Author J. Halfpaap

Author T. Jung

Author R. Becker

Abstract Purpose: The purposes of the study were to evaluate and to quantify the pivot shift phenomenon by using a small and easy to handle measuring device for pivot shift quantification. Methods: Twenty patients (forty knees) with primary torn anterior cruciate ligaments (ACL) were tested under anesthesia, graded by the examiner and by the device according to the IKDC classification [normal (0), glide (1), clunk (2), and gross (3)]. For the grading by the device, a femoral and a tibial miniature inertial sensor measured the acceleration and the angular velocities. Three parameters were used for pivot shift identification and quantification: (1) difference between the positive and negative acceleration peak value (a diff), (2) the maximum jerk (j max), and (3) the standard deviation (SD a) of the acceleration. The ratio between the ACL-deficient and the intact knees was calculated in order to normalize the data. Results: The pivot shift phenomenon could be identified, and all three parameters showed significant higher values in the ACL-deficient knees compared to the intact knees ($p < 0.05$). The grading by examiner did not significantly correlate with a diff ($p = 0.38$; $r = 0.21$), j max ($p = 0.36$; $r = -0.22$), SD a ($p = 0.65$; $r = 0.11$), and grading by the device ($p = 0.62$; $r = 0.12$). Conclusions: The present study has shown that the quantification of the pivot shift test is practicable when inertial sensors are used. The results have shown that the subjective grading of the pivot shift test does not correlate well with objective quantification. © 2012 Springer-Verlag.

A Neyman-Pearson approach to statistical learning

Item Type Journal Article

Author C. Scott

Author R. Nowak

Abstract The Neyman-Pearson (NP) approach to hypothesis testing is useful in situations where different types of error have different consequences or a priori probabilities are unknown. For any $\alpha > 0$, the NP lemma specifies the most powerful test of size α , but assumes the distributions for each hypothesis are known or (in some cases) the likelihood ratio is monotonic in an unknown parameter. This paper investigates an extension of NP theory to situations in which one has no knowledge of the underlying distributions except for a collection of independent and identically distributed (i.i.d.) training examples from each hypothesis. Building on a "fundamental lemma" of Cannon et al., we demonstrate that several concepts from statistical learning theory have counterparts in the NP context. Specifically, we consider constrained versions of empirical risk minimization (NP-ERM) and structural risk minimization (NP-SRM), and prove performance guarantees for both. General conditions are given under which NP-SRM leads to strong universal consistency. We also apply NP-SRM to (dyadic) decision trees to derive rates of convergence. Finally, we present explicit algorithms to implement NP-SRM for histograms and dyadic decision trees. © 2005 IEEE.

A Non-intrusive Quantification Method for Biochar Water Retention Capacity Using A Portable Microwave Sensor and Machine Learning

Item Type Conference Paper

Author D. An

Author H. Niu

Author Y. Chen

Abstract Biomass from agriculture and forestry can be converted to biochar by pyrolysis gasification process and when applied to soil, this becomes a carbon negative technology. How to quantify the effect of biochar applied into soil in terms of water retention capacity accurately, quickly, cost-effectively and in large scale mapping are still a challenging problem. This work for the first time, reported extensive lab tests to demonstrate that a non-intrusive quantification method for biochar water retention capacity using a portable microwave sensor and machine learning is feasible. Scaling up can be achieved by putting the sensor on a mobility platform, either ground or aerial. We reported in this paper details of our materials and methods, and machine learning workflow and results. The significance of this work lays the foundation for future carbon negative technology applications assessment such as soil carbon accounting. We evaluated our nonintrusive quantification method with SVM and LDA classifier algorithm on the data collected from real-world experiments. Results show that our method

achieved a 74.0% recognition accuracy over six different kinds of biochar footprints. © 2021 IEEE.

A note on a priori forecasting and simplicity bias in time series

Item Type Journal Article

Author K. Dingle

Author R. Kamal

Author B. Hamzi

Abstract To what extent can we forecast a time series without fitting to historical data? Can universal patterns of probability help in this task? Deep relations between pattern Kolmogorov complexity and pattern probability have recently been used to make a priori probability predictions in a variety of systems in physics, biology and engineering. Here we study simplicity bias (SB) – an exponential upper bound decay in pattern probability with increasing complexity – in discretised time series extracted from the World Bank Open Data collection. We predict upper bounds on the probability of discretised series patterns, without fitting to trends in the data. Thus we

perform a kind of ‘forecasting without training data’, predicting time series shape patterns a priori, but not the actual numerical value of the series. Additionally we make predictions about which of two discretised series is more likely with accuracy of ~80%, much higher than a 50% baseline rate, just by using the complexity of each series. These results point to a promising perspective on practical time series forecasting and integration with machine learning methods. © 2022 The Author(s)

A novel approach for quantification and analysis of the color doppler twinkling artifact with application in noninvasive surface roughness characterization: An in vitro phantom study

Item Type Journal Article

Author A. Jamzad

Author S.K. Setarehdan

Abstract Objectives-The twinkling artifact is an undesired phenomenon within color Doppler sonograms that usually appears at the site of internal calcifications. Since the appearance of the twinkling artifact is correlated with the roughness of the calculi,

noninvasive roughness estimation of the internal stones may be considered as a potential twinkling artifact application. This article proposes a novel quantitative approach for measurement and analysis of twinkling artifact data for roughness estimation. Methods-A phantom was developed with 7 quantified levels of roughness. The Doppler system was initially calibrated by the proposed procedure to facilitate the analysis. A total of 1050 twinkling artifact images were acquired from the phantom, and 32 novel numerical measures were introduced and computed for each image. The measures were then ranked on the basis of roughness quantification ability using different methods. The performance of the proposed twinkling artifact-based surface roughness quantification method was finally investigated for different combinations of features and classifiers. Results-Eleven features were shown to be the most efficient numerical twinkling artifact measures in roughness characterization. The linear classifier outperformed other methods for twinkling artifact classification. The pixel count measures produced better results among the other categories. The sequential selection method showed higher accuracy than other individual rankings. The best roughness recognition average accuracy of 98.33% was obtained by the first 5 principle components and the linear classifier. Conclusions-The proposed twinkling artifact analysis method could recognize the phantom surface roughness with average accuracy of 98.33%. This method may also be applicable for noninvasive calculi characterization in treatment management. © 2014 by the American Institute of Ultrasound in Medicine.

A novel approach to maximize g-mean in nonstationary data with recurrent imbalance shifts

Item Type Journal Article

Author R. Kulkarni

Author S. Revathy

Author S. Patil

Abstract One of the noteworthy difficulties in the classification of nonstationary data is handling data with class imbalance. Imbalanced data possess the characteristics of having a lot of samples of one class than the other. It, thusly, results in the biased accuracy of a classifier in favour of a majority class. Streaming data may have inherent imbalance resulting from the nature of dataspace or extrinsic imbalance due to its nonstationary environment. In streaming data, timely varying class priors may lead to a shift in imbalance ratio. The researchers have contemplated ensemble learning, online learning, issue of class imbalance and cost-sensitive algorithms autonomously. They have scarcely ever tended to every one of these issues mutually to deal with imbalance shift in nonstationary data. This correspondence shows a novel methodology joining these perspectives to augment G-mean in no stationary data with Recurrent Imbalance Shifts (RIS). This research modifies the state-of-the-art boosting algorithms, 1) AdaC2 to get G-mean based Online AdaC2 for Recurrent Imbalance Shifts (GOA-RIS) and AGOA-RIS (Ageing and G-mean based Online AdaC2 for Recurrent Imbalance Shifts), and 2) CSB2 to get G-mean based Online CSB2 for Recurrent Imbalance Shifts (GOC-RIS) and Ageing and G-mean based Online CSB2 for Recurrent Imbalance Shifts (AGOCRIS). The study has empirically and statistically analysed the performances of the proposed algorithms and Online AdaC2 (OA) and Online CSB2 (OC) algorithms using benchmark datasets. The test

outcomes demonstrate that the proposed algorithms globally beat the performances of OA and OC. © 2021, Zarka Private University. All rights reserved.

Abstract Pattern recognition approaches to the analysis of neuroimaging data have brought new applications such as the classification of patients and healthy controls within reach. In our view, the reliance on expensive neuroimaging techniques which are not well tolerated by many patient groups and the inability of most current biomarker algorithms to accommodate information about prior class frequencies (such as a disorder's prevalence in the general population) are key factors limiting practical application. To overcome both limitations, we propose a probabilistic pattern recognition approach based on cheap and easy-to-use multi-channel near-infrared spectroscopy (fNIRS) measurements. We show the validity of our method by applying it to data from healthy controls ($n = 14$) enabling differentiation between the conditions of a visual checkerboard task. Second, we show that high-accuracy single subject classification of patients with schizophrenia ($n = 40$) and healthy controls ($n = 40$) is possible based on temporal patterns of fNIRS data measured during a working memory task. For classification, we integrate spatial and temporal information at each channel to estimate overall classification accuracy. This yields an overall accuracy of 76% which is comparable to the highest ever achieved in biomarker-based classification of patients with schizophrenia. In summary, the proposed algorithm in combination with fNIRS measurements enables the analysis of sub-second, multivariate temporal patterns of BOLD responses and high-accuracy predictions based on low-cost, easy-to-use fNIRS patterns. In addition, our approach can easily compensate for variable class priors, which is highly advantageous in making predictions in a wide range of clinical neuroimaging applications. © 2012 Wiley Periodicals, Inc.

A novel discriminative feature extraction for acoustic scene classification using RNN based source separation

Item Type Conference Paper

Author S. Mun

Author S. Shon

Author W. Kim

Author D.K. Han

Author H. Ko

Abstract Various types of classifiers and feature extraction methods for acoustic scene classification have been recently proposed in the IEEE Detection and Classification of Acoustic Scenes and Events (DCASE) 2016 Challenge Task 1. The results of the final evaluation, however, have shown that even top 10 ranked teams, showed extremely low accuracy performance in particular class pairs with similar sounds. Due to such sound classes being difficult to distinguish even by human ears, the conventional deep learning based feature extraction methods, as used by most DCASE participating teams, are considered facing performance limitations. To address the low performance problem in similar class pair cases, this letter proposes to employ a recurrent neural network (RNN) based source separation for each class prior to the classification step. Based on the fact that the system can effectively extract trained sound components using the RNN structure, the mid-layer of the RNN can be considered to capture discriminative information of the trained class. Therefore, this letter proposes to use this mid-layer information as novel discriminative features. The proposed feature shows an average classification rate improvement of 2.3% compared to the conventional method, which uses additional classifiers for the similar class pair issue. Abstract Worldwide, rheumatoid diseases account for approximately 37.57/100,000 disability-adjusted life years (DALYs). Early diagnosis of rheumatoid arthritis (RA) can effectively reduce associated risks and improve quality of life. To achieve this, accurate and rapid advanced tools are required. Herein, TiVCrMoC₃, a novel high-entropy two-dimensional (2D) carbide MXene that exhibits excellent electrical conductivity, is prepared and applied to surface-assisted laser desorption ionization mass spectrometry (SALDI-MS) analysis for the first time. TiVCrMoC₃ demonstrates superior performance in small-molecule detection compared with typical inorganic and organic substrates. Moreover, it exhibits ultrahigh sensitivity (limit of detection (LOD) at the 10 pg/mL level), excellent repeatability (coefficient of variation (CV) < 4%), excellent quantitative detection capability (coefficient of determination = 0.99987), clean background, and broad analyte coverage. Results showed that TiVCrMoC₃-assisted laser desorption ionization MS (LDI-MS) is efficient in screening RA diseases, with the advantages of high throughput and low cost. It enables accurate and quantitative analysis of various low-concentration metabolites in 1 µL of biological fluid within seconds. Combined with machine learning, TiVCrMoC₃-assisted LDI-MS is used to accurately diagnose multiple RA samples. A total of 8 potential different small-molecule metabolites between individuals with osteoarthritis (OA) and RA were identified based on relative quantification methods, and their associated metabolic changes were discussed. TiVCrMoC₃-assisted LDI-MS provides a potential tool for the rapid diagnosis of RA and may pave the way for precision medicine. © 2025 The Authors. A Novel Hyperspectral Image Classification Method Using Class-Weighted Domain Adaptation Network

Item Type Journal Article

Author H. Wang

Author Y. Cheng

Author X. Wang

Abstract With the development of science and technology, hyperspectral image (HSI) classification has been studied in depth by researchers as one of the important means of human cognition in living environments and the exploration of surface information. Nevertheless, the shortage of labeled samples is a major difficulty in HSI classification. To address this issue, we propose a novel HSI classification method called class-weighted domain adaptation network (CWDAN). First, the convolutional domain adaption network (ConDAN) is designed to align the marginal distributions and second-order statistics, respectively, of both domains via multi-kernel maximum mean discrepancy (MK-MMD) and CORAL loss. Then, the class-weighted MMD (CWMMD) is defined to simultaneously consider the conditional distribution discrepancy and changes of class prior distributions, and the CWMMD-based domain adaptation term is incorporated into the classical broad learning system (BLS) to construct the weighted conditional broad network (WCBN). The WCBN is applied to reduce the conditional distribution discrepancy and class weight bias across domains, while performing breadth expansion on domain-invariant features to further enhance representation ability. In comparison with several existing mainstream methods, CWDAN has excellent classification performance on eight real

HSI data pairs when only using labeled source domain samples. © 2023 by the authors.

A novel machine learning application: Water quality resilience prediction Model

Item Type Journal Article

Author M. Imani

Author M.M. Hasan

Author L.F. Bittencourt

Author K. McClymont

Author Z. Kapelan

Abstract Resilience-informed water quality management embraces the growing environmental challenges and provides greater accuracy by unpacking the systems' characteristics in response to failure conditions in order to identify more effective opportunities for intervention. Assessing the resilience of water quality requires complex analysis of influential parameters which can be challenging, time consuming and costly to compute. It may also require building detailed conceptual and/or physically process-based models that are difficult to build, calibrate and validate. This study utilises Artificial Neural Network (ANN) to develop a novel application to predict water quality resilience to simplify resilience evaluation. The Fuzzy Analytic Hierarchy Process method is used to rank water basins based on their level of resilience and to identify the ones that demand prompt restoration strategies. The commonly used 'magnitude * duration of being in failure state' quantification method has been used to formulate and evaluate resilience. A 17-years long water quality dataset from the 22 water basins in the State of São Paulo, Brazil, was used to train and test the ANN model. The overall agreement between the measured and simulated WQI resilience values is satisfactory and hence, can be used by planners and decision makers for improved water management. Moreover, comparative analyses show similarities and differences between the 'level of criticalities' reported in each zone by Environment Agency of the state of São Paulo (CETESB) and by the resilience model in this study. © 2021 Elsevier B.V.

A novel method and classification criteria for analyzing urine turbidity and its relationship with urine dry chemical parameters

Item Type Journal Article

Author J. Liu

Author Y. Cheng

Author Z. Zhang

Author L. Zhu

Author H. Zhou

Author H. Zhao

Author X. Ren

Abstract Background Urine turbidity is a significant diagnostic marker for early screening of urinary tract infections, kidney stones, and other related conditions. However, current methods for analyzing urine turbidity often rely on subjective assessments. This study aims to investigate the relationship between urine turbidity and the urine color values measured by spectrophotometer, providing an objective quantification method for both urine turbidity and urine color, while also exploring the underlying causes of urine turbidity. Methods A cross-sectional study was conducted among newly enrolled university students undergoing physical examination in Beijing. Basic demographic information and morning urine samples were collected. Urine turbidity was assessed using human visual evaluation and a urine chemical analyzer, while urine color CIE $L^*a^*b^*$ (International Commission on illumination) was measured using a spectrophotometer. Routine urine chemical examination was also performed. Correlations among urine turbidity, urine color, and urine dry chemical parameters were analyzed. Results A total of 1220 participants (68.7% female, mean age: 23.66 years) were included in the study. Spearman correlation analysis showed that urine turbidity was significantly negatively correlated with L^* (lightness) and significantly positively correlated with a^* (redness) and b^* (yellowness). Regression analysis identified L^* as the most affected parameter by urine turbidity (standardized coefficient $\beta = -1.030$, $p < 0.05$). Receiver operating characteristic (ROC) analysis showed that L^* was highly effective in distinguishing different urine turbidity levels, with $L^* < 89.165$ achieving excellent sensitivity and specificity (AUC=0.984) and 96% accuracy in identifying turbid urine. In addition, urine turbidity was positively correlated with urine specific gravity, protein, and urine color ($p < 0.05$), while its relationship with pH was nonlinear. These findings suggest that multiple factors collectively influence urine turbidity. Conclusion This study provides a novel and objective approach for assessing urine turbidity, advancing the modernization of urine diagnostic practices in traditional medicine. © 2025 Liu et al. A novel method for forest spatial structure heterogeneity evaluation of plantation utilizing point-wise vector network and neighborhood index

Item Type Journal Article

Author H. Qiu

Author H. Zhang

Author K. Lei

Author J. Wang

Author H. Zhang

Author L. Yu

Abstract Existing forest structure heterogeneity studies focus on single-perspective analysis and field investigation, lacking top-down perspective and automated forest heterogeneity quantification methods. Quantifying and elucidating the stand structural heterogeneity differences is challenging in uneven-aged forests. This paper addresses such challenges by presenting a point-wise stand spatial structure heterogeneity evaluation approach through deep learning and multi-dimensional structure index. This method aims to fill this gap of micro-region forest structure heterogeneity evaluation, and optimize the priority region selection of forest management. This research contributes to decreasing the costs of labor-intensive forest management. The approach was applied in a subtropical plantation in Southern China. Results showed that point clouds exhibit great potential in depicting fine-scale stand spatial structure heterogeneity. The precision and the F-score of the individual tree extraction were more than 95 % and 92 % in different forest types, respectively. The analysis of the tree- and plot-level stand structure indicated that the spatial heterogeneity of tree height and crown are at a relatively low level. Mixed forests with pronounced vertical layering are considered to have a more heterogeneous structural composition. Large-scale structure mapping showed that spatial distribution pattern is predominantly characterized by uniform distribution, and the overall degree of competition is relatively low. Priority forest management area were found to be in the northwest and southeast with a relatively high stem density distribution. The top-down 3D perspective of UAV-LiDAR makes up for the limitations of the 2D perspective of UAV images and traditional field measured-based structure calculation. Our method provides a novel and feasible solution for micro area stand structure heterogeneity mapping across various forest types. © 2024 Elsevier B.V.

A novel model to predict O-glycosylation sites using a highly unbalanced dataset

Item Type Journal Article

Author K. Zhou

Author C. Ai

Author P. Dong

Author X. Fan

Author L. Yang

Abstract In silico approaches have become an alternative method to study O-glycosylation. In this paper, we developed a linear interpretable model for O-glycosylation prediction based on an unbalanced dataset, analyzing the underlying biological knowledge of glycosylation. A training set of 4446 sites involving 468 positive sites and 3978 negative sites was developed during this research. The sites were encoded using the amino acid index (AAindex), and the forward stepwise procedure utilized for feature selection. The linear discriminant analysis with an equal a priori probability (PP-LDA) was employed to develop the interpretable model. Performance of the model was verified using both the internal leave-one-out cross-validation and external validation methods. Two non-linear algorithms, the supervised support vector machine and the unsupervised self-organizing competitive neural network, were used as comparisons. The PP-LDA model exhibited improved classification results with accuracy of 82.1 % for crossvalidations and 80.3 % for external prediction. Further analysis of this linear model indicated that the properties at position R1 and the properties relative to hydrophobicity contributed more to the glycosylation prediction. However, the alpha and turn propensities at the C-Terminal, together with physicochemical properties at the N-Terminal, are also relative to the glycosylation activity. This model is not only capable of predicting the possibility of glycosylation using an unbalanced dataset, but is also helpful to understand the underlying biological mechanisms of glycosylation. Considering the publicly accessibility of our prediction model, a downloadable program is provided in our supply materials. ©

A novel multi-featured decision system for multi-classification tasks

Item Type Journal Article

Author T. Xu

Abstract Feature engineering is a difficult task, and for real signal data, it is difficult to find a certain feature that can easily distinguish all classes. Multiple features can provide more information, which means the fusion of multi-feature learning strategies has potential significant advantages. Based on this premise, this paper proposes a multi-class framework based on the multi-featured decision to distinguish all the different classes, and takes automatic dependent surveillance-broadcast (ADS-B) signal data as

an example, first extracts the phase features and wavelet decomposition features of the signal data, then selects the features with high discrimination between classes, then proposes a one-dimensional residual neural network based on 16 convolutional layers to learn the unique features of different features and classes separately, and finally proposes a novel multi-featured decision method based on voting method and a priori probability. Results show that the proposed one-dimensional residual neural network has better performance metrics on the test set compared to some machine learning-based and neural network-based algorithms, with classification accuracies of 86.1%, 84.6% and 83.6% on wavelet decomposition features, raw features and phase features, respectively, on ADS-B preamble signals. The proposed feature decision framework based on the voting method and a priori probability has a recall, precision and F1 value of 80.24%, 89.89% and 84.79% on ADS-B preamble signals, respectively. © 2023 IOP Publishing Ltd.

Abstract During the Long Shut-down (LS2), the beam stopper of the Large Hadron Collider (LHC) was replaced. It was decided to eliminate the extracted two LHC beam dumps, also known as Target Dump for Ejected Beam External (TDE), as radioactive waste. The radiological characterization of the dumps is a vital and a necessary step for the proper classification and subsequent acceptance by the radioactive waste repository. The acceptance criteria require accurate declaration of the activity values of the Easy-to-Measure (ETM) radionuclides. This paper provides an overview of the challenges related to the high contact dose rates (reaching 2 mSv/h) and the heterogeneous distribution of the ETM radionuclides. This work proposes a novel quantification methodology that addresses those challenges. The developed methodologies followed can serve as a guide for addressing similar challenges in other accelerator and nuclear facilities. © 2025 Elsevier Ltd

A one-step biomarker quantification methodology for DCE-MRI of adnexal masses: Capturing kinetic pattern from early to late enhancement

Item Type Journal Article

Author A. Fathi Kazerooni

Author M. Nabil

Author H. Haghighat Khah

Author S. Parviz

Author M. Gity

Author H. Saligheh Rad

Abstract Purpose: To develop a one-step quantification approach that accounts for joint preprocessing and quantification of whole-range kinetics (early and late-phase washout) of dynamic contrast-enhanced (DCE) MRI of indeterminate adnexal

masses. Methods: Preoperative DCE-MRI of 43 (24 benign, 19 malignant) sonographically indeterminate adnexal masses were analyzed prospectively. A five-parameter sigmoid function was implemented to model the enhancement curves calculated within regions of interest. Diagnostic performance of five-parameter sigmoid model parameters (P1 through P5) was compared with pharmacokinetic (PK) modeling, semiquantitative analysis, and three-parameter sigmoid. Statistical analysis was performed using two-tailed student's t-test. Results: The results revealed that P2, representing the enhancement amplitude, is significantly higher, and P5, indicating the terminal phase, is generally negative in malignant lesions ($P < 0.001$). P2 (sensitivity = 79%, specificity = 87.5%, accuracy = 84%, area under the receiver operating characteristic curve = 91%) outperforms classification performances of PK and semiquantitative parameters. A combination of P2 and P5 shows comparable performance (sensitivity = 79%, specificity = 87.5%, accuracy = 84%, area under the receiver operating characteristic curve = 92%) to that of the combination of PK parameters, whereas the five-parameter sigmoid function maintains fewer assumptions than PK. Conclusions: The presented one-step quantification approach is helpful for accurate discrimination of benign from malignant indeterminate adnexal masses. Accordingly, P2 has considerably high diagnostic performance and terminal slope (P5), as a previously overlooked feature, contributes more than widely accepted early-enhancement kinetic features. *Magn Reson Med* 79:1165–1171, 2018. © 2017 International Society for Magnetic Resonance in Medicine. © 2017 International Society for Magnetic Resonance in Medicine

A physics-informed uncertainty quantification framework for deep learning-based real-time lane-change intention prediction

Item Type Journal Article

Author Z. Cao

Author Z. Zheng

Author M. Yildirimoglu

Author S.M.M. Haque

Abstract Lane-change intention prediction represents a significant challenge in autonomous driving, particularly within mixed traffic environments where autonomous vehicles (AV) must interact and share road space with human-driven vehicles. While deep learning has advanced lane-change intention prediction, the absence of real-time uncertainty quantification limits operational robustness. We propose a physics-informed uncertainty quantification framework that integrates seamlessly with prediction models, enabling reliable and interpretable lane-change assessment for autonomous vehicles. We present a framework that advances lane-change intention prediction by overcoming two long-standing challenges: bias from class imbalance in naturalistic data and dependence on precise maneuver labels. It does so through empirical probability distribution maps and a Scenario-Aware Dynamic Distribution Integration (SADI) method that adaptively captures temporal driving patterns while embedding vehicle physics. This physics-informed approach aligns uncertainty

estimates with plausible behavior, yielding reliable and interpretable predictions. Tests on the highD dataset show that, unlike traditional uncertainty quantification methods such as dropout or ensemble methods, our framework delivers real-time reliability scores that remain robust across diverse and evolving traffic scenarios. To validate generalizability across diverse traffic conditions, we further evaluate the framework on the AD4CHE dataset, demonstrating zero-shot transferability without hyperparameter retuning. By embedding vehicle physics into uncertainty estimation, our framework transforms lane-change prediction from brittle heuristics into reliable, real-time assessments that adapt to complex traffic dynamics. © 2026 The Author(s). A Positive-Unlabeled Learning Approach With Self-Correcting Regularized Risk

Item Type Journal Article

Author S. Saha

Author A. Hassan

Author J.H. Paik

Abstract The primary objective of positive unlabeled learning (PU learning) is to train a binary classifier with positively labeled data and unlabeled data. An inherent aspect of this approach involves incorporating the positive class prior of unlabeled data directly into the classification process, which is typically challenging in real-world scenarios. Moreover, existing studies often lack evaluations of PU classifiers without involving the positive class prior (true or estimated) of the unlabeled data, representing a significant research gap. In this article, we introduce a robust, two-step PU learning algorithm by incorporating a potential negative sampler in step 1 (warm start) and minimizing a self-correcting regularized risk function in step 2. The risk function possesses a self-correcting property that attempts to mitigate the weakness of the potential negative sampler in the warm start step. The risk function enables us to enhance robustness in the presence of mislabeled candidate negative samples. We demonstrate the effectiveness of our method on image as well as text benchmarks. Results show that the proposed method consistently outperforms the state-of-the-art (SOTA) PU learning algorithms. © 2020 IEEE.

A positive/unlabeled approach for the segmentation of medical sequences using point-wise supervision

Item Type Journal Article

Author L. Lejeune

Author R. Sznitman

Abstract The ability to quickly annotate medical imaging data plays a critical role in training deep learning frameworks for segmentation. Doing so for image volumes or video sequences is even more pressing as annotating these is particularly burdensome. To alleviate this problem, this work proposes a new method to efficiently segment medical imaging volumes or videos using point-wise annotations only. This allows annotations to be collected extremely quickly and remains applicable to numerous segmentation tasks. Our approach trains a deep learning model using an appropriate Positive/Unlabeled objective function using sparse point-wise annotations. While most methods of this kind assume that the proportion of positive samples in the data is known a-priori, we introduce a novel self-supervised method to estimate this prior efficiently by combining a Bayesian estimation framework and new stopping criteria. Our method iteratively estimates appropriate class priors and yields high segmentation quality for a variety of object types and imaging modalities. In addition, by leveraging a spatio-temporal tracking framework, we regularize our predictions by leveraging the complete data volume. We show experimentally that our approach outperforms state-of-the-art methods tailored to the same problem. © 2021

A practical study on the feasibility of alpha and gamma-tocopherol quantification for distinguishing Iberian pig feeding systems

Item Type Journal Article

Author A.I. Rey

Author D. Amazán

Author J. García-Casco

Abstract This study was undertaken to test the feasibility of using alpha and gamma-tocopherol quantification in fat and muscle to establish a correct classification of Iberian pigs according to their feeding background in practical situations. Samples were obtained over three different seasons from the four categories of pigs described in the Industry Quality Policy (FREE-OUT "bellota"; FREE-OUT-FEED "recebo"; FEEDOUT "campo"; and FEED-IN "cebo"). Linear discriminant functions were calculated with data obtained from seasons 1 and 2 and validated. The classification of fat and muscle samples from season 3 in the four feeding categories according to the calculated discriminant functions achieved an average of 76% success rate in distinguishing the true origin of pig samples. Quantification in muscle seemed to have higher prediction ability. Regression equations to quantify weight gained depending on the gamma-tocopherol concentration had higher R² values for muscle than for fat (R² = 0.81 vs. 0.62). Merging of the feeding categories established by the Quality Policy could raise the accuracy of the alpha and gamma-tocopherol quantification method to up to between 89% and 98%.

A preference learning framework for multiple criteria sorting with diverse additive value models and valued assignment examples

Item Type Journal Article

Author J. Liu

Author M. Kadziński

Author X. Liao

Author X. Mao

Author Y. Wang

Abstract We present a preference learning framework for multiple criteria sorting. We consider sorting procedures applying an additive value model with diverse types of marginal value functions (including linear, piecewise-linear, splined, and general monotone ones) under a unified analytical framework. Differently from the existing sorting methods that infer a preference model from crisp decision examples, where each reference alternative is assigned to a unique class, our framework allows considering valued assignment examples in which a reference alternative can be classified into multiple classes with respective credibility degrees. We propose an optimization model for constructing a preference model from such valued examples by maximizing the credible consistency among reference alternatives. To improve the predictive ability of the constructed model on new instances, we employ the regularization techniques. Moreover, to enhance the capability of addressing large-scale datasets, we introduce a state-of-the-art algorithm that is widely used in the machine learning community to solve the proposed optimization model in a computationally efficient way. Using the constructed additive value model, we determine both crisp and valued assignments for non-reference alternatives. Moreover, we allow the Decision Maker to prioritize the importance of classes and give the method a flexibility to adjust classification performance across classes according to the specified priorities. The practical usefulness of the analytical framework is demonstrated on a real-world dataset by comparing it to several existing sorting methods. © 2020 Elsevier B.V.

A preregistered, open pipeline for early cerebral palsy risk assessment from infant videos

Item Type Journal Article

Author M. Segado

Author L.A. Prosser

Author A.F. Duncan

Author M.J. Johnson

Author K.P. Kording

Abstract Cerebral palsy (CP), affecting approximately 1 in 500 children due to abnormal brain development, impacts movement control. Early risk assessment via the general movements assessment (GMA) at 3–4 months is highly predictive for CP but relies on trained clinicians. Machine-learning-based approaches for predicting GMA score from video have shown considerable promise, but typically rely on dataset-specific preprocessing, custom feature sets, and manually designed model pipelines, which make external benchmarking more difficult. This, combined with strict privacy constraints on sharing data, makes it challenging to train and evaluate models across

datasets, which is important for assessing clinical utility. There is therefore a need to develop approaches that will work across different datasets to enable multi-site dataset aggregation and model training. To address this gap, we developed an end-to-end pipeline that uses off-the-shelf pose estimation, general-purpose feature extraction, and automated machine learning—none of which are tuned to a specific dataset. We applied this approach to a newly generated large dataset of 1053 infants (with approximately 10–12% positive class for adverse GMA outcome, drawn from a high-risk clinical cohort) within a preregistered study design. Model performance was evaluated on a strict “lock-box” test set, which remained untouched during any phase of model development or preprocessing optimization, and only used for evaluation once the final model and pipeline had been preregistered. The developed model achieved moderate predictive accuracy for clinician-assessed GMA scores (area under the receiver operating characteristic curve, ROC-AUC = 0.77; area under the precision-recall curve, PR-AUC = 0.41). The moderate accuracy is noteworthy given the 10–12% positive class prevalence, and power-law scaling of ROC-AUC as a function of increasing dataset size. By releasing de-identified feature data and open-source code, and simplifying the training pipeline using AutoML, our work establishes essential groundwork for future robust, globally relevant CP screening tools suitable for low-resource settings. © The Author(s) 2026. Author E. Jenetzky

Abstract Introduction: The prevalence of rare diseases is very important for health care research. According to the European Surveillance of Congenital Anomalies (EUROCAT) registers, the live prevalence for exstrophy and/or epispadias (grades 1–3) is reported with 1:23,255 (95% CI: 1:26,316; 1:20,000). A Europe-wide prevalence evaluation based on reports from excellence centers estimates a prevalence for exstrophies of 1:32,200 and for isolated epispadias of 1:96,800 in 2010. However, the frequency of exstrophy [International Statistical Classification of Diseases and Related Health Problems revision 10 (ICD-10): Q64.1] and epispadias (ICD-10: Q64.0) treated in different age groups in Germany remains unclear. Material and Method: Public health insurance data from 71 million people (approximately 87% of the population) were provided by the German Institute for Medical Documentation and Information (DIMDI) in accordance to the German Social Insurance Code for this research purpose. DIMDI analyzed the data source for the ICD diagnoses exstrophy and epispadias between 2009 and 2011. As provided data were robust over the years, averaged data are mentioned. Detailed subgroup analysis of small numbers was forbidden due to privacy protection. Results: Annually, 126 persons of all ages with epispadias and 244 with exstrophy are treated as inpatients. In the observed population, 34 infants (<1 year of age) with epispadias and 19 with exstrophy (58% male) are treated as outpatients each year. This corresponds to an estimated live prevalence of 1:11,000 (95% CI: 1:14,700; 1:8,400) for EEC (exstrophy–epispadias complex), more specifically a prevalence of 1:17,142 for epispadias and of 1:30,675 for exstrophy. The male-to-female ratio for exstrophy is 1.4:1 for infants and 1.6:1 for all minors. In children and adolescents, 349 epispadias and 393 exstrophies (up to the age of 17) are treated annually, whereas adults with exstrophy and even more with epispadias make comparatively less use of medical care. Conclusion: With the help of DIMDI data, the live prevalence of bladder exstrophy and epispadias in Germany could be estimated. The prevalence of epispadias was higher than in previous reports, in which milder epispadias phenotypes (grade 1 or 2) may not have been included. These analyses might enlighten knowledge about nationwide incidence and treatment numbers of rare diseases such as the EEC. Copyright © 2021 Ebert, Zwink, Reutter and Jenetzky.

A Property of the CHAID Partitioning Method for Dichotomous Randomized Response Data and Categorical Predictors

Item Type Journal Article

Author P.F. Perri

Author P.G.M. van der Heijden

Abstract In this paper, we present empirical and theoretical results on classification trees for randomized response data. We considered a dichotomous sensitive response variable with the true status intentionally misclassified by the respondents using rules prescribed by a randomized response method. We assumed that classification trees are grown using the Pearson chi-square test as a splitting criterion, and that the randomized response data are analyzed using classification trees as if they were not perturbed. We proved that classification trees analyzing observed randomized response data and estimated true data have a one-to-one correspondence in terms of ranking the splitting variables. This is illustrated using two real data sets. © 2011 Springer Science+Business Media, LLC.

Abstract There are no strategies to predict a patient's response to therapy. In a previous report, we classified Japanese patients into four groups according to the incidence of HLA antigens, by using quantification method III. In that study, we examined the patients' incidence of HLA antigens before surgery and evaluated their outcome according to the HLA classification by quantification method III. The aim of the present study is to evaluate whether HLA classification should be used in the treatment of individual

cancer patients. A consecutive series of 76 Japanese patients who had undergone gastrectomy between July 1998 and January 2000 was evaluated to compare the patients HLA classifications, derived from quantification method III, with their prognoses following gastrectomy. Retrospective analysis of 193 gastric cancer patients revealed that HLA type I, type II, and type IV patients who had received postoperative adjuvant chemotherapy concomitant with PSK survived longer than those who had received postoperative adjuvant chemotherapy, whereas HLA type III patients who had received postoperative adjuvant chemotherapy showed significantly longer survival than those with chemotherapy + PSK. Following these results, we started a prospective study; we treated patients with HLA type I, type II, and type IV for postoperative chemotherapy + PSK, and those with HLA type III for postoperative chemotherapy following gastrectomy. The prospective study showed that patients who had been examined for HLA antigens showed significantly longer survival than those who had not been examined for HLA antigens. From the results of our retrospective and prospective studies, it can be inferred that it is necessary to examine gastric cancer patients for HLA antigens, and that HLA-oriented therapy is a very promising strategy for cancer treatment. We are planning to conduct an important study with control subjects. © 2000, The Japanese Society of Strategies for Cancer Research and Therapy. All rights reserved.

Author T. Williams

Abstract Alphabaculoviruses are lethal dsDNA viruses of Lepidoptera that have high genetic diversity and are transmitted in aggregates within proteinaceous occlusion bodies. This mode of transmission has implications for their efficacy as biological insecticides. A Nicaraguan isolate of *Spodoptera frugiperda* multiple nucleopolyhedrovirus (SfMNPV-NIC) comprising nine genotypic variants has been the subject of considerable study due to the influence of variant interactions on the insecticidal properties of mixed-variant occlusion bodies. As part of a systematic study on the replication and transmission of variant mixtures, a tool for the accurate quantification of a selection of genotypic variants was developed based on the quantitative PCR technique (qPCR). First, primer pairs were designed around a region of high variability in four variants named SfNic-A, SfNic-B, SfNic-C and SfNic-E to produce amplicons of 103–150 bp. Then, using cloned purified amplicons as standards, amplification was demonstrated over a dynamic range of 108–10¹ copies of each target. The assay was efficient (mean $\pm$ SD: 98.5 $\pm$ 0.8%), reproducible, as shown by low inter- and intra-assay coefficients of variation (<5%), and specific to the target variants (99.7–100% specificity across variants). The quantification method was validated on mixtures of genotype-specific amplicons and demonstrated accurate quantification. Finally, mixtures of the four variants were quantified based on mixtures of budded virions and mixtures of DNA extracted from occlusion-derived virions. In both cases, mixed-variant preparations compared favorably to total viral genome numbers by quantification of the polyhedrin (polh) gene that is present in all variants. This technique should prove invaluable in elucidating the influence of variant diversity on the transmission and insecticidal characteristics of this pathogen. © 2024 by the authors.

A Quantification Method for Environmental Exposure Based on Computer Image Processing Technology and Its Applications

Item Type Conference Paper**Author** R. Zheng**Editor** Trajkovic L.**Editor** Agaian S.S.**Editor** Avola D.**Editor** He J.

Abstract With the advancement of computer image recognition technology, traditional exposure measurement methods urgently need improvements in effectiveness and measurement accuracy. This study employs a method based on image processing and computer vision technology, combined with a wearable device aiming to measure individual exposure to geographic environments. A spatiotemporal weighting algorithm was applied to dynamically adjust exposure data, and comparisons with traditional methods were conducted for validation. Experimental results demonstrate that the proposed method can accurately measure exposure across different environments, particularly achieving higher classification accuracy in natural and built environments. Compared with traditional questionnaire-based approaches and geographic information system methods, the proposed method exhibits significant advantages in real-time assessment, accuracy, and detail capture of exposure. In natural environments, the study revealed significantly higher exposure levels to green vegetation and water bodies compared to urban roads. In cultural environments, commercial areas showed higher exposure levels, reflecting the influence of population density and social activities. Additionally, the stability and applicability of the method in real-world scenarios were validated, consistently providing reliable measurement results across different geographical regions and environmental conditions. This study empirically demonstrates an innovative application of computer vision technology, with significant prospects for public health applications. It advances the value of big data in interdisciplinary research. © 2025 IOS Press.

A quantitative study of geometric characteristics of urban space based on the correlation with microclimate

Item Type Journal Article**Author** H. Ji**Author** Y. Peng**Author** W. Ding

Abstract With the sustainability of contemporary cities gaining more and more attention, interest in the correlation between urban geometry and urban microclimate is increasing. On this basis, this paper aims to investigate the quantification of geometric characteristics of urban space. Based on a combination of easily accessible software packages, a quantitative method composed of spatial partition, spatial characteristic indices (area, shape, and openness), and a spatial classification chart is proposed for the study of the correlation between urban spatial geometry and urban microclimate. Two blocks with different spatial geometric characteristics of the Xinjiekou central area in Nanjing are selected as the cases to verify the operability and effectiveness of this method. The results reveal that complex real urban space can be quantitatively described and classified by this spatial quantification method. In addition, a possible correlation between urban spatial geometry and urban wind environment is demonstrated by using the method, which may also be applicable to the correlation study between urban spatial geometry and other environmental issues.

A RAIR–ATC transcriptional axis and multimodal drug-response modelling reveal class-level vulnerabilities in thyroid cancer

Abstract Introduction – Radioiodine-refractory papillary thyroid carcinoma (RAIR PTC) and anaplastic thyroid carcinoma (ATC) are clinically challenging thyroid cancer states, yet the molecular continuum between radioiodine refractoriness, anaplastic transformation and targeted drug sensitivity remains unclear. We hypothesised that

RAIR and ATC share a common transcriptional axis that can be distilled into a transferable signature to prioritise targeted therapies in RAIR-like models. **Methods** – We integrated RNA-seq and microarray cohorts (TCGA-THCA, one RAIR vs. radioiodine-avid PTC cohort, and five ATC cohorts) to derive RAIR/ATC gene modules and annotate pathway activity (MSigDB Hallmark). A single-sample RAIR signature was applied to TCGA tumours and DepMap thyroid cell lines. We combined RAIR scores with PRISM drug-response AUC data (18 thyroid cell lines) to quantify differential sensitivity (Δ AUC) and trained an interpretable multimodal ridge model integrating cell and drug features to predict AUC. External transferability and pharmacology-oriented mechanisms were assessed in an independent thyroid RNA-seq cohort (GSE126698) using ssGSEA and mechanism-relevant pathways. **Results** – RAIR and ATC upregulated modules converged on an EMT–angiogenesis–inflammatory/interferon axis, with ATC representing a more extreme state. The RAIR signature stratified TCGA tumours with graded activation of these programs and was largely independent of BRAF and TERT promoter status, while preserving pathway associations when transferred to DepMap. In PRISM, VEGFR/KDR and RAF/BRAF inhibitor classes showed the most negative class-averaged Δ AUC values, indicating preferential activity in RAIR-high thyroid lines. The multimodal ridge model improved AUC prediction over cell-only or drug-only baselines and was concordant with class-level sensitivity patterns. In GSE126698, RAIR scores retained robust associations with hypoxia and interferon/inflammatory programs and aligned with drug-mechanism pathways including KRAS signaling up and PI3K–AKT–mTOR signaling. Initial in vitro validation in a single RAIR-high/ATC-like thyroid cancer model provided proof-of-concept support for these predictions, with sorafenib showing dose-dependent cytotoxicity and suppression of RAF–MAPK signalling. **Conclusion** – A module-based RAIR signature captures a disease-focused component of a broader RAIR–ATC axis, transfers to cell-line models and can be embedded into an interpretable multimodal framework for drug-response prediction and targeted drug-class prioritisation, prioritising VEGFR/KDR and RAF/BRAF inhibitor classes as candidates for further translational evaluation in RAIR-like thyroid models. Abstract A highly specific and sensitive proton nuclear magnetic resonance (¹H-NMR) method has been developed for the quantification of ephedrine alkaloid derivatives in Ephedra herbal commercial prescriptions. At the region of δ 4.0 to 5.0 ppm in the ¹H NMR spectrum, the characteristic signals are separated well from each other, and six analogues in total, methylephedrine (ME), ephedrine (EP), norephedrine (NE), norpseudoephedrine (NP), pseudoephedrine (PE), and methylpseudoephedrine (MP) could be identified. The quantities of these compounds are calculated by the relative ratio of the integral values of the target peak for each compound to the known concentrations of the internal standard anthracene. The present method allows for a

rapid and simple quantification of ephedrine alkaloid derivatives in Ephedra-related commercial prescriptions without any preliminary purification steps and standard compounds, and accordingly it can be a powerful tool to verify different Ephedra species. In comparison to conventional chromatographic methods, the advantages of this method include the fact that no standard compounds are required, the quantification can be directly performed on the crude extracts, a better selectivity for various ephedrine alkaloid derivatives, and the fact that a very significant time-gain may be achieved. © 2021 by the authors. A Rapid, Accurate and Machine-Agnostic Segmentation and Quantification Method for CT-Based COVID-19 Diagnosis

Item Type Journal Article**Author** L. Zhou**Author** Z. Li**Author** J. Zhou**Author** H. Li**Author** Y. Chen**Author** Y. Huang**Author** D. Xie**Author** L. Zhao**Author** M. Fan**Author** S. Hashmi**Author** F. Abdelkareem**Author** R. Eiada**Author** X. Xiao**Author** L. Li**Author** Z. Qiu**Author** X. Gao

Abstract COVID-19 has caused a global pandemic and become the most urgent threat to the entire world. Tremendous efforts and resources have been invested in developing diagnosis, prognosis and treatment strategies to combat the disease. Although nucleic acid detection has been mainly used as the gold standard to confirm this RNA virus-based disease, it has been shown that such a strategy has a high false negative rate, especially for patients in the early stage, and thus CT imaging has been applied as a major diagnostic modality in confirming positive COVID-19. Despite the various, urgent advances in developing artificial intelligence (AI)-based computer-aided systems for CT-based COVID-19 diagnosis, most of the existing methods can only perform classification, whereas the state-of-the-art segmentation method requires a high level of human intervention. In this paper, we propose a fully-automatic, rapid, accurate, and machine-agnostic method that can segment and quantify the infection regions on CT scans from different sources. Our method is founded upon two innovations: 1) the first CT scan simulator for COVID-19, by fitting the dynamic change of real patients' data measured at different time points, which greatly alleviates the data scarcity issue; and 2) a novel deep learning algorithm to solve the large-scene-small-object problem, which decomposes the 3D segmentation problem into three 2D ones, and thus reduces the model complexity by an order of magnitude and, at the same time, significantly improves the segmentation accuracy. Comprehensive experimental results over multi-country, multi-hospital, and multi-machine datasets demonstrate the superior performance of our method over the existing ones and suggest its important application value in combating the disease. © 1982-2012 IEEE.

Abstract Emerging infectious diseases may become serious threats to wildlife, a prominent example being the white-nose disease (WND). In case of WND, the cold-loving fungus *Pseudogymnoascus destructans* colonizes bats during hibernation, invades the skin and has already lead to the death of millions of bats in North America. *P. destructans* most likely originated from Europe, where it also causes lesions but without associated mortalities. However, it is still unclear how European bats cope with the fungus. Hence, it is important to have tools that precisely characterise disease progression. Because hibernation is a physiological state during which bats are vulnerable to disturbance, in-situ assessments of the clinical status should be carried out minimal-invasively to avoid detrimental impacts on bats. However, currently available disease assessment methods require handling/touching bats and are therefore invasive: i) UV-light trans-illumination of wing membranes to detect lesions and ii) a qPCR-based quantification of fungal material from wing membrane swabs. Since *P. destructans* (‘Pd’) becomes visible on all furless skin with distinct distribution patterns, we investigated the use of visible symptoms to assess levels of infections without handling/touching bats. We introduce a technique which we termed ‘Visual Pd-score’ (a visual classification scheme), which can be applied without disturbing the animals. To assess its reliability, we used *P. destructans* infected greater mouse-eared bats (*Myotis myotis*) to compare the novel method with the two existing golden-standard techniques. Our results show that infection levels obtained from all three techniques are correlated. Importantly, the information carried by the Visual Pd-score is most similar to a composite index combining the information from the qPCR-based and UV-light quantification methods. We conclude that the Visual Pd-score represents a promising index to better characterise disease severity as it is simultaneously representative for fungal colonization and wing damage. We discuss advantages and disadvantages of the applied techniques and conclude that the Visual Pd-score is particularly useful for routine hibernacula counts or large-scale *P. destructans*-surveillance. In combination with the lesion detection technique the new method is also applicable to immunological studies where both fungal colonization and associated damage have to be investigated, while qPCRs from swabs of all body parts are especially useful if it is necessary to detect cryptic infections, e.g. during the early hibernation period. © 2021 Museum and Institute of Zoology PAS. Abstract Quantification is a supervised learning task that consists in predicting, given a set of classes C and a set D of unlabelled items, the prevalence (or relative frequency) $p_c(D)$ of each class $c \in C$ in D . Quantification can in principle be solved by classifying all the unlabelled items and counting how many of them have been attributed to each class. However, this classify and count approach has been shown to yield suboptimal quantification accuracy; this has established quantification as a task of its own, and given rise to a number of methods specifically devised for it. We propose a recurrent neural network architecture for quantification (that we call QuaNet) that observes the classification predictions to learn higher-order quantification embeddings, which are then refined by incorporating quantification predictions of simple classify-and-count-like methods. We test QuaNet on sentiment quantification on text, showing that it substantially outperforms several state-of-the-art baselines. © 2018 Copyright

Abstract Arbiter Physical Unclonable Functions (APUFs), widely used strong PUFs, are highly sensitive to environmental noise, yet the quantitative link between noise and reliability remains unclear. This paper introduces a Reliability-Noise-Delay (RND) quantification method grounded in statistical analysis of the APUF delay model. By modeling noise, we uncover CRP instability patterns under varying noise levels and derive a closed-form relationship between reliability and noise. Leveraging RND, the delay difference between last-stage paths is calculated without extra hardware by using environmental noise measurements and CRP reliability. We develop an efficient n-stages APUF modeling approach requiring only n+1 CRPs with known reliability, significantly reducing computational complexity and resource demands compared to conventional machine-learning techniques. Furthermore, we propose a screening strategy to identify high- and low-reliability CRPs: at a noise level of 0.15, low-reliability CRP reliability drops from 75 % (random) to 57 %, while high-reliability CRPs reach 99 %. Our method offers an effective tool for APUF modeling and optimization in noisy environments. © 2025 Elsevier Ltd

Abstract Precipitation Use Efficiency (PUE) is a key ecological indicator for evaluating how vegetation converts precipitation into biomass or productivity. A thorough analysis of its quantification methods and driving mechanisms is of great significance for improving regional precipitation use efficiency and ensuring agricultural and ecological water security. In this study, we conducted a comprehensive literature search without time restrictions in the Web of Science and China National Knowledge Infrastructure (CNKI) databases, using “Precipitation Use Efficiency” and “PUE” as core keywords. After retrieval, a strict “independent dual-screening plus cross-checking” procedure was adopted with unified inclusion and exclusion criteria to ensure literature quality. Only highly relevant and methodologically rigorous studies were retained, resulting in a final set of 80 eligible publications. Key information was systematically extracted using content analysis, followed by integrated summarization and inductive analysis. This paper systematically illustrates the ecological connotation of PUE, compares diverse quantification and research methods with their applicable conditions, analyzes spatiotemporal differentiation characteristics and multidimensional driving mechanisms, summarizes practical approaches for PUE improvement, and reviews current research limitations. It represents a systematic integration and refinement of the research framework of precipitation use efficiency. The results can provide targeted theoretical support for revealing the driving mechanisms of PUE and promoting the efficient utilization of precipitation resources. © 2026 by the authors.

A review of quantification methodologies for multi-hazard interrelationships

Item Type Journal Article

Author A. Tilloy

Author B.D. Malamud

Author H. Winter

Author A. Joly-Laugel

Abstract Globally and yearly, individual hazards and hazard interrelations have the potential to result in socio-economic losses. Here, in this critical review, we use grey- and peer-review literature to identify and compare current research available for the quantification of hazard interrelations, focussing on 14 different natural hazards. We first provide a historical context for quantitative single hazard and multi-hazard assessment. We then construct a literature database with 146 references related to multi-hazard interrelations. We use our literature database to identify trends for hazard interrelation and multi-hazard and from these group hazard interrelations into five types: triggering, change condition, compound, independence and mutually exclusive. Our critical review identifies 19 different modelling methods to quantify natural hazard interrelationships which we cluster into three broad modelling approaches: stochastic, empirical, and mechanistic. We then synthesize results of our classification of quantification methods for hazard interrelationships and using two matrices illustrate this in practice for 24 different interrelations between 14 natural hazards, one for cascading hazards (temporal order in the multi-hazard event) and one for compound hazards (two or more hazards acting together). Finally, we provide examples of applications for each the three quantitative modelling approaches defined. We believe that this review will lead to a better understanding of quantification methodologies for hazard interrelations between different sub-disciplines that focus on natural hazards, thus aiding cross-disciplinary approaches for better understanding potential risk related to multi-hazard events. © 2019 The Authors

A Review of Super-Resolution Single-Molecule Localization Microscopy Cluster Analysis and Quantification Methods

Item Type Journal Article

Author I.M. Khater

Author I.R. Nabi

Author G. Hamarneh

Abstract Single-molecule localization microscopy (SMLM) is a relatively new imaging modality, winning the 2014 Nobel Prize in Chemistry, and considered as one of the key super-resolution techniques. SMLM resolution goes beyond the diffraction limit of light microscopy and achieves resolution on the order of 10–20 nm. SMLM thus enables imaging single molecules and study of the low-level molecular interactions at the subcellular level. In contrast to standard microscopy imaging that produces 2D pixel or 3D voxel grid data, SMLM generates big data of 2D or 3D point clouds with millions of localizations and associated uncertainties. This unprecedented breakthrough in imaging helps researchers employ SMLM in many fields within biology and medicine, such as studying cancerous cells and cell-mediated immunity and accelerating drug discovery. However, SMLM data quantification and interpretation methods have yet to keep pace with the rapid advancement of SMLM imaging. Researchers have been actively exploring new computational methods for SMLM data analysis to extract biosignatures of various biological structures and functions. In this survey, we describe the state-of-the-art clustering methods adopted to analyze and quantify SMLM data and examine the capabilities and shortcomings of the surveyed methods. We classify the methods according to (1) the biological application (i.e., the imaged molecules/structures), (2) the data acquisition (such as imaging modality, dimension, resolution, and number of localizations), and (3) the analysis details (2D versus 3D, field of view versus region of interest, use of

machine-learning and multi-scale analysis, biosignature extraction, etc.). We observe that the majority of methods that are based on second-order statistics are sensitive to noise and imaging artifacts, have not been applied to 3D data, do not leverage machine-learning formulations, and are not scalable for big-data analysis. Finally, we summarize state-of-the-art methodology, discuss some key open challenges, and identify future opportunities for better modeling and design of an integrated computational pipeline to address the key challenges. Recent developments in super-resolution SMLM imaging techniques enable researchers to study macromolecular structures at the nanometer scale. However, SMLM data quantification and interpretation methods have yet to keep pace with the rapid advancement of SMLM imaging. This article provides a balanced and comprehensive review of state-of-the-art SMLM image analysis methods and ties disparate approaches together in a cohesive manner. Researchers are actively exploring new computational methods to analyze SMLM data, including recent approaches to use data-driven and machine-learning approaches. However, the validation of the SMLM clustering methods remains an open challenge. Potential future directions using multi-modality imaging (e.g., SMLM and electron microscopy) might help validate quantitative SMLM image analysis methods. Super-resolution single-molecule localization microscopy (SMLM) enables localization of components of macromolecular complexes at the nanometer scale. However, determining a complex structure from SMLM data-clustering analysis faces challenges of imaging artifacts, big data, 2D versus 3D data, and so forth. In this Review, we provide a holistic overview of state-of-the-art computational methods leveraged to quantify SMLM data. We classify the methods and list their pros and cons to help the researcher optimally consider the most appropriate quantification method. Finally, we show how the field is growing and draw conclusions about the applicability of data-driven approaches as well as methods validation and benchmarking. © 2020 The Author(s)

Abstract Uncertainty quantification (UQ) methods play a pivotal role in reducing the impact of uncertainties during both optimization and decision making processes. They have been applied to solve a variety of real-world problems in science and engineering. Bayesian approximation and ensemble learning techniques are two widely-used types of uncertainty quantification (UQ) methods. In this regard, researchers have proposed different UQ methods and examined their performance in a variety of applications

such as computer vision (e.g., self-driving cars and object detection), image processing (e.g., image restoration), medical image analysis (e.g., medical image classification and segmentation), natural language processing (e.g., text classification, social media texts and recidivism risk-scoring), bioinformatics, etc. This study reviews recent advances in UQ methods used in deep learning, investigates the application of these methods in reinforcement learning, and highlights fundamental research challenges and directions associated with UQ. © 2021 The Authors

A review of uncertainty quantification in medical image analysis: Probabilistic and non-probabilistic methods

Item Type Journal Article

Author L. Huang

Author S. Ruan

Author Y. Xing

Author M. Feng

Abstract The comprehensive integration of machine learning healthcare models within clinical practice remains suboptimal, notwithstanding the proliferation of high-performing solutions reported in the literature. A predominant factor hindering widespread adoption pertains to an insufficiency of evidence affirming the reliability of the aforementioned models. Recently, uncertainty quantification methods have been proposed as a potential solution to quantify the reliability of machine learning models and thus increase the interpretability and acceptability of the results. In this review, we offer a comprehensive overview of the prevailing methods proposed to quantify the uncertainty inherent in machine learning models developed for various medical image tasks. Contrary to earlier reviews that exclusively focused on probabilistic methods, this review also explores non-probabilistic approaches, thereby furnishing a more holistic survey of research pertaining to uncertainty quantification for machine learning models. Analysis of medical images with the summary and discussion on medical applications and the corresponding uncertainty evaluation protocols are presented, which focus on the specific challenges of uncertainty in medical image analysis. We also highlight some potential future research work at the end. Generally, this review aims to allow researchers from both clinical and technical backgrounds to gain a quick and yet in-depth understanding of the research in uncertainty quantification for medical image analysis machine learning models. © 2024 The Authors

A review on rice plant phenotyping traits estimation for disease and growth management using modern ML techniques

Item Type Journal Article**Author** B. Patel**Author** A. Sharaff

Abstract Over the past decades, rice crops have been crucially acknowledged as one of the most powerful energy streams for the production of resources. Plant phenotyping trait estimation includes the external feature evaluation of the plants for production growth. Phenotyping using machine learning techniques outperforms the other imaging techniques for the analysis of traits including leaf, seed, branch, panicle, flower root, shoot, etc. Rice plants, categorized by multiple traits such as growth analysis and disease management, are considered a contributing factor to the agricultural, economic, and communal losses in the upcoming development of the agricultural field. The last 15 years' diagnosis of plant disease in relation to image processing techniques has remained an area of interest among researchers. Several disease detections, identification, and quantification methods have been developed and applied to a wide variety of crops. This paper reviews the related research papers from the period between 2007 and 2023, with a focus on the development of the state of the art. The related studies are compared based on image segmentation, feature extraction, feature selection, and classification. This paper also outlines the current achievements, limitations, and suggestions for future research associated with the diagnosis of rice plant growth analysis and disease identification using machine learning techniques. © The Author(s), under exclusive licence to Springer Science+Business Media, LLC, part of Springer Nature 2023.

A review on quantification learning

Item Type Journal Article**Author** P. González**Author** A. Castaño**Author** N.V. Chawla**Author** J.J. Del Coz

Abstract The task of quantification consists in providing an aggregate estimation (e.g., the class distribution in a classification problem) for unseen test sets, applying a model that is trained using a training set with a different data distribution. Several real-world applications demand this kind of method that does not require predictions for individual examples and just focuses on obtaining accurate estimates at an aggregate level. During the past few years, several quantification methods have been proposed from different perspectives and with different goals. This article presents a unified review of the main approaches with the aim of serving as an introductory tutorial for newcomers in the field. © 2017 ACM.

A risk-based comparison of classification systems

Item Type Conference Paper

Author S. Thorsen

Author S. Wagenman

Author M.E. Oxley

Author K.W. Bauer

Abstract Performance measures for families of classification system families that rely upon the analysis of receiver operating characteristics (ROCs), such as area under the ROC curve (AUC), often fail to fully address the issue of risk, especially for classification systems involving more than two classes. For the general case, we denote matrices of class prevalence, costs, and class-conditional probabilities, and assume costs are subjectively fixed, acceptable estimates for expected values of class-conditional probabilities exist, and mutual independence between a variable in one such matrix and those of any other matrix. The ROC Risk Functional (RRF), valid for any finite number of classes, has an associated parameter argument, which specifies a member of a family of classification systems, and for which there is an associated classification system minimizing Bayes risk over the family. We typify joint distributions for class prevalences over standard simplices by means of uniform and beta distributions, and create a family of classification systems using actual data, testing independence assumptions under two such class prevalence distributions. Examples are given where the risk is minimized under two different sets of costs. © 2009 SPIE.

A Robotic-Based Framework for Quantifying Surface Cracks of Concrete Shear Walls

Item Type Conference Paper**Author** P. Bazrafshan**Author** A. Ebrahimkhanlou**Editor** Farhangdoust S.**Editor** Guemes A.**Editor** Chang F.-K.

Abstract The inherently subjective and manual nature of current structural assessment procedures undermines the reliability of such practices. As a result, researchers are using artificial intelligence and robots to encourage autonomy and create methods that are more objective and less biased. Robots are equipped with cameras and sensors to collect information about the structure, such as images of the crack patterns of concrete structures. In this paper, a robotic framework is proposed to utilize the collected images of reinforced concrete shear walls (RCSWs) with crack patterns, and then those images are used to quantify the level of damage. Crack pattern images are from the load steps of a quasi-static test on an RCSW. To quantify the extent of damage, crack patterns are first converted to a mathematical representation, a graph. Next, a machine learning algorithm is trained to predict the energy dissipated during each load cycle based on the graphs. Results reveal that the presented graph-based damage quantification method is able to quantify the level of structural damage. High R2 scores of the machine learning regression (above 0.98) attest to the success of the

proposed robotic-based framework. © 2023 by DEStech Publications, Inc. All rights reserved

A robust and interpretable machine learning approach using multimodal biological data to predict future pathological tau accumulation

Item Type Journal Article

Abstract The early stages of Alzheimer's disease (AD) involve interactions between multiple pathophysiological processes. Although these processes are well studied, we still lack robust tools to predict individualised trajectories of disease progression. Here, we employ a robust and interpretable machine learning approach to combine multimodal biological data and predict future pathological tau accumulation. In particular, we use machine learning to quantify interactions between key pathological markers (β -amyloid, medial temporal lobe atrophy, tau and APOE 4) at mildly impaired and asymptomatic stages of AD. Using baseline non-tau markers we derive a prognostic index that: (a) stratifies patients based on future pathological tau accumulation, (b) predicts individualised regional future rate of tau accumulation, and (c) translates predictions from deep phenotyping patient cohorts to cognitively normal individuals. Our results propose a robust approach for fine scale stratification and prognostication with translation impact for clinical trial design targeting the earliest stages of AD. © 2022, The Author(s).

Abstract Ensuring the quality of datasets containing electroencephalography signals remains challenging due to heterogeneous acquisition protocols, diverse preprocessing practices, and inconsistent annotation standards. Existing toolboxes mainly focus on signal cleaning and pipeline checks, while generic data quality frameworks lack domain specificity and do not provide an interpretable dataset-level score for electroencephalography datasets used in tasks such as affect recognition and event-related paradigms. This work introduces a platform for dataset-level quality assessment of electroencephalography collections tailored to these downstream tasks. The platform computes a set of indicators that capture session completeness, consistency of session length, class balance, annotation timing, signal-to-noise ratio, outlier prevalence, feature information content, and class separability. It then combines these indicators into a normalized global Quality Score ranging from 0 to 100. The aggregation relies on order-preserving mappings and subject-wise summarization to enable robust comparisons across datasets and to prevent longer recordings from dominating the score. The evaluation uses six public datasets from affect recognition, event-related paradigm and motor imagery, all processed under identical protocols. Classification performance is reported using Balanced Accuracy and Area Under the ROC Curve. The global score reflects differences in data integrity, temporal consistency, and separability while remaining interpretable across heterogeneous collections. In addition, correlation analyses indicate positive associations between separability-oriented indicators and downstream performance, and negative associations with a higher prevalence of outliers. Targeted training adjustments guided by these indicators, including the removal of highly contaminated windows and loss reweighting based on class priors, consistently improve

performance. Implementation and configuration files are publicly available to support reproducibility and adoption. © 2013 IEEE.

A seismic risk classification framework for non-structural elements

Item Type Journal Article

Author G.J. O'Reilly

Author G.M. Calvi

Abstract The ability to quantify the seismic risk associated with structural and non-structural elements is a critical aspect of earthquake engineering. While methods to improve the understanding of structural response to earthquake shaking and how to quantify their risk have been studied, non-structural elements (NSEs) have more recently emerged as a crucial aspect to address given their pertinence in overall building performance and loss-related issues. This article describes the development of a risk quantification methodology for NSEs whereby the mean annual frequency of exceeding an NSE's

damage state is computed and rated as part of a risk classification scheme using recently developed approaches. The basis of the methodology is described in detail followed by an example implementation, where the details surrounding hazard, structural and non-structural response are quantified consistently, ensuring that uncertainties are also incorporated to be in line with modern performance-based earthquake engineering. Discussion is provided surrounding the potential future use of such an NSE risk classification scheme for both structural engineers looking to improve the performance of their buildings via NSE performance and also manufacturers. © 2021, The Author(s), under exclusive licence to Springer Nature B.V.

Abstract Marine Protected Areas (MPA) increasingly rely on automatic identification system (AIS) data to monitor fishing activity. Enforcement remains difficult because AIS is self-reported, labels of fishing behaviour are scarce, and traffic patterns differ strongly between regions. This study develops a hierarchical machine learning framework that estimates the probability of fishing from AIS position time series using only latitude and longitude. First, a self-supervised temporal encoder is trained on millions of unlabeled AIS messages to learn motion embeddings that summarize 75-minute vessel trajectories. Supervised classifiers are then trained on these embeddings to predict fishing vessel type, active fishing behaviour, and fishing gear type. Finally, a label-shift calibration step combines these outputs with operational assumptions about local vessel composition, fishing activity levels, and gear usage. This step adapts the globally trained models to the specific conditions of the St. Anns Bank MPA to produce locally calibrated fishing probabilities. On held-out data, the vessel-type and behaviour classifiers achieve areas under the receiver operating characteristic curve of 0.91 and 0.94, and average precision scores of 0.86 and 0.88, respectively, while the gear classifier obtained moderate overall performance, performing best for common gears. When applied to two years of AIS data from St. Anns Bank, the framework successfully highlights a sparse set of trajectories, allowing for more focused inspection. These results show that self-supervised motion embeddings, combined with probabilistic fusion and operational calibration, offer a label-efficient and adaptable approach to AIS-based monitoring in marine protected areas. A Semi-Supervised Transfer Approach Based on Pairwise Learning for Tensile Strength Prediction of Hot-Rolled Cord Steel

Item Type Journal Article**Author** Z. Zhang**Author** Z. Lv**Author** F. He**Author** Y. Zhou

Abstract The tensile strength prediction of cord steel is critically importance for ensuring product quality and mitigating failure risks; however, the scarcity of labeled data, particularly for customized steel grades, presents a significant challenge. To address this challenge, a multi-source dataset is introduced, comprising labeled data from source steel grades and unlabeled data from target steel grades, to improve predictive accuracy. Accordingly, a Semi-Supervised Transfer Learning approach based on Pairwise Deviation Regression Network, termed PDRN-SSTL, is proposed. First, the Pairwise Deviation Regression Network reformulates regression as learning label deviations between sample pairs, thereby alleviating cross-domain label shift and capturing relative sample relationships. Second, an unsupervised domain adaptation strategy is employed to construct a pre-trained model that extracts common features while reducing distributional discrepancies between source and target domains. Subsequently, the shallow-layer parameters are frozen, and the model is fine-tuned using limited labeled target-domain data together with a consistency constraint on unlabeled data, thereby further improving the predictive accuracy. Experiments on two customized steel grades, SWRH72A-C and SWRH72A-D, demonstrate the superiority of the proposed method, achieving MAPE values of 1.369% and 1.447%, and 3% Relative Error Hit Rate of 94.23% and 88.24%, respectively. Comparative and ablation studies further confirm its effectiveness. © 2026 Wiley-VCH GmbH.

Author P. Chophuk

Abstract The increasing volume of municipal solid waste has created a demand for reliable waste- sorting systems with a low-cost sensing configuration. However, the RGB and RGB-depth (RGB-D) vision methods remain sensitive to illumination variation, occlusion, deformation, and visual similarity between recyclable materials, such as transparent plastic and glass. This study addresses these issues by presenting a sensing-to-sorting multimodal robotic waste-sorting pipeline integrating RGB-D vision, low-cost AS7265x visible–near-infrared spectral sensing, adaptive Bayesian fusion, and robotic pick-and-place execution. The vision module uses YOLOv8s instance segmentation for detection and localization, whereas the spectral module uses CatBoost to classify the 18-channel reflectance signatures. The fusion strategy combines vision and spectral probabilities using confidence-aware weighting, contact validation, uncertainty indicators, cross-modal agreement, class priors, and confusion-matrix likelihoods. The experiments used 2,000 RGB images with 24,848 annotated instances and 1,000 spectral samples across four classes: glass, metal, paper, and plastic. YOLOv8s achieved 0.960 mAP50 and 0.819 mAP50–95, whereas CatBoost achieved 73.0% accuracy. Real-world validation using a 600-object evaluation set tested under three lighting conditions showed that the proposed method achieved an accuracy and macro-F1 scores of 0.831 ± 0.023 and 0.829 ± 0.024 , respectively, improving the average accuracy by approximately 10.9 and 11.8

percentage points over the vision- and spectral-only approaches, respectively. These results demonstrate improved robotic recyclable waste classification under practical lighting conditions with stable performance across lighting levels, thereby indicating the potential of the proposed system for small- and medium-scale recycling applications under laboratory conveyor-belt conditions. © 2013 IEEE.

A Simple Method for Classifier Accuracy Prediction Under Prior Probability Shift

Item Type Conference Paper

Author L. Volpi

Author A. Moreo

Author F. Sebastiani

Editor Pedreschi D.

Editor Naretto F.

Editor Pellungrini R.

Abstract The standard technique for predicting the accuracy that a classifier will have on unseen data (classifier accuracy prediction – CAP) is cross-validation (CV). However, CV relies on the assumption that the training data and the test data are sampled from the same distribution, an assumption that is often violated in many real-world scenarios. When such violations occur (i.e., in the presence of dataset shift), the estimates returned by CV are unreliable. In this paper we propose a CAP method specifically designed to address prior probability shift (PPS), an instance of dataset shift in which the training and test distributions are characterized by different class priors. By solving a system of n^2 independent linear equations, with n the number of classes, our method estimates the n^2 entries of the contingency table of the test data, and thus allows estimating any specific evaluation measure. Since a key step in this method involves predicting the class priors of the test data, we further observe a connection between our method and the field of “learning to quantify”. Our experiments show that, when combined with state-of-the-art quantification techniques, under PPS our method tends to outperform existing CAP methods. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2025.

Abstract BACKGROUND: Microscopic image analysis based on image processing is required for quantitative evaluation of decellularization. Existing methods are not widely used because of expensive commercial software, and machine learning-based techniques lack generality for decellularization because many high-resolution image data has to be processed. OBJECTIVE: In this study, we developed an image processing algorithm for quantitative analysis of tissues and cells in a general microscopic image. METHODS: The proposed method extracts the color images obtained by the microscope into reference images consisting of grayscale, red (R), green (G), and blue (B) information and transforms each into a binary image. The transformed images were extracted by separating the cells and tissues through outlier noise elimination, logical multiplication and labeling. In order to verify the method, decellularization of porcine aortic valve was performed by the electrical method. Slice samples were obtained by time and the proposed method was applied. RESULTS: The experimental results show that the segmentation of cells and tissues, and quantitative analysis of the number of cells and changes in tissue area during the decellularization process was possible. CONCLUSIONS: The proposed method shows that cell and tissue extraction and quantitative numerical analysis were possible in different brightness of microscopic images. © 2020-IOS Press and the authors. A Soil Carbon Content Quantification Method Using A Miniature Millimeter Wave Radar Sensor and Machine Learning

Item Type Conference Paper

Author D. An

Author Y.Q. Chen

Abstract Soil carbon content plays an essential role in combating climate change, water cycling, and sustaining soil biodiversity. However, the conventional way of quantifying soil carbon content is labor intensive, lack of precision, slow, and costly. On large spatial scale, assessment of the effect of carbon (biochar) applied to the soil for soil health conditioning, remains to be very difficult. This paper for the first time demonstrates the viability using a millimeter-wave sensing method for quantifying soil carbon content. It can also distinguish biochar types from different biomass species. Furthermore, soil moisture monitoring, and biochar water retention capacity can also be quantified by utilizing the same miniature millimeter wave radar sensor empowered by machine learning. Specifically, in this study, we present our research materials, methodology, machine learning workflow, results, and the explanation and interpretation based on the physical principles of the millimeter wave radar array sensor in the context of soil carbon content. We validated our quantification method with supervised machine learning algorithm using real soil data collected in the field mixed with known biochar contents. The results show that our technique achieved a 95.7 per cent recognition accuracy across seven different biochar types. The work laid the foundation for future real-time, large spatial-scale evaluation and assessment of soil carbon content using biochar amendments or other related carbon-negative technologies. Thus, soil carbon content site-specific management can be made possible. © 2022 IEEE.

Abstract Fragmentomics features of cell-free DNA represent promising non-invasive biomarkers for cancer diagnosis. A lack of systematic evaluation of biases in feature quantification hinders the adoption of such applications. We compare features derived from whole-genome sequencing of ten healthy donors using nine library kits and ten data-processing routes and validated in 1182 plasma samples from published studies. Our results clarify the variations from library preparation and feature quantification methods. We design the Trim Align Pipeline and cfDNAPro R package as unified interfaces for data pre-processing, feature extraction, and visualization to standardize multi-modal feature engineering and integration for machine learning. © The Author(s) 2025.

A statistical approach to the confusion matrix for classification problems using machine learning

Item Type Journal Article

Author R. Sanchez-Marquez

Author J. Jabaloyes Vivas

Abstract The kappa coefficient and accuracy are widely utilised metrics for evaluating classification systems in machine learning and quality inspections. However, traditional kappa suffers a significant drawback: its value depends on class prevalence (the proportion of instances in each category), which can misrepresent a system's actual performance. Furthermore, relying solely on point estimates for both kappa and accuracy overlooks the crucial impact of sample size and estimation error. This paper addresses these critical limitations by providing a comprehensive and practical method for estimating the lower bound of the intrinsic kappa coefficient and accuracy, generalised to classification problems with any number of categories. Unlike its traditional counterpart, the “intrinsic” kappa is robust to sample prevalence, offering a more reliable measure of a classifier's inherent ability. We develop both exact and approximate methods for estimating these lower bounds. Our results demonstrate that the approximate methods yield estimations remarkably close to those from the exact method across a wide range of sample sizes and misclassified instances. This reliability is further validated through extensive Monte Carlo simulations and benchmarking on diverse machine learning datasets with varying degrees of class imbalance. These findings confirm the proposed framework's practical utility for providing a stable, uncertainty-aware performance measure in high-stakes applications. Real-life examples further illustrate the straightforward application of these robust estimation methods for practitioners. © 2026 Elsevier B.V.

A stochastic gradient descent algorithm for structural risk minimisation

Item Type Conference Paper

Editor Takimoto E.
Abstract Structural risk minimisation (SRM) is a general complexity regularization method which automatically selects the model complexity that approximately minimises the misclassification error probability of the empirical risk minimiser. It does so by adding a complexity penalty term $\epsilon(m, k)$ to the empirical risk of the candidate hypotheses and then for any fixed sample size m it minimises the sum with respect to the model complexity variable k . When learning multicategory classification there are M subsamples m_i , corresponding to the M pattern classes with a priori probabilities p_i , $1 \leq i \leq M$. Using the usual representation for a multi-category classifier as M individual boolean classifiers, the penalty becomes $\sum_{i=1}^M p_i \epsilon(m_i, k_i)$. If the m_i are given then the standard SRM trivially applies here by minimizing the penalised empirical risk with respect to k_i , $1, \dots, M$. However, in situations where the total sample size $\sum_{i=1}^M m_i$ needs to be minimal one needs to also minimize the penalised empirical risk with respect to the variables m_i , $i = 1, \dots, M$. The obvious problem is that the empirical risk can only

be defined after the subsamples (and hence their sizes) are given (known). Utilising an on-line stochastic gradient descent approach, this paper overcomes this difficulty and introduces a sample-querying algorithm which extends the standard SRM principle. It minimises the penalised empirical risk not only with respect to the k_i , as the standard SRM does, but also with respect to the m_i , $i = 1, \dots, M$. The challenge here is in defining a stochastic empirical criterion which when minimised yields a sequence of subsample-size vectors which asymptotically achieve the Bayes' optimal error convergence rate. © Springer-Verlag Berlin Heidelberg 2003.

A Study on Threat Analysis and Risk Assessment Based on the 'Asset Container' Method and CWSS

Item Type Journal Article**Author** Y. Kawanishi**Author** H. Nishihara**Author** H. Yoshida**Author** H. Yamamoto**Author** H. Inoue

Abstract In recent years, legislation and standardization of cyber security management for cyber-physical systems such as automotive systems have been progressing steadily. ISO/SAE 21434, published in 2021, addresses the management and analysis of electrical systems within road vehicles from a cybersecurity perspective. It also recommends some methods for the threat analysis and risk assessment (TARA) process. However, there are two problems in the evaluation methods derived from conventional security analysis approaches. One problem is related to the insufficient evaluation of attack feasibilities for cyber-physical systems by the CVSS-based approach. Another problem is the unclear relationship between damage factors in analyzing the impact of damage to each asset. In this paper, we focus on the TARA process, and apply an 'asset container' method for threat classification, proposed by the authors at DECSoS 2017, and a CWSS-based risk quantification method. Moreover, we can also add some perspective to improve risk evaluation suitable for automotive systems. Following our past studies on methodologies to evaluate the risk of such special cyber-physical systems, we can quantify risks limited to some cyber-physical systems, such as direct access attacks to in-vehicle networks. © 2013 IEEE.

A survey on forensic age estimation through DNA methylation: recent progress and future directions towards legal age estimation

Item Type Journal Article

Author R. Gonzalez-Romero

Author V. Suarez-Ulloa

Author O. Ibañez

Abstract DNA methylation (DNAm) has emerged as one of the most promising molecular biomarkers for age estimation (AE), offering a powerful complement to traditional anthropological and radiological methods. Its potential spans forensic, biomedical, and humanitarian domains, particularly in the identification of deceased individuals and the estimation of legal age in living persons. Despite its rapid development, the forensic implementation of DNAm-based AE models remains challenged by issues of validation, dataset diversity, and tissue-specific variability. This survey provides an up-to-date overview of DNAm-based AE models developed between 2019 and 2025. We catalogued and analyzed published models according to their data origin, tissue type, methylation quantification method, and mathematical approach. We also distinguish between models designed to estimate chronological age in living individuals and those focused on age-at-death estimation in deceased persons. Our analysis highlights trends toward tissue-specific model optimization, targeted approaches with a small number of markers, and the integration of machine learning to improve predictive performance. Special attention is given to the development of pediatric and young-adult epigenetic clocks tailored to the estimation of legal age, an area with growing societal and humanitarian relevance, particularly in migration and child protection contexts. By identifying the main methodological advances, limitations, and challenges, this review outlines a roadmap for the next generation of DNAm-based AE models, emphasizing the need for standardized validation protocols, increased population diversity, and interdisciplinary approaches that integrate molecular, radiological, and computational tools. © 2026 The Authors.

A survey on state of art approaches in handling imbalance, positive and unlabelled data

Item Type Conference Paper

Author N. Deepa

Author R. Sumathi

Abstract Machine learning algorithm extends its horizon in various application domains. Real time applications in various sectors which can be effectively handled with machine learning techniques lack from it due to the unavailability of the required data. In such cases the data may be imbalanced, with a single class labeled and other unlabelled. However, this will be the prevailing scenario in future and has to be addressed. This work concentrates on studying the various approaches that are in practice to handle these kinds of data. In specific, it concentrates on approaches used for handling imbalance data sets and the recent works in it, methods used for handling positive unlabelled data. Though there are few solutions in practice for handling imbalance data and positive unlabelled data. Approaches that work at the data level and algorithm level approach for handling the former and techniques such as biased learning and class prior models for handling the later are in practice. One class classifier is another approach that can be used for addressing the problem that arises with the class imbalance in the dataset and

related issues. It has also been noted from the literature that one class classifier will be more suitable but it has not been widely used in addressing the problems such as class rarity. It can be inferred from this study that the one class classifier would play a significant role in various domains in future. © 2022 IEEE.

A Survey on Uncertainty Quantification Methods for Deep Learning

Item Type Journal Article

Author W. He

Author Z. Jiang

Author T. Xiao

Author Z. Xu

Author Y. Li

Abstract Deep neural networks (DNNs) have achieved tremendous success in computer vision, natural language processing, and scientific and engineering domains. However, DNNs can make unexpected, incorrect, yet overconfident predictions, leading to serious consequences in high-stakes applications such as autonomous driving,

medical diagnosis, and disaster response. Uncertainty quantification (UQ) estimates the confidence of DNN predictions in addition to their accuracy. In recent years, many UQ methods have been developed for DNNs. It is valuable to systematically categorize these methods and compare their strengths and limitations. Existing surveys mostly categorize UQ methodologies by neural network architecture or Bayesian formulation, while overlooking the uncertainty sources each method addresses, making it difficult to select an appropriate approach in practice. To fill this gap, this article presents a taxonomy of UQ methods for DNNs based on uncertainty sources (e.g., data versus model uncertainty). We summarize the advantages and disadvantages of each category, and illustrate how UQ can be applied to machine learning problems (e.g., active learning, out-of-distribution robustness, and deep reinforcement learning). We also identify future research directions, including UQ for large language models (LLMs), AI-driven scientific simulations, and DNNs with structured outputs. © 2026 Copyright held by the owner/author(s).

A theoretical treatment of the sources of variability in the output of pattern classifiers

Item Type Conference Paper

Author S. Gupta

Author M.K. Markey

Abstract Previously, several instances of variability in the output of pattern classifiers that have the same Receiver Operating Characteristic (ROC) curve have been observed. We present a theoretical framework for understanding some sources of this variability, which result in classifiers with monotonically related outputs. We restrict our analysis to pattern classifiers that discriminate between two linearly separable classes. We show that variability in the output of pattern classifiers can arise due to differences in the functional mappings between their inputs and outputs. We further identify some practical situations wherein such variability in the output of such pattern classifiers arises. These include situations in which there are differences in (a) the datasets employed for training and evaluation of classifiers, (b) the a priori probabilities of the two classes, or (c) the stochastic processes employed for training the different pattern classifiers. Previously, we proposed a technique based on the matching of the histograms of differently distributed classifier output to reduce the variability in their diagnostic performance and their output values. Here, we prove theoretically and demonstrate empirically on simulated data, that for monotonically related classifier outputs, this technique successfully learns the true monotonic transformation function that exists between different pattern classifier outputs.

A toolkit for quantifying individual response to herbal extracts in metabolic and inflammatory stress

Item Type Journal Article**Author** S.-Y. Park**Author** O. Kwon**Author** T. van den Broek**Author** J. Bouwman**Author** J.Y. Kim

Abstract This study developed a health assessment tool to analyze dynamic stress responses and resilience with the PhenFlex challenge. This study integrated a health space model and machine learning to quantify and visualize the impact of herbal extracts on inflammatory and metabolic health at the individual level. Two randomized, double-blind, placebo-controlled crossover trials were conducted involving participants with PhenFlex challenge after overnight fasting. Blood samples were collected, and a machine learning algorithm was used to predict health estimation scores based on metabolic and inflammatory responses. The resulting health space model visually represents individuals' health status in a 2-D space. Intervention with herbal extracts (e.g., *Angelica keiskei*, AK, and *Capsosiphon fulvescens*, CF) resulted in higher health scores in the health space, indicating improved health. This research emphasizes the quantification of phenotypic changes for personalized nutrition and health optimization. Overall, this study provides a valuable toolkit for validating herbal extract efficacy and extends its application to personalized nutrition. © The Author(s) 2025.

A two dimensional accuracy-based measure for classification performance

Item Type Journal Article

Author M. Carbonero-Ruz

Author F.J. Martínez-Estudillo

Author F. Fernández-Navarro

Author D. Becerra-Alonso

Author A.C. Martínez-Estudillo

Abstract Accuracy has been used traditionally to evaluate the performance of classifiers. However, it is well known that accuracy is not able to capture all the different factors that characterize the performance of a multiclass classifier. In this manuscript, accuracy is studied and analyzed as a weighted average of the classification rate of each class. This perspective allows us to propose the dispersion of the classification rate of each class as its complementary measure. In this sense, a graphical performance metric, which is defined in a two dimensional space composed by accuracy and dispersion, is proposed to evaluate the performance of classifiers. We show that the combined values of accuracy and dispersion must fall within a clearly bounded two dimensional region, different for each problem. The nature of this region depends only on the a priori probability of each class, and not on the classifier used. Thus, the performance of multiclassifiers is represented in a two dimensional space where the models can be compared in a more fair manner, providing greater awareness of the strategies that are more accurate when trying to improve the performance of a classifier. Furthermore we experimentally analyze the behavior of seven different performance metrics based on the computation of the confusion matrix values in several scenarios, identifying clusters and relationships between measures. As shown in the experimentation, the graphical metric proposed is specially suitable in challenging, highly imbalanced and with a high number of classes datasets. The approach proposed is a novel point of view to address the evaluation of multiclassifiers and it is an alternative to other evaluation measures used in machine learning. © 2016 Elsevier Inc.

A two-step anomaly detection based method for PU classification in imbalanced data sets

Item Type Journal Article

Author C. Ortega Vázquez

Author S. vanden Broucke

Author J. De Weerd

Abstract Several machine learning applications, including genetics and fraud detection, suffer from incomplete label information. In such applications, a classifier can only train from positive and unlabeled (PU) examples in which the unlabeled data consist of both positive and negative examples. Despite a substantial presence of PU learning in the literature, few works have considered a class imbalance setting. Hence, we propose a novel two-step method that exploits anomaly detection to identify hidden positives within the unlabeled data. Our method allows the end-user to choose the anomaly detector depending on preference or domain knowledge. Moreover, we introduce Nearest-Neighbor Isolation Forest (NNIF), a novel semi-supervised anomaly detector based on the Isolation Forest. In contrast to unsupervised anomaly detectors, NNIF can utilize all available label information. Empirical analysis shows that our method generally outperforms, using NNIF as the anomaly detector, state-of-the-art PU learning methods for imbalanced data sets under different labeling mechanisms. Further experiments suggest that our two-step method shows strong robustness to wrong class prior estimates. © 2023, The Author(s), under exclusive licence to Springer Science+Business Media LLC, part of Springer Nature.

A Unified Framework for Multi-view Multi-class Object Pose Estimation

Item Type Conference Paper**Author** C. Li**Author** J. Bai**Author** G.D. Hager**Editor** Weiss Y.**Editor** Ferrari V.**Editor** Sminchisescu C.**Editor** Hebert M.

Abstract One[NOSPACE] [NOSPACE][SPACE]core challenge in object pose estimation is to ensure accurate and robust performance for large numbers of diverse foreground objects amidst complex background clutter. In this work, we present a scalable framework for accurately inferring six Degree-of-Freedom (6-DoF) pose for a large number of object classes from single or multiple views. To learn discriminative pose features, we integrate three new capabilities into a deep Convolutional Neural Network (CNN): an inference scheme that combines both classification and pose regression based on a uniform tessellation of the Special Euclidean group in three dimensions (SE(3)), the fusion of class priors into the training process via a tiled class map, and an additional regularization using deep supervision with an object mask. Further, an efficient multi-view framework is formulated to address single-view ambiguity. We show that this framework consistently improves the performance of the single-view network. We evaluate

our method on three large-scale benchmarks: YCB-Video, JHUScene-50 and ObjectNet-3D. Our approach achieves competitive or superior performance over the current state-of-the-art methods. © 2018, Springer Nature Switzerland AG.

A Unified View of Double-Weighting for Marginal Distribution Shift

Item Type Journal Article

Author J.I. Segovia-Martín

Author S. Mazuelas

Author A. Liu

Abstract Supervised classification traditionally assumes that training and testing samples are drawn from the same underlying distribution. However, practical scenarios are often affected by distribution shifts, such as covariate and label shifts. Most existing

techniques for correcting distribution shifts are based on a reweighted approach that weights training samples, assigning lower relevance to the samples that are unlikely at testing. However, these methods may achieve poor performance when the weights obtained take large values at certain training samples. In addition, in multi-source cases, existing methods do not exploit complementary information among sources, and equally combine sources for all instances. In this paper, we establish a unified learning framework for distribution shift adaptation. We present a double-weighting approach to deal with distribution shifts, considering weight functions associated with both training and testing samples. For the multi-source case, the presented methods assign source-dependent weights for training and testing samples, where weights are obtained jointly using information from all sources. We also present generalization bounds for the proposed methods that show a significant increase in the effective sample size compared with existing approaches. Empirically, the proposed methods achieve enhanced classification performance in both synthetic and empirical experiments. © 2025, Transactions on Machine Learning Research. All rights reserved.

A unified view of label shift estimation

Item Type Conference Paper

Author S. Garg

Author Y. Wu

Author S. Balakrishnan

Author Z.C. Lipton

Abstract Under label shift, the label distribution $p(y)$ might change but the class-conditional distributions $p(x|y)$ do not. There are two dominant approaches for estimating the label marginal. BBSE, a moment-matching approach based on confusion matrices, is provably consistent and provides interpretable error

bounds. However, a maximum likelihood estimation approach, which we call MLLS, dominates empirically. In this paper, we present a unified view of the two methods and the first theoretical characterization of MLLS. Our contributions include (i) consistency conditions for MLLS, which include calibration of the classifier and a confusion matrix invertibility condition that BBSE also requires; (ii) a unified framework, casting BBSE as roughly equivalent to MLLS for a particular choice of calibration method; and (iii) a decomposition of MLLS's finite-sample error into terms reflecting miscalibration and estimation error. Our analysis attributes BBSE's statistical inefficiency to a loss of information due to coarse calibration. Experiments on synthetic data, MNIST, and CIFAR10 support our findings. © 2020 Neural information processing systems foundation. All rights reserved.

A variational approach for learning from positive and unlabeled data

Item Type Conference Paper

Author H. Chen

Author F. Liu

Author Y. Wang

Author L. Zhao

Author H. Wu

Abstract Learning binary classifiers only from positive and unlabeled (PU) data is an important and challenging task in many real-world applications, including web text classification, disease gene identification and fraud detection, where negative samples are difficult to verify experimentally. Most recent PU learning methods are developed based on the misclassification risk of the supervised learning type, and they may suffer from inaccurate estimates of class prior probabilities. In this paper, we introduce a variational principle for PU learning that allows us to quantitatively evaluate the modeling error of the Bayesian classifier directly from given data. This leads to a loss function which can be efficiently calculated without involving class prior estimation or any other intermediate estimation problems, and the variational learning method can then be employed to optimize the classifier under general conditions. We illustrate the effectiveness of the proposed variational method on a number of benchmark examples. © 2020 Neural information processing systems foundation. All rights reserved.

Abstract Rock fragments (RFs) play an important role in soils that can influence land use and management decisions. Rock fragment concentrations most often are visually estimated (VE) in the field, for which accuracy strongly depends on experience and practice of soil classifiers. The direct measurement (DM) method is more accurate, but is costly and labor-intensive. Due to its importance, a simple and inexpensive method for estimating RF concentrations without destructive soil sampling is necessary. The development of camera technology and digital image processing provide an opportunity for soil descriptions and quantitative analyses using an alternative soil profile imaging (PI) method. Therefore, the objective of this study was to explore the potential for RF concentration estimation using a PI method as compared to the VE and DM methods. Apart from VE and DM, different image processing procedures inside the PI method were compared in a natural, gravelly, alluvial profile (Entisol) with low contrast among RFs in order to develop an alternative and efficient RF quantification method. Results showed that the hue-saturation-value (HSV) color model performed better than the red-green-blue color model for identifying RFs. The proposed profile imaging method accurately segmented 84.9% of the RFs from the soil matrix. The PI had a greater correlation with DM ($r = 0.81$) compared to the VE method ($r = 0.78$). Results showed that the alternative PI method could be used to accurately and efficiently estimate RF concentrations in a natural, gravelly soil profile with low contrast among RFs. © 2020 Elsevier B.V.

Abstract One objective in Precision Agriculture is to minimize the volume of herbicides that are applied to the fields through the use of site-specific weed management systems. This paper outlines an automatic computer vision system for the

detection and differential spraying of *Avena sterilis*, a noxious weed growing in cereal crops. With such purpose we have designed a hybrid decision making system based on the Bayesian and Fuzzy k-Means (FkM) classifiers, where the a priori probability required by the Bayes framework is supplied by the FkM. This makes the main finding of this paper. The method performance is compared against other available strategies. © 2007 Springer-Verlag Berlin Heidelberg.

Absolute Quantification of Bacteria in the Microbiome and Its Application

Item Type Journal Article

Author J.-X. Guo

Author Y.-Z. Gao

Abstract The advent of genomics and deep sequencing technologies has facilitated the development of absolute quantification techniques, which offer researchers more objective and precise sequencing outcomes. Unlike traditional relative quantification methods, which provide comparative data, absolute quantification delivers definitive measurements of genes or taxa. This analytical approach mitigates the potential for extraneous influences when comparing disparate samples, thereby reducing analytical errors. The implementation of absolute quantification techniques enhances our comprehension of microbial community structures, ecological dynamics, and their associations with host health or disease conditions. This chapter emphasizes a straightforward and broadly applicable method for genomic quantification, which necessitates the incorporation of a specified amount of internal standard DNA into the

samples, eliminating the need for subsequent adjustments during library construction and sequencing. By assessing the proportion of internal standard DNA across various samples, sequencing data can be transformed into absolute quantification metrics. The internal standard method for absolute quantification is versatile and can be effectively utilized across multiple domains, including disease diagnosis, microbial ecology research, the fermentation industry, and environmental monitoring. Overall, absolute quantification methods furnish a more accurate and holistic perspective for microbiome research. © The Author(s), under exclusive license to Springer Science+Business Media, LLC, part of Springer Nature 2026.

Absolute quantitative metagenomic analysis reveals unique gut bacteria underlying berberine and metformin's anti-metabolic disorders effects

Item Type Journal Article**Author** J. Zhan**Author** B. Cheng**Author** K. Guo**Author** X. Tao**Author** X. Cai**Author** Z. Li**Author** Z. Tang**Author** J. Zhan**Author** C. Wu

Abstract This study aimed to evaluate the potential functional bacteria in the efficacy of two drugs in ameliorating diet-induced metabolic disorder model using absolute and relative quantification methods and to evaluate the benefit of absolute quantification compared with relative quantification. The gut microbiota is implicated in the pathogenesis of various chronic diseases, including diet-induced metabolic disorder model. Berberine (BBR) and metformin (MET) are commonly used in the clinical management of metabolic disorder, yet their effects on gut microbiota regulation differ. This study employs both relative and absolute quantitative methods to assess the differential impacts of these drugs on the modulation of gut microbiota in metabolic disorder mice. Both BBR and MET effectively ameliorate the condition of metabolic disorder. While some relative quantitative sequencing results contradicted the absolute sequencing data, the latter was more consistent with the actual microbial community composition. Absolute quantitative sequencing provides a more accurate reflection of the drug's effects. Notably, both absolute and relative quantitative sequencing demonstrated an upregulation of Akkermansia. **IMPORTANCE** Our study underscores the importance of absolute quantitative analysis in accurately representing the true microbial counts in a sample and evaluating the modulatory effects of drugs on the microbiome, which plays a vital role in the study of the microbiome. ABSTENTION IN REGRESSION

Item Type Conference Paper
Author C. Garcia-Cardona
Author J. Mohd-Yusof
Author T. Bhattacharya
Editor Papadrakakis M.
Editor Papadopoulos V.
Editor Stefanou G.

Abstract Identifying noisy samples and outliers at training time is crucial to achieve good performance and improve robustness of deep learning models. However, this process can be difficult and excessively time consuming if attempted by hand, especially for large data sets. Moreover, in realistic situations, there are gradations in our judgement about noisy samples. In this work, we extend the Deep Abstention Classifier (DAC) framework to regression problems and devise a deep abstaining regressor (DAR) model. This is a forgiving strategy that limits the detrimental effect of noisy samples on the performance of the predictive model, while, at the same time, retaining information in ambiguous cases. We apply the new DAR formulation to synthetic and real data sets and demonstrate that the model is able to identify noisy samples, reducing their influence during training, while learning to quantify the uncertainty in the predictions via a heteroscedastic criterion. DAR constitutes a new tool for the machine learning practitioner, producing actionable uncertainty quantification predictions and helping with the automatic curation of data. This may be an efficient way to reduce the burden of

manual labelling for evaluation by a human-in-the-loop. © 2023 UNCECOMP Proceedings. All rights reserved.

Accelerated Bayesian Calibration and Uncertainty Quantification of RANS Turbulence Model Parameters for Stratified Atmospheric Boundary Layer Flows

Item Type Journal Article

Author E.Y. Shin

Author M.F. Howland

Abstract In operational weather models, the effects of turbulence in the atmospheric boundary layer (ABL) on the resolved flow are modeled using turbulence parameterizations. These parameterizations typically use a predetermined set of model parameters that are tuned to limited data from canonical flows. Using these fixed parameters results in deterministic predictions that neglect uncertainty in the unresolved turbulence processes. In this study, we perform a machine learning-accelerated Bayesian inversion of a single-column model of the ABL. This approach is used to calibrate

and quantify uncertainty in model parameters of Reynolds-averaged Navier–Stokes turbulence models. To verify the data-driven uncertainty quantification methodology, we test in an idealized setup in which a prescribed but unobserved set of parameters is learned from noisy approximations of the model output. Following this verification, we learn the parameters and their uncertainties in two different turbulence models conditioned on scale-resolving large-eddy simulation data over a range of ABL stabilities. We show how Bayesian inversion of a numerical model improves flow predictions by investigating the underlying mean momentum budgets. Further, we show that uncertainty quantification based on neutral ABL surface layer data recovers the relationships between parameters that have been predicted using theoretical modeling, but that learning the parameters based on stable ABL data or data from outside the surface layer can lead to different parameter relationships than neutral surface layer theory. Efforts to systematically reduce parameter uncertainty reveal that (1) sampling wind speed up to the ABL height can reduce uncertainty in key model parameters by up to, and (2) assimilating fluid flow quantities beyond first-order moment statistics can further reduce uncertainty in ways that baseline wind speed assimilation alone cannot achieve. The parameters learned using Bayesian uncertainty quantification generally yield lower error than standard deterministic parameters in out-of-sample tests and also provide uncertainty intervals on predictions. © The Author(s) 2025.

Accelerating ensemble uncertainty estimates in supervised materials property regression models

Item Type Journal Article

Author V. Agrawal

Author S. Zhang

Author L.E. Schultz

Author D. Morgan

Abstract A method is proposed to accelerate ensemble uncertainty quantification methods by replacing the ensemble method inference with a single model. An ensemble of N models is approximately N times more computationally demanding compared to a similar complexity single model when it is used for inference. We focus on regression models for material properties. Three material data sets were studied which include property data related to dilute solute diffusion, perovskite stability, and super conduction critical temperatures. We generated uncertainties from calibrated ensemble models for the aforementioned datasets. We explored fitting a single model to replace ensemble uncertainty estimates, which allows us to estimate uncertainties without the need for a full ensemble. Our approach is based on three models: Model A for predictive accuracy, Model AE for ensemble-based uncertainty prediction, and Model B, fit to data from Model AE, to be used for predicting the values of AE but with only one model evaluation. Model B leverages synthetic data augmentation to estimate uncertainties efficiently. This approach offers a highly flexible method of uncertainty quantification that can approximate that of ensemble methods but only requires a single extra model evaluation over Model A during inference. We evaluate the performance of this approach on a set of problems in materials sciences using modest-sized datasets with fewer than 100 features, demonstrating its potential generalizability to similar models and datasets. © 2024 Elsevier B.V.

Accounting for Label Shift of Positive Unlabeled Data under Selection Bias

Item Type Journal Article

Author J. Mielniczuk

Author A. Wawrzęńczyk

Abstract We consider the scenario when two samples of positive unlabeled (PU) data are available and for the second sample the change in prior probability of classes occurs while distributions of predictors in classes remain the same (label shift setting). The selection of positive elements may be object-dependent. We study the properties of the underlying probabilistic structure under the novel augmented PU scenario, proving in particular that label shift occurs also for unlabeled populations. We introduce and investigate an estimator of prior probability for label-shifted population. Furthermore, in this case we construct and analyze behavior of Bayes classifier in this setting. It turns out to be a Bayes classifier for the unlabeled class with a modified threshold. This gives rise to its three empirical counterparts which are compared on benchmark data sets. © 2025 Jan Mielniczuk et al., published by Sciendo.

Accuracy assessment in convolutional neural network-based deep learning remote sensing studies—part 1: Literature review

Item Type Journal Article

Author A.E. Maxwell

Author T.A. Warner

Author L.A. Guillén

Abstract Convolutional neural network (CNN)-based deep learning (DL) is a powerful, recently developed image classification approach. With origins in the computer vision and image processing communities, the accuracy assessment methods developed for CNN-based DL use a wide range of metrics that may be unfamiliar to the remote sensing (RS) community. To explore the differences between traditional RS and DL RS methods, we surveyed a random selection of 100 papers from the RS DL literature. The results show that RS DL studies have largely abandoned traditional RS accuracy assessment terminology, though some of the accuracy measures typically used in DL papers, most notably precision and recall, have direct equivalents in traditional RS terminology. Some of the DL accuracy terms have multiple names, or are equivalent to another measure. In our sample, DL studies only rarely reported a complete confusion matrix, and when they did so, it was even more rare that the confusion matrix estimated population properties. On the other hand, some DL studies are increasingly paying attention to the role of class prevalence in designing accuracy assessment approaches. DL studies that evaluate the decision boundary threshold over a range of values tend to use the precision-recall (P-R) curve, the associated area under the curve (AUC) measures of average precision (AP) and mean average precision (mAP), rather than the traditional receiver operating characteristic (ROC) curve and its AUC. DL studies are also notable for testing the generalization of their models on entirely new datasets, including data from new areas, new acquisition times, or even new sensors. © 2021 by the authors. Accuracy of Estimated Ratios as Affected by Dynamic Classification Errors

Item Type Journal Article

Author A. Van Delden

Author S. Scholtus

Author J. Burger

Author Q. Meertens

Abstract Within the field of official statistics, we are often interested in the relative change of statistical indicators through time. A typical example is economic growth measured as the ratio of gross domestic product at two consecutive time periods. In this article, we investigate the accuracy of such ratios when the numerator and denominator describe a subpopulation. Subpopulations are always identified by a classification variable, which might contain classification errors. Our main objective is to quantify the bias and variance of statistical estimates of ratios of statistical indicators that are affected by classification errors. Previous studies have already shown how to estimate the bias and variance of statistical indicators for a single subpopulation as affected by classification errors. For estimated ratios, such results are not yet available in the

academic literature. In this article, we will provide those results. More specifically, we will investigate three situations: the classification errors for the numerator and denominator are (1) completely dependent, (2) completely independent, or (3) partially dependent. For these three cases, we derive estimators of the bias and variance using a Taylor expansion and a bootstrap approach. By means of a simulation study, we show that the Taylor expansion is valid unless the distribution of the target variable of the numerator or the denominator is highly skewed. The methods are applied to two widely differing case studies: one on classification errors made by a machine learning classifier (independent errors) and one on classification errors in register data (partially dependent errors). This illustrates that our method can be useful for a wide range of applications. © 2022 The Author(s). Accuracy of whole slide image based image analysis is adversely affected by preanalytical factors such as stained tissue slide and paraffin block age

Item Type Journal Article

Author N. Shaker

Author A.V. Parwani

Abstract Background: Personalized medicine and accurate quantification of tumor and biomarker expression have become the cornerstone of cancer diagnostics. This requires Quality Control (QC) of research tissue samples to confirm adequate targeted tumor tissue sampling. Digitalization of stained tissue slides offer a precious way to archive, preserve, and retrieve necessary information when needed. This study is aimed to assess the most significant pre-analytic and analytic factors that might contribute to the efficacy of obtaining accurate whole slide images (WSIs) interpretation. Various studies are needed to identify such factors to allow for appropriate AI application and adequate tumor area/percentage quantification. Methods: Hematoxyline and Eosine (H&E) stained WSIs collected from tissue specimens provided by the Cooperative Human Tissue Network (CHTN) Midwestern Division (CHTNMWD) were analyzed. Tissue specimens were processed, fixed, stained, and scanned contemporaneously (within 1 month). Two cohorts of malignant, colorectal cancer, 20X WSI (ScanscopeXT, Leica Biosystems, Illinois), were assembled. The study identified a “recent cohort” that included 76 WSIs created on 2018 or later. “Aged cohort” included 73 WSIs from specimens procured in the period of (2012-2014). Twenty recent WSIs of adenocarcinoma cases were used to construct WSIs analysis algorithms (VIS, Visiopharm A/S, Denmark) using machine learning to produce morphometric maps and calculate tissue and tumor areas. Results: Algorithmic analysis of 69 WSIs from rescanned aged slides vs. that of contemporaneous WSIs concluded 18 (28%) similar finding in tumor areas (within 10%), 56 (82%) had identical tissue areas, and 54 (79%) had similar tumor percentages. Conclusion: WSIs of aged H&E slides and stained paraffin block re-cuts produce different tumor quantification compared to those of original scanned slides most likely due to pre-analytical factors. The difference in tumor area detected between original and rescanned WSIs trended upward in the period between 2012 and 2014. Less tumor area was detected as the slides age. Recut and H&E-stained tissues from stored paraffin blocks may detect more tumor due to excess eosinophilia. These results highlights the value of documenting archives of H&E WSIs collected at the procurement time. Such images provide a superior archive over glass slides and Formalin-Fixed Paraffin-Embedded (FFPE) blocks and contribute better to WSIs analysis application. © 2022 The Authors

Accurate Classification of Pathological Whole-Slide Images for Out-of-Distribution Generalization

Item Type Journal Article

Author K. Sun

Author K. Huang

Author J. Huang

Author M. Zhou

Author G. Yu

Abstract WSI-based classification often suffers from out-of-distribution (OOD) generalization due to the distribution mismatch between training on mixed patches from multiple WSIs and testing on individual WSIs with varying tissue compositions. This prior shift impairs model generalization and degrades performance. To address this issue, we propose two distribution alignment strategies: intra-WSI rearrange and inter-WSI rearrange, which, respectively, regulate patch distribution within individual WSIs and across different WSIs. These strategies are embedded into a transformer-based multi-instance learning (MIL) framework enabling more accurate and robust classification. Our method achieves excellent AUC scores of 0.959 and 0.963 on the CAMELYON16 and TCGA-NSCLC datasets, respectively. Moreover, it reaches an average AUC of 0.974 in 5-fold cross-validation on a private CRC dataset, matching the performance of patch-based approaches. Ablation studies further validate the effectiveness of our proposed strategies in mitigating the OOD challenge in WSI classification. Overall, these strategies enhance the robustness and accuracy of WSI-based models in handling OOD challenges. Copyright © 2025 Kai Sun et al. Abstract How can we classify graph-structured data only with positive labels? Graph-based positive-unlabeled (PU) learning is to train a binary classifier given only the positive labels when the relationship between examples is given as a graph. The problem is of great importance for various tasks such as detecting malicious accounts in a social network, which are difficult to be modeled by supervised learning when the true negative labels are absent. Previous works for graph-based PU learning assume that the prior distribution of positive nodes is known in advance, which is not true in many real-world cases. In this work, we propose GRAB (Graph-based Risk minimization with iterAtive Belief propagation), a

novel end-to-end approach for graph-based PU learning that requires no class prior. GRAB models a given graph as a Markov network and runs the marginalization and update steps iteratively. The marginalization step estimates the marginals of latent variables, while the update step trains a classifier network utilizing the computed priors in the objective function. Extensive experiments on five datasets show that GRAB achieves state-of-the-art accuracy, even compared with previous methods that are given the true prior. © 2021 IEEE.

Accurate quantification of choline-to-creatine ratio as a biomarker to distinguish osteosarcoma patients from normal subjects employing proton magnetic resonance spectroscopy imaging at 3 tesla

Item Type Journal Article

Author S.K. Alavijeh

Author F. Pashaei

Author M. Malek

Author H.S. Rad

Abstract Purpose: This study focused on accurate quantification of a maximum of Choline-to-Creatine ratio (Max (Cho/Cr)) in 10 Osteosarcoma patients, in comparison with 5 healthy volunteers as our control group using proton Magnetic Resonance Spectroscopy Imaging (1H-MRSI). Materials and Methods: Max (Cho/Cr) were obtained in 10 patients with Osteosarcoma over their corresponding ratio maps containing diseased tissue, to be compared with Cho/Cr in 5 healthy volunteers at 3T, employing MRSI (Performed Employing Pointed-resolved Spectroscopy (PRESS), TR/TE: 2500s /135 ms) with water-suppression. An extra unsuppressed water Single-Voxel Spectroscopy (SVS) was acquired to provide phase information for further Eddy Current Correction (ECC). Multi-stage preprocessing was applied. Subtract QUEST MRSI as a time-domain technique was employed to accurately quantify the metabolites' ratios and to estimate the baseline. Results: An optimal database for Subtract QUEST was achieved based on multiple trials evaluated by acceptable peak-fitting and Cramer-Rao-Bound (CRB). Lipids at frequencies of 0.94 and 1.33ppm were combined to increase the accuracy of the Lipid estimation. Conclusion: Estimation of Max (Cho/Cr) evaluated over Cho/Cr spatial maps to distinguish Osteosarcoma patients from normal subjects suggested that the proposed quantification method leads to high power and linear classifier with a high degree of reproducibility, considering 1H-MRSI at 3T machine as a high efficacy diagnostic tool for musculoskeletal radiology. Accurate quantification of soil organic matter content using VNIR-SWIR spectra: The role of straw and spectrally active materials

Item Type Journal Article

Author C. Tan

Author H. Luan

Author Q. He

Author S. Yu

Author M. Zheng

Author L. Wang

Abstract Soil organic matter (SOM) is crucial for carbon sequestration and sustainable agriculture, yet traditional quantification methods are challenging to apply at large scales. Hyperspectral technology combined with machine-learning offers promising prospects for rapid quantification. This study explores the impact of using VNIR-SWIR spectra on SOM quantification in regions characterized by distinctive soil properties and agricultural activity. Specifically, we propose an innovative approach using 105 soil samples from Yueyang City, China, to refine the range of spectrally active materials and evaluate the effectiveness of iron oxides and straw on SOM quantification. Three feature construction methods (conventional (VNIR-SWIR spectra), optimal (information spectrum subset, ISS), and straw-merged ISS (SISS)) and seven models were employed to evaluate the contributions of iron oxides and straw in SOM quantification. The results indicate that the SISS improved the generalization (RPD and R²) of nonlinear and linear models by approximately 9 % and 4 %, respectively. The relative contributions of straw and iron oxides in modelling are approximately 35 % and 10 %, respectively. Our research successfully developed the SISS by refining the range of spectrally active materials and considering the background formed by the soil properties of the study area. We used it to evaluate the impact of straw on SOM quantification and demonstrated that the spectroscopic characterization of SOM can assess the carbon sequestration benefits of agricultural activities. This approach can be applied to regions with similar soil properties globally, offering a new perspective for SOM quantification. © 2024 Elsevier B.V.

Accurately quantifying a billion instances per second

Item Type Conference Paper**Author** W. Hassan**Author** A. Maletzke**Author** G. Batista**Editor** Webb G.**Editor** Zhang Z.**Editor** Tseng V.S.**Editor** Williams G.**Editor** Vlachos M.**Editor** Cao L.

Abstract Quantification is a thriving research area that develops methods to estimate the class prior probabilities in an unlabelled set of observations. Quantification and classification share several similarities. For instance, the most straightforward quantification method, Classify & Count (CC), directly counts the output of a classifier. However, CC has a systematic bias that makes it increasingly misestimate the counts as the class distribution drifts away from a distribution it perfectly quantifies. This issue has motivated the development of more reliable quantification methods. Such newer methods can consistently outperform CC at the cost of a significant increase in processing requirements. Yet, for a large number of applications, quantification speed is an additional criterion that must be considered. Frequently, quantification methods need to deal with large amounts of data or fast-paced streams, as it is the case of news feeding, tweets and sensor data. In this paper, we propose Sample Mean Matching (SMM), a highly efficient algorithm able to quantify billions of data instances per second. We compare SMM to a set of 14 established and state-of-the-art quantifiers in an empirical analysis comprising 25 benchmark and real-world datasets. We show

that SMM is competitive with state-of-the-art methods with no statistical difference in counting accuracy, and it is orders of magnitude faster than the vast majority of the algorithms. © 2020 IEEE.

Achieving Reliable and Fair Skin Lesion Diagnosis via Unsupervised Domain Adaptation

Item Type Conference Paper

Author J. Wang

Author Y. Zhang

Author Z. Ding

Author J. Hamm

Abstract The development of reliable and fair diagnostic systems is often constrained by the scarcity of labeled data. To address this challenge, our work explores the feasibility of unsupervised domain adaptation (UDA) to integrate large external datasets for developing reliable classifiers. The adoption of UDA with multiple sources can simultaneously enrich the training set and bridge the domain gap between different skin lesion datasets, which vary due to distinct acquisition

protocols. Particularly, UDA shows practical promise for improving diagnostic reliability when training with a custom skin lesion dataset, where only limited labeled data are available from the target domain. In this study, we investigate three UDA training schemes based on source data utilization: single-source, combined-source, and multi-source UDA. Our findings demonstrate the effectiveness of applying UDA on multiple sources for binary and multi-class classification. A strong correlation between test error and label shift in multi-class tasks has been observed in the experiment. Crucially, our study shows that UDA can effectively mitigate bias against minority groups and enhance fairness in diagnostic systems, while maintaining superior classification performance. This is achieved even without directly implementing fairness-focused techniques. This success is potentially attributed to the increased and well-adapted demographic information obtained from multiple sources. © 2024 IEEE.

ACML 2015 - 7th Asian Conference on Machine Learning

Item Type Journal Article

Abstract The proceedings contain 28 papers. The topics discussed include: detecting accounting frauds in publicly traded U.S. firms: a machine learning approach; improving Sybil detection via graph pruning and regularization techniques; class-prior estimation for learning from positive and unlabeled data; curriculum learning of Bayesian network structure; expectation propagation for rectified linear Poisson regression; preference relation-based Markov random fields for recommender systems; surrogate regret bounds for generalized classification performance metrics; streaming variational inference for Dirichlet process mixtures; continuous target shift adaptation in supervised learning; proximal average approximated incremental gradient method for composite penalty regularized empirical risk minimization; a unified framework for jointly learning distributed representations of word and attributes; regularized policy gradients: direct variance reduction in policy gradient estimation; budgeted bandit problems with continuous random costs; statistical unfolded logic learning; and integration of single-view graphs with diffusion of tensor product graphs for multi-view spectral clustering.

ACon2: Adaptive Conformal Consensus for Provable Blockchain Oracles

Item Type Conference Paper

Author S. Park

Author O. Bastani

Author T. Kim

Abstract Blockchains with smart contracts are distributed ledger systems that achieve block-state consistency among distributed nodes by only allowing deterministic operations of smart contracts. However, the power of smart contracts is enabled by interacting with stochastic off-chain data, which in turn opens the possibility to undermine the block-state consistency. To address this issue, an oracle smart contract is used to provide a single consistent source of external data; but, simultaneously, this introduces a single point of failure, which is called the oracle problem. To address the oracle problem, we propose an adaptive conformal consensus (ACon2) algorithm that derives a consensus set of data from multiple

oracle contracts via the recent advance in online uncertainty quantification learning. Interesting, the consensus set provides a desired correctness guarantee under distribution shift and Byzantine adversaries. We demonstrate the efficacy of the proposed algorithm on two price datasets and an Ethereum case study. In particular, the Solidity implementation of the proposed algorithm shows the potential practicality of the proposed algorithm, implying that online machine learning algorithms are applicable to address security issues in blockchains. © USENIX Security 2023. Acoustic classification of mosquitoes using convolutional neural networks combined with activity circadian rhythm information

Item Type Journal Article

Author J. Kim

Author J. Oh

Author T.-Y. Heo

Abstract Many researchers have used sound sensors to record audio data from insects, and used these data as inputs of machine learning algorithms to classify insect species. In image classification, the convolutional neural network (CNN), a well-known deep learning algorithm, achieves better performance than any other machine learning algorithm. This performance is affected by the characteristics of the convolution filter (ConvFilter) learned inside the network. Furthermore, CNN performs well in sound classification. Unlike image classification, however, there is little research on suitable ConvFilters for sound classification. Therefore, we compare the performances of three convolution filters, 1D-ConvFilter, 3×1 2D-ConvFilter, and 3×3 2D-ConvFilter, in two different network configurations, when classifying mosquitoes using audio data. In insect sound classification, most machine learning researchers use only audio data as input. However, a classification model, which combines other information such as activity circadian rhythm, should intuitively yield improved classification results. To utilize such relevant additional information, we propose a method that defines this information as a priori probabilities and combines them with CNN outputs. Of the networks, VGG13 with 3×3 2D-ConvFilter showed the best performance in classifying mosquito species, with an accuracy of 80.8%. Moreover, adding activity circadian rhythm information to the networks showed an average performance improvement of 5.5%. The VGG13 network with 1D-ConvFilter achieved the highest accuracy of 85.7% with the additional activity circadian rhythm information. © 2021, Universidad Internacional de la Rioja. Acoustic language model classes for large vocabulary continuous speech recognizer

Item Type Conference Paper

Author V. Fischer

Author S.J. Kunzmann

Abstract In a maximum a posteriori probability approach to speech recognition stochastic n-gram language models are used for the estimation of a word sequence's a priori probability. In any practical implementation of a large vocabulary speech recognition system the language model acts as a hypotheses filter that has to differ between candidate words with similar acoustic evidence. For that purpose, the combination of word based and class based language models is attractive, because it allows to fall back to the more reliable estimates of the class based model in case of sparse training data. However, class language models can differ between words from the same class only in terms of a priori probability. To improve the discriminative power for words with similar acoustic score, it is therefore useful to put similar sounding words into different classes. Based on the above considerations, the paper presents an automatic procedure for the optimal classification of a large vocabulary into classes with acoustic dissimilar words. In combination with a standard word based trigram model the so created acoustic class language model provides a relative reduction in word error rate of up to 16 percent and performs slightly better than a perplexity minimizing automatically created class language model.

Active Learning and the Saerens-Latinne-Decaestecker Algorithm: An Evaluation

Item Type Conference Paper

Author A. Molinari

Author A. Esuli

Author F. Sebastiani

Editor Tamine L.

Editor Amigo E.

Editor Mothe J.

Abstract The Saerens-Latinne-Decaestecker (SLD) algorithm is a method whose goal is improving the quality of the posterior probabilities (or simply “posteriors”) returned by a probabilistic classifier in scenarios characterized by prior probability shift (PPS) between the training set and the unlabelled (“test”) set. This is an important task, (a) because posteriors are of the utmost importance in downstream tasks such as, e.g., multiclass classification and cost-sensitive classification, and (b) because PPS is ubiquitous in many applications. In this paper we explore whether using SLD can indeed improve the quality of posteriors returned by a classifier trained via active learning (AL), a class of machine learning (ML) techniques that indeed tend to generate substantial PPS. Specifically, we target AL via relevance sampling (ALvRS) and AL via uncertainty sampling (ALvUS), two AL techniques that are very well-known especially because, due to their low computational cost, are suitable to being applied in scenarios characterized by large datasets. We present experimental results obtained on the RCV1-v2 dataset, showing that SLD fails to deliver better-quality posteriors with both ALvRS and ALvUS, thus contradicting previous findings in the literature, and that this is due not to the amount of PPS that these techniques generate, but to how the examples they prioritize for annotation are distributed. © 2022 Copyright for this paper by its authors. Abstract Real-world applications of mobile robotics call for increased autonomy, requiring reliable perception systems. Since manually tuned perception algorithms are difficult to adapt to new operating environments, systems based on supervised learning are necessary for future progress in autonomous navigation. Data labeling is a major concern when supervised learning is applied to the large-scale problems occurring in realistic robotics applications. We believe that algorithms for automatically selecting important data for labeling are necessary, and propose to employ active learning techniques to reduce the amount of labeling required to learn from a data set. In this paper we show that several standard active learning algorithms can be adapted to meet specific constraints characteristic to our domain, such as the need to learn from data with severely unbalanced class priors. We validate the solutions we propose by extensive experimentation on multiple realistic data sets captured with a robotic vehicle. Based on our results for the task of obstacle detection, we conclude that active learning techniques are applicable to our domain, and they can lead to significant reductions in the labeling effort required to use supervised learning in outdoor perception. © 2005 Massachusetts Institute of Technology.

Active Sequential Two-Sample Testing

Item Type Journal Article

Author W. Li

Author P. Kadambi

Author P. Saidi

Author K.N. Ramamurthy

Author G. Dasarathy

Author V. Berisha

Abstract A two-sample hypothesis test is a statistical procedure used to determine whether the distributions generating two samples are identical. We consider the two-sample testing problem in a new scenario where the sample measurements (or sample features) are inexpensive to access, but their group memberships (or labels) are costly. To address the problem, we devise the first active sequential two-sample testing framework that not only sequentially but also actively queries. Our test statistic is a likelihood ratio where one likelihood is found by maximization over all class priors, and the other is provided by a probabilistic classification model. The classification model is adaptively updated and used to predict where the (unlabelled) features have a high dependency on labels; labeling the “high-dependency” features leads to the increased power of the proposed testing framework. In theory, we provide the proof that our framework produces an anytime-valid p-value. In addition, we characterize the proposed framework’s gain in testing power by analyzing the mutual information between the feature and label variables in asymptotic and finite-sample scenarios. In practice, we introduce an instantiation of our framework and evaluate it

using several experiments; the experiments on the synthetic, MNIST, and application-specific datasets demonstrate that the testing power of the instantiated active sequential test significantly increases while the Type I error is under control. © 2024, Transactions on Machine Learning Research. Adapt, Generate, and Supervise: Geometry-Aware Diffusion-Guided SAM Framework for Remote Sensing Semantic Segmentation

Item Type Journal Article
Author W. Zhou
Author J. Xie
Author C. Xu
Author Y. Liu
Author Y. Wang
Abstract Foundation models such as the segment anything model (SAM) have remarkable generalization capabilities in natural image segmentation. However, their application to remote sensing (RS) semantic segmentation faces significant challenges. The single-modal architecture of SAM cannot effectively utilize multimodal RS data; its vision Transformer encoder lacks sensitivity to multiscale spatial structures that are characteristic of RS imagery, and its dependence on manual prompts hinders large-scale automation. To address these challenges, we propose a geometry-aware diffusion-guided SAM framework (GeoSAM) that transforms SAM into fully automated multimodal semantic segmentation through three synergistic innovations. First, we introduce a multiscale geometric-aware adaptation module (GeoAdapter) that hierarchically integrates RGB images with normalized digital surface model (nDSM) data within the encoder. GeoAdapter incorporates a novel class-prior generator that combines geometric convolution, prototype similarity matching, and statistical modeling to produce structure-aware guidance for semantic–geometric feature fusion. Second, we present a diffusion prompt module (DPM) that pioneers

the use of conditional diffusion models for automatic prompt generation in RS applications, eliminating manual interactions through semantic-feature-guided denoising diffusion implicit model (DDIM) sampling. Third, we propose a prompt-level supervision strategy (PLSS) that mitigates training–inference distribution discrepancies through constraints on semantic consistency and structural alignment, ensuring robust prompt generation across different phases. Extensive experiments demonstrate state-of-the-art performance: 90.92% mean accuracy (mAcc) and 82.71% mean intersection over union (mIoU) on Vaihingen, and 85.28% mAcc and 75.49% mIoU on Potsdam, with improvements of 16.52% mAcc and 16.29% mIoU over original SAM on Vaihingen. © 1980-2012 IEEE.

Adapting a classification rule to local and global shift when only unlabelled data are available

Item Type Journal Article**Author** V. Hofer

Abstract For evolving populations the training data and the test data need not follow the same distribution. Thus, the performance of a prediction model will deteriorate over the course of time. This requires the re-estimation of the prediction model after some time. However, in many applications e.g. credit scoring, new labelled data are not available for re-estimation due to verification latency, i.e. label delay. Thus, methods which enable a prediction model to adapt to distributional changes by using only unlabelled data are highly desirable. A shift adaptation method for binary classification is presented here. The model is based on mixture distributions. The conditional feature distributions are determined at the time where labelled data are available, and the unconditional feature distribution is determined at the time where new unlabelled data are accessible. These mixture distributions provide information on the old and the new positions of subpopulations. A transition model then describes how the subpopulations of each class have drifted to form the new unconditional feature distribution. Assuming that the conditional distributions are reorganised using a minimum of energy, a two-step estimation procedure results. First, for a given class prior distribution the transfer of probability mass is estimated such that the energy required to obtain the new unconditional distribution by a local transfer of the old conditional distributions is a minimum. Since the optimal solution of the resulting transportation problem measures the distance between the old and the new distributions, the change of the class prior distribution is found in a second step by solving the transportation problem for varying class prior distributions and selecting the value for which the objective function is a minimum. Using the solution of the transportation problem and the component parameters of the unconditional feature distribution, the new conditional feature distribution can be determined. This thus allows for a shift adaptation of the classification rule. The performance of the proposed model is investigated using a large real-world dataset on default rates in Danish companies. The results show that the shift adaptation improves classification results. © 2014 Published by Elsevier B.V.

Adapting a standardised international 24 h dietary recall methodology (GloboDiet software) for research and dietary surveillance in Korea

Item Type Journal Article**Author** M.K. Park**Author** J.Y. Park**Author** G. Nicolas**Author** H.Y. Paik**Author** J. Kim**Author** N. Slimani

Abstract During the past decades, a rapid nutritional transition has been observed along with economic growth in the KOR. Since this dramatic change in diet has been frequently associated with cancer and other non-communicable diseases, dietary monitoring is essential to understand the association. Benefiting from pre-existing standardised dietary methodologies, the present study aimed to evaluate the feasibility and describe the development of a Korean version of the international computerised 24 h dietary recall method (GloboDiet software) and its complementary tools, developed at the International Agency for Research on Cancer (IARC), WHO. Following established international Standard Operating Procedures and guidelines, about seventy common and country-specific databases on foods, recipes, dietary supplements, quantification methods and coefficients were customised and translated. The main results of the present study highlight the specific adaptations made to adapt the GloboDiet software for research and dietary surveillance in Korea. New (sub-) subgroups were added into the existing common food classification, and new descriptors were added to the facets to classify and describe specific Korean foods. Quantification methods were critically evaluated and adapted considering the foods and food packages available in the Korean market. Furthermore, a picture book of foods/dishes was prepared including new pictures and food portion sizes relevant to Korean diet. The development of the Korean version of GloboDiet demonstrated that it was possible to adapt the IARC-WHO international dietary tool to an Asian context without compromising its concept of standardisation and software structure. It, thus, confirms that this international dietary methodology, used so far only in Europe, is flexible and robust enough to be customised for other regions worldwide. © 2015 The Authors.

Adapting Classifiers to Changing Class Priors During Deployment

Item Type Conference Paper

Author N. Daba

Editor Silvestri F.

Abstract Conventional classifiers are trained and evaluated using “balanced” data sets in which all classes are equally present. Classifiers are now trained on large data sets such as ImageNet, and are now able to classify hundreds (if not thousands) of different classes. On one hand, it is desirable to train such general-purpose classifier on a very large number of classes so that it performs well regardless of the settings in which it is deployed. On the other hand, it is unlikely that all classes known to the classifier will occur in every deployment scenario, or that they will occur with the same prior probability. In reality, only a relatively small subset of the known classes may be present in a particular setting or environment. For example, a classifier will encounter mostly animals if its deployed in a zoo or for monitoring wildlife, aircraft and service vehicles at an airport, or various types

of automobiles and commercial vehicles if is used for monitoring traffic. Furthermore, the exact class priors are generally unknown and can vary over time. In this paper, we explore different methods for estimating the class priors based on the output of the classifier itself. We then show that incorporating the estimated class priors in the overall decision scheme enables the classifier to increase its run-time accuracy in the context of its deployment scenario. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2025.

Abstract Objective The present study describes the procedure and approaches needed to adapt and harmonise the GloboDiet methodology, a computer- and interview-based 24 h dietary recall, for use in two Latin American pilot countries, Brazil and Mexico. Design About seventy common and country-specific databases on foods, recipes, dietary supplements, quantification methods and coefficients were customised and translated following standardised guidelines, starting from existing Spanish and Portuguese versions. Setting Brazil and Mexico. Subjects Not applicable. Results New subgroups were added into the existing common food classification together with new descriptors required to better classify and describe specific Brazilian and Mexican foods. Quantification methods were critically evaluated and adapted considering types and quantities of food consumed in these two countries, using data available from previous surveys. Furthermore, the photos to be used for quantification purposes were identified for compilation in country-specific but standardised picture booklets. Conclusions The completion of the customisation of the GloboDiet Latin America versions in these two pilot countries provides new insights into the adaptability of this dietary international tool to the Latin American context. The ultimate purpose is to enable dietary intake comparisons within and between Latin American countries, support building capacities and foster regional and international collaborations. The development of the GloboDiet methodology could represent a major benefit for Latin America in terms of standardised dietary methodologies for multiple surveillance, research and prevention purposes. Abstract The standard supervised learning paradigm works effectively when training data shares the same distribution as the upcoming testing samples. However, this stationary assumption is often violated in real-world applications, especially when testing data appear in an online fashion. In this paper, we formulate and investigate the problem of online label shift (OLaS): the learner trains an initial model from the labeled offline data and then deploys it to an unlabeled online environment where the underlying label distribution changes over time but the label-conditional density does not. The non-stationarity nature and the lack of supervision make the problem challenging to be tackled. To address the difficulty,

we construct a new unbiased risk estimator that utilizes the unlabeled data, which exhibits many benign properties albeit with potential non-convexity. Building upon that, we propose novel online ensemble algorithms to deal with the non-stationarity of the environments. Our approach enjoys optimal dynamic regret, indicating that the performance is competitive with a clairvoyant who knows the online environments in hindsight and then chooses the best decision for each round. The obtained dynamic regret bound scales with the intensity and pattern of label distribution shift, hence exhibiting the adaptivity in the OLaS problem. Extensive experiments are conducted to validate the effectiveness and support our theoretical findings. © 2022 Neural information processing systems foundation. All rights reserved.

Adapting to the Unknown: Training-Free Audio-Visual Event Perception with Dynamic Thresholds

Item Type Conference Paper

Author E. Shaar

Author A. Shaulov

Author G. Chechik

Author L. Wolf

Abstract In the domain of audio-visual event perception, which focuses on the temporal localization and classification of events across distinct modalities (audio and visual), existing approaches are constrained by the vocabulary available in their training data. This limitation significantly impedes their capacity to generalize to novel, unseen event categories. Furthermore, the annotation process for this task is labor-intensive, requiring extensive manual labeling across modalities and temporal segments, limiting the scalability of current methods. Current state-of-the-art models ignore the shifts in event distributions over time, reducing their ability to adjust to changing video dynamics. Additionally, previous methods rely on late fusion to combine audio and visual information. While straightforward, this approach results in a significant loss of multimodal interactions. To address these challenges, we propose AudioVisual Adaptive Video Analysis (AV2A), a model-agnostic approach that requires no further training and integrates a score-level fusion technique to retain richer multimodal interactions. AV2A also includes a within-video label shift algorithm, leveraging input video data and predictions from prior frames to dynamically adjust event distributions for subsequent frames. Moreover, we present the first training-free, open-vocabulary baseline for audio-visual event perception, demonstrating that AV2A achieves substantial improvements over naive training-free baselines. We demonstrate the effectiveness of AV2A on both zero-shot and weakly-supervised state-of-the-art methods, achieving notable improvements in performance metrics over existing approaches. Adaptive Conformal Prediction for Quantum Machine Learning

Item Type Journal Article

Author D. Spencer

Author S. Nicholls

Author M. Caprio

Abstract Quantum machine learning seeks to leverage quantum computers to improve upon classical machine learning algorithms. Currently, robust uncertainty quantification methods remain underdeveloped in the quantum domain, despite the critical need for reliable and trustworthy predictions. Recent work has introduced quantum conformal prediction, a framework that produces prediction sets that are guaranteed to contain the true outcome with a user-specified probability. In this work, we formalise how the time-varying noise inherent in quantum processors can undermine conformal guarantees, even when calibration and test data are exchangeable. To address this challenge, we draw on Adaptive Conformal Inference, a method which maintains validity over time via repeated recalibration. We introduce Adaptive Quantum Conformal Prediction (AQCP), an algorithm which provides asymptotic average coverage guarantees under arbitrary hardware noise conditions. Empirical studies on an IBM quantum processor demonstrate that AQCP achieves the target coverage level and exhibits greater stability than quantum conformal prediction. © 2026, Transactions on Machine Learning Research. Adaptive Conformal Prediction Intervals Using Data-Dependent Weights With Application to Seismic Response Prediction

Item Type Journal Article

Author P. Hajibabae

Author F. Pourkamali-Anaraki

Author M.A. Hariri-Ardebili

Abstract Machine learning often lacks transparent performance indicators, especially in generating point predictions. This paper addresses this limitation through conformal prediction, a non-parametric forecasting technique seamlessly integrating with regression algorithms to produce prediction intervals at specified confidence levels. A crucial element in conformal prediction is the non-conformity score, traditionally based on absolute residual errors. In this work, we propose a novel approach, introducing data-dependent weights for computing non-conformity scores. This enhancement, considering the distances of training instances from the test sample, aims to improve overall algorithm performance. Empirical investigations across various real-world regression data sets, including scientific data, evaluate the efficiency and validity of prediction intervals from different uncertainty quantification methods. Results show that prediction intervals computed with data-dependent weights adapt to estimator uncertainty, offering more precise predictions in certain scenarios and appropriately conservative predictions in high uncertainty situations. Additionally, we compare predictive regions generated by conformal prediction with those from Gaussian Process Regression (GPR) for scientific data in structural engineering. To augment conformal prediction, we explore Conformalized Quantile Regression (CQR), a recent innovation combining conformal prediction with classical quantile regression, claiming full adaptability to heteroscedasticity. Our findings indicate that conformal prediction methods using data-dependent non-conformity scores achieve a 1% higher effective coverage level and a 15% reduction in prediction interval widths compared to other methods. The comparative analysis against GPR and CQR underscores the practical value of our approach in providing accurate prediction intervals in scientific and engineering domains. © 2013 IEEE.

Adaptive continual botnet detection with self-supervised prototypical networks and few-shot learning for evolving botnet detection

Item Type Journal Article

Author N. Junar

Author K. Arockiasamy

Abstract Introduction – One of the problems faced by botnet intrusion detection systems is the detection of unknown attacks or zero-day attacks. Zero-day attacks give security analysts very little time for action since there is only little information that is known about the new attack that is launched, given very few samples available for the training process. Class imbalance issues faced by many benchmark datasets also reduce the ability to detect a zero-day attack. It leads to very few samples of a particular class, which makes it difficult to trace different types of the same attack. The rapid evolution of botnets also poses a challenge to the existing models, which often fail to adapt to the new attack patterns without catastrophic forgetting of previously learned knowledge. Methods – The objective of this study was to develop a model for adaptive botnet detection in cases of zero-day attacks and imbalanced dataset availability. The study integrates self-supervised learning (SSL), enhanced prototypical networks with attention mechanisms, and few-shot learning (FSL) to overcome the existing issues. Wasserstein generative adversarial network with gradient penalty (WGAN-GP) generates synthetic samples to handle class imbalance. An adaptive continual learning module is used, which combines elastic weight consolidation (EWC) and an experience replay buffer which enables the model to accommodate new botnet behaviors while preserving performance on previously seen samples. Moreover, a drift detector using the KS test, Wasserstein distance, and class-prior shift triggers model adaptation when concept drift is identified. Results – The performance of the proposed model was evaluated on the CIC IoT dataset 2023, which demonstrated an exceptional accuracy of 98.50%, outperforming the traditional baselines. Few-shot learning evaluations show strong generalization with as few as 1–5 shots per class. This result shows the overall achievement of the model

in zero-day attack detection and real-time adaptation to the evolving botnet threats. Discussion – The findings demonstrate that the proposed framework provides an effective approach for zero-day botnet attack detection while maintaining knowledge of previously observed attacks. The combination of few-shot learning and adaptive continual learning improves the model's ability to respond to emerging botnet behaviours without requiring extensive retraining. Thus, the proposed approach shows potential for adaptive and real-time botnet detection in evolving IoT network environments. Copyright © 2026 Junar and Arockiasamy.

Adaptive learning of bayesian networks for the qualification of traffic data by contaminated dirichlet density functions

Item Type Conference Paper

Author M. Junghans

Author H.-J. Jentschel

Abstract The concept of Bayesian Networks (BNs) is an established method to model data fusion in sensor networks of several equal or different sensors. Although the method is powerful, there is a particular need for accurate sensors, the consideration of the affecting external, e.g. environmental conditions, and internal influences, e.g. the physical life of the sensor, in the sensor model and an accurate a-priori knowledge about the underlying process. In this paper an adaptive algorithm for learning BNs is introduced, which is applied to update the time-variant a-priori probabilities in sensor networks. This algorithm makes use of

Contaminated Dirichlet Density Functions (CDDFs). The effectiveness of adaptive learning is demonstrated for vehicle classification in traffic surveillance. © IEEE.

Adaptive learning of minority class prior to minority oversampling

Item Type Journal Article

Author P. Sadhukhan

Author S. Palit

Abstract The minority oversampling techniques have substantiated their appropriateness and utility in the domain of class-imbalance learning. However, this does not affirm the true class of the synthetic minority points. In this work, Adaptive Learning of Minority Class prior to Minority Oversampling (ALMCMO), we work towards bridging this gap by estimating the minority set before oversampling the synthetic points. We estimate a varying and adaptive volume of minority space around the minority points. We aim to guarantee the class-memberships of the synthetic minority points by sampling them from the estimated minority spaces. In our empirical study,

we have used six comparing methods, 23 datasets and two classifiers. The results indicate the certain superiority of the proposed method over the six competing schemes. © 2020

Adaptive real time traffic prediction using deep neural networks

Item Type Journal Article

Author P.R. Iyer

Author S.R. Iyer

Author R. Ramesh

Author M.R. Anala

Author K.N. Subramanya

Abstract The ever-increasing sale of vehicles and the steady increase in population density in metropolitan cities have raised many growing concerns, most importantly commute time, air and noise pollution levels. Traffic congestion can be alleviated by opting adaptive traffic light systems, instead of fixed-time traffic signals. In this paper, a system is proposed which can detect, classify and count vehicles passing through any traffic junction using a single camera (as opposed to multi-sensor approaches). The detection and classification are done using SSD Neural Network object detection algorithm. The count of each class (2-wheelers, cars, trucks, buses etc.) is used to

predict the signal green-time for the next cycle. The model self-adjusts every cycle by utilizing weighted moving averages. This system works well because the change in the density of traffic on any given road is gradual, spanning multiple traffic stops throughout the day. © 2019 Institute of Advanced Engineering and Science. Adaptive skew-sensitive ensembles for face recognition in video surveillance

Item Type Journal Article

Author M. De-La-Torre

Author E. Granger

Author R. Sabourin

Author D.O. Gorodnichy

Abstract Decision support systems for surveillance rely more and more on face recognition (FR) to detect target individuals of interest captured with video cameras. FR is a challenging problem in video surveillance due to variations in capture conditions, to camera interoperability, and to the limited representativeness of target facial models used for matching. Although adaptive classifier ensembles have been applied for robust face matching, it is often assumed that the proportions of faces captured for target and non-target individuals are balanced, known a priori, and do not change

over time. Recently, some techniques have been proposed to adapt the fusion function of an ensemble according to class imbalance of the input data stream. For instance, Skew-Sensitive Boolean combination (SSBC) is a active approach that estimates target vs. non-target proportions periodically during operations using Hellinger distance, and adapts its ensemble fusion function to operational class imbalance. Beyond the challenges of estimating class imbalance, such techniques commonly generate diverse pools of classifiers by selecting balanced training data, limiting the potential diversity produced using the abundant non-target data. In this paper, adaptive skew-sensitive ensembles are proposed to combine classifiers trained by selecting data with varying levels of imbalance and complexity, to sustain a high level the performance for video-to-video FR. Faces captured for each person in the scene are tracked and regrouped into trajectories. During enrollment, captures in a reference trajectory are combined with selected non-target captures to generate a pool of 2-class classifiers using data with various levels of imbalance and complexity. During operations, the level of imbalance is periodically estimated from the input trajectories using the HDx quantification method, and pre-computed histogram representations of imbalanced data distributions. This approach allows one to adapt pre-computed histograms and ensemble fusion functions based on the imbalance and complexity of operational data. Finally, the ensemble scores are accumulated of trajectories for robust spatio-temporal recognition. Results on synthetic data show that adapting the fusion function of ensemble trained with different complexities and levels of imbalance can significantly improve performance. Results on the Face in Action video data show that the proposed method can outperform reference techniques (including SSBC and meta-classification) in imbalanced video surveillance environments. Transaction-based analysis shows that performance is consistently higher across operational imbalances. Individual-specific analysis indicates that goat- and lamb-like individuals can benefit the most from adaptation to the operational imbalance. Finally, trajectory-based analysis shows that a video-to-video FR system based on the proposed approach can maintain, and even improve overall system discrimination. © 2015 Elsevier Ltd. ADBSCSL: adaptive DBSCAN-SMOTE with cost-sensitive learning to enhance diagnostic accuracy for imbalanced medical datasets

Item Type Journal Article

Author M. Kavitha

Author M. Kasthuri

Abstract Medical diagnosis is complicated by imbalanced datasets, in which biased models cannot distinguish minority class cases like rare diseases. To improve diagnosis accuracy, this research introduces ADBSCSL, which stands for adaptive DBSCAN-SMOTE with cost-sensitive learning. Adaptive DBSCAN, SMOTE, and cost-sensitive learning handle skewed data well. Adaptive DBSCAN clusters minority class occurrences. It changes parameters to dataset density change. The diversity of the density condition cannot have caused the minority class to misidentify. SMOTE is then applied to these clusters to increase synthetic examples and class balance. It reduces misclassification costs using cost-sensitive learning. This pushes the model toward minority class priority and avoids majority class bias. The approach was evaluated on brain stroke, cerebral stroke, and autism spectrum disorder datasets. ADBSCSL F1-scores of 91.8% and 90.6% indicate accuracy over 90% on brain stroke and cerebral stroke datasets. On ASD datasets, it had 100% accuracy, precision, recall, and F1-score. Results show that the ADBSCSL increases classification performance, making it a powerful and efficient tool for medicine diagnosis with highly imbalanced datasets. ADC-derived spatial features can accurately classify adnexal lesions

Item Type Journal Article

Author A. Fathi Kazerooni

Author H. Saligheh Rad

Abstract Background: The role of quantitative apparent diffusion coefficient (ADC) maps in differentiating adnexal masses is unresolved. Purpose/Hypothesis: To propose an objective diagnostic method devised based on spatial features for predicting benignity/malignancy of adnexal masses in ADC maps. Study Type: Prospective. Population: In all, 70 women with sonographically indeterminate and histopathologically confirmed adnexal masses (38 benign, 3 borderline, and 29 malignant) were considered for this study. Field Strength/Sequence: Conventional and diffusion-weighted magnetic resonance (MR) images (b-values = 50, 400, 1000 s/mm²) were acquired on a 3T scanner. Assessment: For each patient, two radiologists in consensus manually delineated lesion borders in whole ADC map volumes, which were consequently analyzed using spatial models (first-order histogram [FOH], gray-

level co-occurrence matrix [GLCM], run-length matrix [RLM], and Gabor filters). Two independent radiologists were asked to identify the attributed (benign/malignant) classes of adnexal masses based on morphological features on conventional MRI. Statistical Tests: Leave-one-out cross-validated feature selection followed by cross-validated classification were applied to the feature space to choose the spatial models that best discriminate benign from malignant adnexal lesions. Two schemes of feature selection/classification were evaluated: 1) including all benign and malignant masses, and 2) scheme 1 after excluding endometrioma, hemorrhagic cysts, and teratoma (14 benign, 29 malignant masses). The constructed feature subspaces for benign/malignant lesion differentiation were tested for classification of benign/borderline/malignant and also borderline/malignant adnexal lesions. Results: The selected feature subspace consisting of RLM features differentiated benign from malignant adnexal masses with a classification accuracy of ~92%. The same model discriminated benign, borderline, and malignant lesions with 87% and borderline from malignant with 100% accuracy. Qualitative assessment of the radiologists based on conventional MRI features reached an accuracy of 80%. Data Conclusion: The spatial quantification methodology proposed in this study, which works based on cellular distributions within ADC maps of adnexal masses, may provide a helpful computer-aided strategy for objective characterization of adnexal masses. Addressing class distribution issues of the drawing vs writing classification in an ink stroke sequence

Item Type Conference Paper**Author** X. Wang**Author** M. Biswas**Author** S. Raghupathy

Abstract Complicated by temporal correlations among the strokes and varying distributions of the underlying classes, the drawing/writing classification of ink strokes in a digital ink file poses interesting challenges. In this paper, we present our efforts in addressing some of the issues. First, we describe how we adjust the outputs of the neural network to a priori probabilities of new observations to produce more accurate estimates of the posterior probabilities. Second, we describe how to adapt the parameters of the HMM to new data sets. Albeit the fact that the emission probabilities of the HMM are computed indirectly from the outputs of the neural network, our modified Baum-Welch algorithm still finds the correct estimates for the HMM's parameters. We also present experimental results of our new algorithms on 6 real-world data sets. The results show that our methods increase the F-Measures of both the drawing and the writing classes on the more "drawing-intensive" data sets which have stronger temporal correlations. But they do not perform well on the more "writing-intensive" data sets. Copyright © 2007.

Addressing Dataset Shift for Trustworthy Deep Learning Diagnostic Ultrasound Decision Support

Item Type Journal Article

Author C. Zhu

Author M.D. Noseworthy

Author T.E. Doyle

Abstract Ultrasound (US) is the most widely used medical imaging modality due to its low cost, portability, real time imaging ability and use of non-ionizing radiation. However, unlike other imaging modalities such as CT or MRI, it is a heavily operator dependent, requiring trained expertise to leverage these benefits. Recently there has been an explosion of interest in AI across the medical community and many are turning to the growing trend of deep learning (DL) models to assist in diagnosis. However, due to possible differences in training and deployment, model performance suffers which can lead to misdiagnosis and operator hesitancy. This issue is known as dataset shift. Two aims to address dataset shift were proposed. The first was to quantify how US operator skill and hardware affects acquired images. The second was to use this skill quantification method to screen and match data to deep learning models to improve performance. A CAE Healthcare BLUE phantom with mock lesions was scanned by three operators using three different US systems (Siemens S3000, Clarius L15, and Ultrasonix SonixTouch) producing 39013 images. DL models were trained on a specific set to classify the presence of a simulated tumour and tested with data from differing sets. Principle Component Analysis (PCA) for dimension reduction was applied, then K-Means clustering was used to separate images generated by operator and hardware into clusters. This clustering algorithm was then used to screen incoming images during deployment to best match input to an appropriate DL model which is trained specifically to classify that type of operator or hardware. Results showed a noticeable difference when models were given data from differing datasets with the largest accuracy drop being 81.26% to 31.26%. Overall, operator differences more significantly affected DL model performance. Clustering models had much higher success separating hardware data compared to operator data. The proposed method reflects this result with a much higher accuracy across the hardware test set compared to the operator data. © 2023, The Author(s), under exclusive license to Springer-Verlag GmbH, DE, part of Springer Nature.

Addressing Measurement Error in Random Forests Using Quantitative Bias Analysis

Item Type Journal Article

Author T. Jiang

Author J.L. Gradus

Author T.L. Lash

Author M.P. Fox

Abstract Although variables are often measured with error, the impact of measurement error on machine-learning predictions is seldom quantified. The purpose of this study was to assess the impact of measurement error on the performance of random-forest models and variable importance. First, we assessed the impact of misclassification (i.e., measurement error of categorical variables) of predictors on random-forest model performance (e.g., accuracy, sensitivity) and variable importance (mean decrease in accuracy) using data from the National Comorbidity Survey Replication (2001-2003). Second, we created simulated data sets in which we knew the true

model performance and variable importance measures and could verify that quantitative bias analysis was recovering the truth in misclassified versions of the data sets. Our findings showed that measurement error in the data used to construct random forests can distort model performance and variable importance measures and that bias analysis can recover the correct results. This study highlights the utility of applying quantitative bias analysis in machine learning to quantify the impact of measurement error on study results. © 2021 The Author(s). Adjusting the outputs of a classifier to new a Priori probabilities: A simple procedure

Item Type Journal Article

Author M. Saerens

Author P. Latinne

Author C. Decaestecker

Abstract It sometimes happens (for instance in case control studies) that a classifier is trained on a data set that does not reflect the true a priori probabilities of the target classes on real-world data. This may have a negative effect on the classification accuracy obtained on the real-world data set, especially when the classifier's decisions are based on the a posteriori probabilities of class membership. Indeed, in this case, the trained classifier provides estimates of the a posteriori probabilities that are not valid for this real-world data set (they rely on the a priori probabilities of the training set). Applying the classifier as is (without correcting its outputs with respect to these new conditions) on this new data set may thus be suboptimal. In this note, we present a simple iterative procedure for adjusting the outputs of the trained classifier with respect to these new a priori probabilities without having to refit the model, even when these probabilities are not known in advance. As a by-product, estimates of the new a priori probabilities are also obtained. This iterative algorithm is a straightforward instance of the expectation-maximization (EM) algorithm and is shown to maximize the likelihood of the new data. Thereafter, we discuss a statistical test that can be applied to decide if the a priori class probabilities have changed from the training set to the real-world data. The procedure is illustrated on different classification problems involving a multilayer neural network, and comparisons with a standard procedure for a priori probability estimation are provided. Our original method, based on the EM algorithm, is shown to be superior to the standard one for a priori probability estimation. Experimental results also indicate that the classifier with adjusted outputs always performs better than the original one in terms of classification accuracy, when the a priori probability conditions differ from the training set to the real-world data. The gain in classification accuracy can be significant.

Abstract Resistant starch (RS) is a vital dietary component with notable health benefits, but tradition quantification methods are labor-intensive, costly, and unsuitable for large-scale applications. This study introduced an innovative data-driven framework integrating Near-Infrared (NIR) spectroscopy with Convolutional Neural Networks (CNN) and data augmentation to achieve rapid, cost-effective RS prediction. Achieving exceptional accuracy ($R_p^2 = 0.992$), the CNN model outperformed traditional methods like Partial Least Squares Regression (PLSR) and Support Vector Machine Regression (SVMR). To overcome the “black-box” limitation of deep learning, SHapley Additive exPlanations (SHAP) were innovatively employed, pinpointing critical wavelengths (2000–2500 nm), significantly narrowing the spectral range while providing meaningful insights into the contribution of specific wavelengths to RS prediction. This optimized spectral enhanced data acquisition efficiency, reduces analytical costs, and simplifies operational complexity, establishing a practical and scalable solution for deploying NIR spectroscopy in food quality assessment and production-line applications. © 2025 Elsevier Ltd

Advances in machine learning for the detection and characterization of microplastics in the environment

Item Type Journal Article

Author M.M. Khanam

Author M.K. Uddin

Author J.U. Kazi

Abstract Microplastics are increasingly recognized as a pervasive pollutant in both aquatic and terrestrial environments, raising pressing concerns about their ecological impacts and implications for human health. Traditional detection and quantification methods—including manual microscopy and standalone spectroscopic techniques—offer reliable accuracy but are limited by labor-intensive procedures and low throughput. Recent advances in machine learning (ML) have revolutionized the field of microplastic research by automating and enhancing detection processes. In particular, algorithms such as support vector machines, random forests, and convolutional neural networks have demonstrated considerable success in classifying microplastics based on chemical signatures and visual characteristics. This review offers a comprehensive overview of ML approaches utilized for monitoring microplastic contamination across diverse aquatic settings. Spectral techniques, including infrared and Raman spectroscopy, leverage molecular vibrations to facilitate highly specific identification of polymer types, even within heterogeneous matrices. Image-based methods make use of sophisticated computer vision techniques to classify microplastics by shape, size, and color, reducing the subjectivity inherent in manual counting. Extending these capabilities further, hyperspectral imaging combines spatial and spectral data to generate comprehensive chemical maps, enabling the simultaneous assessment of polymer composition and distribution. Integrating ML algorithms into these various approaches has improved sensitivity, speed, and scalability, thereby addressing critical challenges in high-throughput and real-time monitoring. Despite these advances, key obstacles remain, including the need for larger, higher-quality datasets and the development of robust models capable of handling complex environmental conditions. Nevertheless, ongoing improvements in imaging hardware and ML methodologies hold significant promise for establishing more effective, automated, and accurate strategies for microplastic detection. By providing a comprehensive overview of current technologies and future opportunities, this review aims to guide researchers and stakeholders in developing science-based solutions for mitigating the global threat of microplastic pollution. Advances in theoretical calculation of single-atom catalysts for electrochemical nitrogen reduction to ammonia

Item Type Journal Article

Author W. Gan

Author X. Zhang

Author Z. Ji

Author Y. Xue

Abstract Theoretical calculation is one of the important means to study the mechanism of catalytic reactions and design high-performance catalysts, which can not only visualize the electronic structure of the active sites and the adsorption configurations of reactants at atomic level, but also can quickly assess catalytic performance by simulating reaction paths, and significantly reduce development cycles and costs. In this paper, we systematically introduced the application of theoretical calculations in the research and development of electrochemical nitrogen reduction of ammonia synthesis (eNRR) with single-atom catalysts (SACs), including the study of the catalytic mechanisms, high-throughput screening of catalysts, and theoretical design of catalysts. The theoretical activities of eNRR single-atom catalysts on different supports were summarized, and the existing problems and development prospects in current research were discussed. Meanwhile multiple strategic approaches, such as optimizing high-throughput calculations, introducing multiscale simulations and

advanced quantification methods, and integrating machine learning techniques, were proposed to improve the screening efficiency and performance prediction of electrochemical catalysts, accelerate the precise construction and development of catalysts, and promote the industrialization process of eNRR. © (2025), (Huagong Jinzhan/Chemical Industry and Engineering Progress). Abstract Chronic liver disease poses significant challenges to healthcare systems, which frequently struggle to meet the needs of end-stage liver disease patients. Early detection and management are essential because liver damage and fibrosis are potentially reversible. However, the implementation of population-wide screenings is hindered by the asymptomatic nature of early chronic liver disease, along with the risks and costs associated with traditional diagnostics, such as liver biopsies. This study pioneers the development of innovative, minimally invasive methods capable of improving the outcomes of liver disease patients by identifying liver disease biomarkers using quantification methods with translational potential. A targeted mass spectrometry assay based on stable isotope standard protein epitope signature tags (SIS-PrESTs) was employed for the absolute quantification of 108 proteins in just two microliters of plasma. The plasma profiles were derived from patients of various liver disease stages and etiologies, including healthy controls. A set of potential biomarkers for stratifying liver fibrosis was identified through differential expression analysis and supervised machine learning. These findings offer promising alternatives for improved diagnostics and personalized treatment strategies in liver disease management. Moreover, our approach is fully compatible with existing technologies that facilitate the robust quantification of clinically relevant protein targets via minimally disruptive sampling methods. © 2025 by the authors.

Abstract Machine learning and artificial intelligence (ML/AI) methods have been used successfully in recent years to solve problems in many areas, including image recognition, unsupervised and supervised classification, game-playing, system identification and prediction, and autonomous vehicle control. Data-driven machine learning methods have also been applied to fusion energy research for over 2 decades, including significant advances in the areas of disruption prediction, surrogate model generation, and experimental planning. The advent of powerful and dedicated computers specialized for large-scale parallel computation, as well as advances in statistical inference algorithms, have greatly enhanced the capabilities of these computational approaches to extract scientific knowledge and bridge gaps between theoretical models and practical implementations. Large-scale commercial success of various ML/AI applications in recent years, including robotics, industrial processes, online image recognition, financial system prediction, and autonomous vehicles, have further demonstrated the potential for data-driven methods to produce dramatic transformations in many fields. These advances, along with the urgency of need to bridge key gaps in knowledge for design and operation of reactors such as ITER, have driven planned expansion of efforts in ML/AI within the US government and around the world. The Department of Energy (DOE) Office of Science programs in Fusion Energy Sciences (FES) and Advanced Scientific Computing Research (ASCR) have organized several activities to identify best strategies and approaches for applying ML/AI methods to fusion energy research. This paper describes the results of a joint FES/ASCR DOE-sponsored Research Needs Workshop on Advancing Fusion with Machine Learning, held April 30–May 2, 2019, in Gaithersburg, MD (full report available at https://science.osti.gov/-/media/fes/pdf/workshop-reports/FES_ASCR_Machine_Learning_Report.pdf). The workshop drew on broad representation from both FES and ASCR scientific communities, and

identified seven Priority Research Opportunities (PRO's) with high potential for advancing fusion energy. In addition to the PRO topics themselves, the workshop identified research guidelines to maximize the effectiveness of ML/AI methods in fusion energy science, which include focusing on uncertainty quantification, methods for quantifying regions of validity of models and algorithms, and applying highly integrated teams of ML/AI mathematicians, computer scientists, and fusion energy scientists with domain expertise in the relevant areas. © 2020, The Author(s).

Advancing Gastrointestinal Cancer Risk Prediction With Patient-Centered
Machine Learning: Machine Learning Modeling Study

Item Type Journal Article

Author D. Baublyte

Author J. Lee

Author M. Gunathilake

Author J. Kim

Abstract Background: Gastrointestinal (GI) cancers are a significant health concern in South Korea. Recently, machine learning (ML) models have emerged as powerful tools to support early screening efforts and identify people at risk before disease onset. However, the low incidence of GI malignancies in prospective cohorts leads to severe class imbalance, often causing ML models to favor the majority “healthy” class at the expense of clinical sensitivity. Objective: This study aimed to evaluate class imbalance mitigation strategies and develop ML-based GI cancer risk prediction models using noninvasive and minimally invasive predictors linked to modifiable behavioral and metabolic risk factors. Methods: We analyzed a prospective cohort (n=7652) with 156 incident GI cancer cases (2%) identified over a 14-year follow-up period. The data were randomly split into training (5356/7652, 70%) and testing (2296/7652, 30%) sets. To address class imbalance while preserving observed population structure, we developed a patient-centered undersampling technique (PCUSTe) based on the logic of frequency-matched case-control studies. PCUSTe was compared with commonly used resampling approaches, including synthetic minority oversampling (SMOTE), adaptive synthetic sampling (ADASYN), and SMOTE with edited nearest neighbors (ENN). Six classifiers were implemented, including both batch and incremental training variants. To account for the prior shift introduced by resampling, probability correction was applied. Model performance was evaluated on the independent test set using a classification threshold equal to the observed event proportion (cumulative incidence) in the training data and then across thresholds reflecting incidence values between 1% and 5%. Primary performance metrics included sensitivity, specificity, Matthews correlation coefficient, and area under the receiver operating characteristic curve (AUC). Results: Models trained using PCUSTe demonstrated improved sensitivity compared with standard resampling techniques, particularly for more complex classifiers. The incrementally trained stochastic gradient descent model achieved the highest overall performance trained on PCUSTe data with a sensitivity of 0.77 (95% CI 0.64-0.89), specificity of 0.65 (95% CI 0.63-0.67), AUC of 0.77 (95% CI 0.70-0.84), and Matthews correlation coefficient of 0.12 (95% CI 0.08-0.16). In contrast, logistic regression achieved balanced performance without resampling (sensitivity 0.70, 95% CI 0.57-0.83; specificity 0.71, 95% CI 0.69-0.72; AUC 0.75, 95% CI 0.68-0.82). Our results showed that PCUSTe primarily enhanced sensitivity in more complex models at the expense of specificity. Conclusions: Integrating epidemiological principles, including covariate frequency matching and threshold selection based on the observed cumulative incidence in the training data, improved minority class detection in GI cancer risk prediction. However, model performance varied by algorithm, and in some cases, decision threshold adjustment alone achieved comparable or superior results to data resampling. These findings highlight the importance of carefully selecting imbalance mitigation strategies based on modeling objectives. The resulting models achieved sensitivity levels that may be suitable for early risk identification in cohort settings and could contribute to personalized risk stratification and targeted prevention or screening strategies. © Daina Baublyte, Jeonghee Lee, Madhawa Gunathilake, Jeongseon Kim.

Advancing Imbalanced Domain Adaptation: Cluster-Level Discrepancy Minimization With a Comprehensive Benchmark

Item Type Journal Article

Author J. Yang

Author J. Yang

Author S. Wang

Author S. Cao

Author H. Zou

Author L. Xie

Abstract Unsupervised domain adaptation methods have been proposed to tackle the problem of covariate shift by minimizing the distribution discrepancy between the feature embeddings of source domain and target domain. However, the standard evaluation protocols assume that the conditional label distributions of the two domains are invariant, which is usually not consistent with the real-world scenarios such as long-tailed distribution of visual categories. In this article, the imbalanced domain adaptation (IDA) is formulated for a more realistic scenario where both label shift and covariate shift occur between the two domains. Theoretically, when label shift exists, aligning the marginal distributions may result in negative transfer. Therefore, a novel cluster-level discrepancy minimization (CDM) is developed. CDM proposes cross-domain similarity learning to learn tight and discriminative clusters, which are utilized for both feature-level and distribution-level discrepancy minimization, palliating the negative effect of label shift during domain transfer. Theoretical

justifications further demonstrate that CDM minimizes the target risk in a progressive manner. To corroborate the effectiveness of CDM, we propose two evaluation protocols according to the real-world situation and benchmark existing domain adaptation approaches. Extensive experiments demonstrate that negative transfer does occur due to label shift, while our approach achieves significant improvement on imbalanced datasets, including Office-31, Image-CLEF, and Office-Home. © 2022 IEEE.

Abstract Emerging environmental contaminants (EECs) such as pharmaceuticals, pesticides, and industrial chemicals pose significant challenges for detection and identification due to their structural diversity and lack of analytical standards. Traditional targeted screening methods often fail to detect these compounds, making non-target analysis (NTA) using high-resolution mass spectrometry (HRMS) essential for identifying unknown or suspected contaminants. However, interpreting the vast datasets generated by HRMS is complex and requires advanced data processing techniques. Recent advancements in machine learning (ML) models offer great potential for enhancing NTA applications. As such, we reviewed key developments, including optimizing workflows using computational tools, improved chemical structure identification, advanced quantification methods, and enhanced toxicity prediction capabilities. It also discusses challenges and future perspectives in the field, such as refining ML tools for complex mixtures, improving inter-laboratory validation, and further integrating computational models into environmental risk assessment frameworks. By addressing these challenges, ML-assisted NTA can significantly enhance the detection, quantification, and evaluation of EECs, ultimately contributing to more effective environmental monitoring and public health protection. © 2025 The Authors

Advancing radiotherapy with deep Learning: A review of dose prediction models

Item Type Journal Article

Author P. Darkhor

Author B. Hashemi

Author A. Farajollahi

Author A. Jodeiri

Author A. Ghasemi

Abstract Background Artificial intelligence (AI), especially deep learning algorithms, holds significant promise in transforming radiation therapy by enabling more precise, personalized, and efficient treatment planning. In particular, deep learning models have demonstrated their utility in critical tasks such as dose prediction, helping to streamline complex processes and improve patient outcomes. Methods This paper provides a comprehensive review of recent research on deep learning applications for radiotherapy dose prediction, highlighting the architectures, datasets, and methodologies used. Results The review highlights the advancements in accuracy, efficiency, and robustness achieved by deep learning-based dose prediction models. These approaches help reduce treatment planning time and minimize human error, thereby improving clinical workflows. Conclusion Deep learning offers promising solutions to enhance radiotherapy dose delivery. Future research should focus on developing the generalized dose prediction models, multi-institutional validation frameworks, explainable AI approaches for clinical trust, real-time adaptation capabilities, uncertainty quantification methods, and strategies for handling rare anatomical variations. © 2026 Associazione Italiana di Fisica Medica e Sanitaria.

Advancing Skyborne Technologies and High-Resolution Satellites for Pasture Monitoring and Improved Management: A Review

Item Type Journal Article

Author M.G. Ogungbuyi

Author C. Mohammed

Author I. Ara

Author A.M. Fischer

Author M.T. Harrison

Abstract The timely and accurate quantification of grassland biomass is a prerequisite for sustainable grazing management. With advances in artificial intelligence, the launch of new satellites, and perceived efficiency gains in the time and cost of the quantification of remote methods, there has been growing interest in using satellite imagery and machine learning to quantify pastures at the field scale. Here, we systematically reviewed 214 journal articles published between 1991 to 2021 to determine how vegetation indices derived from satellite imagery impacted the type and quantification of pasture indicators. We reveal that previous studies have been limited by highly spatiotemporal satellite imagery and prognostic analytics. While the number of studies on pasture classification, degradation, productivity, and management has increased exponentially over the last five years, the majority of vegetation parameters have been derived from satellite imagery using simple linear regression approaches, which, as a corollary, often result in site-specific parameterization that become spurious when extrapolated to new sites or production systems. Few studies have successfully invoked machine learning as retrievals to understand the relationship between image patterns and accurately quantify the biophysical variables, although many studies have purported to do so. Satellite imagery has contributed to the ability to quantify pasture indicators but has faced the barrier of monitoring at the paddock/field scale (20 hectares or less) due to (1) low

sensor (coarse pixel) resolution, (2) infrequent satellite passes, with visibility in many locations often constrained by cloud cover, and (3) the prohibitive cost of accessing fine-resolution imagery. These issues are perhaps a reflection of historical efforts, which have been directed at the continental or global scales, rather than at the field level. Indeed, we found less than 20 studies that quantified pasture biomass at pixel resolutions of less than 50 hectares. As such, the use of remote sensing technologies by agricultural practitioners has been relatively low compared with the adoption of physical agronomic interventions (such as ‘no-till’ practices). We contend that (1) considerable opportunity for advancement may lie in fusing optical and radar imagery or hybrid imagery through the combination of optical sensors, (2) there is a greater accessibility of satellite imagery for research, teaching, and education, and (3) developers who understand the value proposition of satellite imagery to end users will collectively fast track the advancement and uptake of remote sensing applications in agriculture. © 2023 by the authors.

Adversarial confound regression and uncertainty measurements to classify heterogeneous clinical MRI in Mass General Brigham

Item Type Journal Article

Author M. Leming

Author S. Das

Author H. Im

Abstract In this work, we introduce a novel deep learning architecture, MUCRAN (Multi-Confound Regression Adversarial Network), to train a deep learning model on clinical brain MRI while regressing demographic and technical confounding factors. We trained MUCRAN using 17,076 clinical T1 Axial brain MRIs collected from Massachusetts General Hospital before 2019 and demonstrated that MUCRAN could successfully regress major confounding factors in the vast clinical dataset. We also applied a method for quantifying uncertainty across an ensemble of these models to automatically exclude out-of-distribution data in AD detection. By combining MUCRAN and the uncertainty quantification method, we showed consistent and significant increases in the AD detection accuracy for newly collected MGH data (post-2019; 84.6% with MUCRAN vs. 72.5% without MUCRAN) and for data from other hospitals (90.3% from Brigham and Women's Hospital and 81.0% from other hospitals). MUCRAN offers a generalizable approach for deep-learning-based disease detection in heterogenous clinical data. © 2023 Leming et al. Adversarial Open-Set Domain Adaptation for Cross-Condition Fault Diagnosis of Marine Gearboxes

Item Type Conference Paper

Author M. Xie

Author Y. Hao

Author Q. Yuan

Author X. Lu

Editor Linlin T.

Abstract The gearbox is a critical component of the ship propulsion system, and its health directly impacts operational safety and reliability. Conventional deep-learning-based diagnostic methods, however, struggle under cross-condition scenarios due to domain shift and the presence of unseen fault types. To address these challenges, we propose an Adversarial Open-Set Domain Adaptation (AOSDA) framework. AOSDA employs a dual-path adversarial training scheme: one path constructs and refines decision boundaries for known faults in both source and target domains, driving target-domain features into alignment; the other path actively pushes unknown-fault features away from these boundaries. We further incorporate evidential deep learning to quantify domain uncertainty and adaptively adjust the threshold for unknown-class detection, thereby enhancing robustness in high-noise environments. A ResNet-based time-frequency feature extractor captures both local and global signal characteristics. We evaluate AOSDA on six cross-condition transfer tasks drawn from two public bearing and gearbox vibration datasets, systematically comparing against four state-of-the-art baselines. Results show that AOSDA achieves the highest classification accuracy for both known and unknown faults (93.2% and 91.6%, respectively). t-SNE visualizations illustrate its synergistic effect on feature alignment and unknown-fault separation, and confusion-matrix analysis confirms high recall for unknown faults alongside high precision for known faults. The proposed method thus offers an effective solution for intelligent operation and maintenance of marine gearboxes under dynamic conditions and open set fault scenarios. © 2025 IEEE.

Adversarial Positive-Unlabeled Learning-Based Invasive Plant Detection in Alpine Wetland Using Jilin-1 and Sentinel-2 Imageries

Item Type Journal Article**Author** E. Zhu**Author** A. Samat**Author** E. Li**Author** R. Xu**Author** W. Li**Author** W. Li

Abstract Invasive plants (IPs) pose a significant threat to local ecosystems. Recent advances in remote sensing (RS) and deep learning (DL) significantly improved the accuracy of IP detection. However, mainstream DL methods often require large, high-quality labeled data, leading to resource inefficiencies. In this study, a deep learning framework called adversarial positive-unlabeled learning (APUL) was proposed to achieve high-precision IP detection using a limited number of target plant samples. APUL employs a dual-branch discriminator to constrain the class prior-free classifier, effectively harnessing information from positive-unlabeled data through the adversarial process and enhancing the accuracy of IP detection. The framework was

tested on very high-resolution Jilin-1 and Sentinel-2 imagery of Bayinbuluke grasslands in Xinjiang, where the invasion of *Pedicularis kansuensis* has caused serious ecological and livestock damage. Results indicate that the adversarial structure can significantly improve the performance of positive-unlabeled learning (PUL) methods, and the class prior-free approach outperforms traditional PUL methods in IP detection. APUL achieved an overall accuracy of 92.2% and an F1-score of 0.80, revealing that *Pedicularis kansuensis* has invaded 4.43% of the local plant population in the Bayinbuluke grasslands, underscoring the urgent need for timely control measures. © 2025 by the authors.

Abstract In this work, we propose an adversarial unsupervised domain adaptation (UDA) method under inherent conditional and label shifts, in which we aim to align the distributions w.r.t. both $p(x|y)$ and $p(y)$. Since labels are inaccessible in a target domain, conventional adversarial UDA methods assume that $p(y)$ is invariant across domains and rely on aligning $p(x)$ as an alternative to the $p(x|y)$ alignment. To address this, we provide a thorough theoretical and empirical analysis of the conventional adversarial UDA methods under both conditional and label shifts, and propose a novel and practical alternative optimization scheme for adversarial UDA. Specifically, we infer the marginal $p(y)$ and align $p(x|y)$ iteratively at the training stage, and precisely align the posterior $p(y|x)$ at the testing stage. Our experimental results demonstrate its effectiveness on both classification and segmentation UDA and partial UDA. © 2021 IEEE

Agnostically Learning Multi-Index Models with Queries

Item Type Conference Paper

Author I. Diakonikolas

Author V. Kotonis

Author C. Tzamos

Author N. Zarifis

Abstract We study the power of query access for the fundamental task of agnostic learning under the Gaussian distribution. In the agnostic model, no assumptions are made on the labels of the examples and the goal is to compute a hypothesis that is competitive with the best-fit function in a known class, i.e., it achieves error $\text{opt} + \epsilon$, where opt is the error of the best function in the class. We focus on a general family of Multi-Index Models (MIMs), which are d -variate functions that depend only on few relevant directions, i.e., have the form $G(Wx)$ for an unknown link function G and a $k \times d$ matrix W . Multi-index models cover a wide range of commonly studied function classes, including real-valued function classes such as constant-depth neural networks with ReLU activations, and Boolean concept classes such as intersections of halfspaces. Our main result shows that query access gives significant runtime improvements over random examples for agnostically learning both real-valued and Boolean-valued MIMs. Under standard regularity assumptions for the link function (namely, bounded variation or surface area), we give an agnostic query learner for MIMs with running time $O(k) \text{poly}(1/\epsilon) \text{poly}(d)$. In contrast, algorithms that rely only on random labeled examples inherently require $d \text{poly}(1/\epsilon)$ samples and runtime, even for the basic problem of agnostically learning a single ReLU or a halfspace. As special cases of our general approach, we obtain the following results: •For the class of depth- ℓ , width- S ReLU networks on $\mathbb{R}^d$, our agnostic query learner runs in time $\text{poly}(d) 2^{\text{poly}(\ell S/\epsilon)}$. This bound qualitatively matches the runtime of an algorithm by [1] for the realizable PAC setting with random examples. •For the class of arbitrary intersections of k halfspaces on $\mathbb{R}^d$, our agnostic query learner runs in time $\text{poly}(d) 2^{\text{poly}(\log(k)/\epsilon)}$. Prior to our work, no improvement over the agnostic PAC model complexity (without queries) was known, even for the case of a single halfspace. In both these settings, we provide evidence that the $2^{\text{poly}(1/\epsilon)}$ runtime dependence is required for proper query learners, even for agnostically learning a single ReLU or halfspace. Our algorithmic result establishes a strong computational separation between the agnostic PAC and the agnostic PAC+Query models under the Gaussian distribution for a range of natural function classes. Prior to our work, no such separation was known for any natural concept class - even for the case of a single halfspace, for which it was an

open problem posed by Feldman [2]. Our results are enabled by a general dimension-reduction technique that leverages query access to estimate gradients of (a smoothed version of) the underlying label function. © 2024 IEEE.

Abstract Every real-world scenario is now digitally replicated in order to reduce paperwork and human labor costs. Machine Learning (ML) models are also being used to make predictions in these applications. Accurate forecasting requires knowledge of these machine learning models and their distinguishing features. The datasets we use as input for each of these different types of ML models, yielding different results. The choice of an ML model for a dataset is critical. A loan risk model is used to show how ML models for a dataset can be linked together. The purpose of this study is to look into how we could use machine learning to quantify or forecast mortgage credit risk. This phrase refers to the process of evaluating massive amounts of data in order to derive useful information for making decisions in a variety of fields. If credit risk is considered, a method based on an examination of what caused and how mortgage credit risk affected credit defaults during the still-current economic crisis of 2021 will be tried. Various approaches to credit risk calculation will be examined, ranging from the most basic to the most complex. In addition, we will conduct a case study on a sample of mortgage loans and compare the results of three different analytical approaches, logistic regression, decision tree, and gradient boost to see which one produced the most commercially useful insights. © 2018 Tsinghua University Press.

AI-Powered Digital Twins for Building Energy Management: Modeling Frameworks, Validation and Uncertainty Quantification, Smart Grid Integration, and Deployment Roadmap

Item Type Journal Article

Author Ł. Łach

Abstract The global buildings and construction sector remains a dominant contributor to anthropogenic climate change, and deep decarbonization has positioned digital twin technology as a transformative pathway for intelligent building energy management. Despite considerable research momentum, the field lacks a coherent synthesis mapping AI capabilities onto the full digital twin lifecycle—from sensor-driven calibration through real-world deployment to district-scale operation. This review addresses this gap through six objectives: analyzing AI-enhanced modeling approaches for building digital twins; examining data infrastructure and interoperability requirements; evaluating validation, calibration, and uncertainty quantification practices; synthesizing real-world implementation evidence across diverse building typologies; assessing integration with renewable energy systems and smart grids; and identifying challenges, research gaps, and a strategic deployment roadmap. Physics-based, data-driven, and hybrid modeling strategies occupy distinct and complementary roles. Physics-informed surrogate models preserve thermodynamic interpretability while reducing computational overhead; deep learning architectures—including recurrent networks and reinforcement learning agents—deliver adaptive control; and federated learning frameworks enable privacy-preserving optimization across distributed building portfolios. Rigorous multi-metric validation aligned with established calibration standards proves essential for trustworthy deployment, while Bayesian and ensemble-based uncertainty quantification methods emerge as indispensable components of operationally credible digital twins. Evidence from real-world deployments in residential, commercial, healthcare, and industrial facilities confirms that AI-powered digital twins consistently deliver substantial energy savings and measurable improvements in occupant comfort. Scaling to district and urban levels introduces challenges in data governance, computational architecture, and multi-stakeholder coordination, yet federated digital twin frameworks are beginning to demonstrate viable pathways. The paper concludes with a decade-long strategic roadmap spanning technological maturation, market development, regulatory alignment, and decarbonization impact—positioning AI-enhanced digital twins not as incremental optimization tools, but as the foundational infrastructure for the coordinated transformation of the global building stock. © 2026 by the author.

ALEX: Towards Effective Graph Transfer Learning with Noisy Labels

Item Type Conference Paper**Author** J. Yuan**Author** X. Luo**Author** Y. Qin**Author** Z. Mao**Author** W. Ju**Author** M. Zhang

Abstract Graph Neural Networks (GNNs) have garnered considerable interest due to their exceptional performance in a wide range of graph machine learning tasks. Nevertheless, the majority of GNN-based approaches have been examined using well-annotated benchmark datasets, leading to suboptimal performance in real-world graph learning scenarios. To bridge this gap, the present paper investigates the problem of graph transfer learning in the presence of label noise, which transfers knowledge from a noisy source graph to an unlabeled target graph. We introduce a novel technique termed Balance Alignment and Information-aware Examination (ALEX) to address this challenge. ALEX first employs singular value decomposition to generate different views with crucial structural semantics, which help provide robust node representations using graph contrastive learning. To mitigate both label shift and domain shift, we estimate a prior distribution to build subgraphs with balanced label distributions. Building on this foundation, an adversarial domain discriminator is incorporated for the implicit domain alignment of complex multi-modal distributions. Furthermore, we project node representations into a different space, optimizing the mutual information between the projected features and labels. Subsequently, the inconsistency of similarity structures is evaluated to identify noisy samples with potential overfitting. Comprehensive experiments on various benchmark datasets substantiate the outstanding superiority of the proposed ALEX in different settings. © 2023 ACM.

Algorithmic statistics, prediction and machine learning

Item Type Conference Paper
Author A. Milovanov
Editor Vollmer H.
Editor Ollinger N.
Editor LIFO, Cedex 2, Orleans Universite d'Orleans
Abstract Algorithmic statistics considers the following problem: given a binary string x (e.g., some experimental data), find a "good" explanation of this data. It uses algorithmic information theory to define formally what is a good explanation. In

this paper we extend this framework in two directions. First, the explanations are not only interesting in themselves but also used for prediction: we want to know what kind of data we may reasonably expect in similar situations (repeating the same experiment). We show that some kind of hierarchy can be constructed both in terms of algorithmic statistics and using the notion of a priori probability, and these two approaches turn out to be equivalent (Theorem 5). Second, a more realistic approach that goes back to machine learning theory, assumes that we have not a single data string x but some set of "positive examples" $x_1, \dots, x_l$ that all belong to some unknown set A , a property that we want to learn. We want this set A to contain all positive examples and to be as small and simple as possible. We show how algorithmic statistic can be extended to cover this situation (Theorem 11). © Alexey Milovanov; licensed under Creative Commons License CC-BY.

Aligning Evaluation with Clinical Priorities: Calibration, Label Shift, and Error Costs

Item Type Conference Paper

Author G.A. Flores

Author A.H. Smith

Author J.A. Fukuyama

Author A.C. Wilson

Abstract Machine learning-based decision support systems are increasingly deployed in clinical settings, where probabilistic scoring functions are used to inform and prioritize patient management decisions. However, widely used scoring rules, such as accuracy and AUC-ROC, fail to adequately reflect key clinical priorities, including calibration, robustness to distributional shifts, and sensitivity to asymmetric error costs. In this work, we propose a principled yet practical evaluation framework for selecting calibrated thresholded classifiers that explicitly accounts for uncertainty in class prevalences and domain-specific cost asymmetries. Building on the theory of proper scoring rules, particularly the Schervish representation, we derive an adjusted variant of cross-entropy (log score) that averages cost-weighted performance over clinically relevant ranges of class balance. The resulting evaluation is simple to apply, sensitive to clinical deployment conditions, and designed to prioritize models that are both calibrated and robust to real-world variations. © 2025 Neural information processing systems foundation. ALM-PU: positive and unlabeled learning with constrained optimization

Item Type Journal Article**Author** J. Wei**Author** Y. Wu**Author** B. Shi**Author** K. Li**Author** B. Dong

Abstract Positive and Unlabeled Learning (PUL) is a special semi-supervised learning paradigm trained on datasets comprising positive and unlabeled samples, and it is widely applied in many real-world applications. Due to the lack of reliable labeled negative samples, PUL is much more challenging than traditional semi-supervised learning. Previous works primarily focus on two fronts: applying varying loss weights for different samples or leveraging algorithms to construct auxiliary datasets with reliable labels. Despite the impressive performance the previous works have already achieved, they are still faced with the challenge of negative classification bias, while struggling to get rid of the need for class prior knowledge. In this paper, we have transformed the PUL task into a constrained optimization problem, and propose a new PUL framework to solve it, namely ALM-PU. More detailed, our ALM-PU aims to minimize the classifier's classification loss on reliable labeled set as the ultimate optimization goal, while subject to the constraint of reducing the cost on the unlabeled set to a certain extent. Subsequently, ALM-PU integrates the primary objective with the constraints to construct the PUL-constrained optimization framework, and implement it in the neural network structure. During the training process, our approach corrects the model's negative classification bias, achieving superior classification performance compared to previous methods. Additionally, a prediction sequence-based algorithm is utilized to aid the classifier in better distinguishing positive from negative samples with training results. We conducted extensive experiments on multiple PUL benchmarks. ALM-PU achieves an average improvement of 2% in key metrics, attaining state-of-the-art performance. These findings validate the effectiveness of our ALM-PU approach. Complete code and more experimental details can be found at ALM-PU. © The Author(s), under exclusive licence to Springer Science+Business Media LLC, part of Springer Nature 2025.

Alterations of Bile Acids and Gut Microbiota in Obesity Induced by High Fat Diet in Rat Model

Item Type Journal Article

Author H. Lin

Author Y. An

Author H. Tang

Author Y. Wang

Abstract Obesity has become a worldwide health issue and has attracted much public attention. In the current study, we aim to elucidate the roles of bile acids and their associations with gut microbiota during obesity development, employing high fat diet (HFD)-induced obesity in a rat model. We collected feces and plasma, liver tissues, and segments of intestinal tissues and a developed bile acids quantification method by employing an ultraperformance liquid chromatography coupled with mass spectrometry detection (UPLC-MS) strategy. We then assessed bile acids fluxes in the biological matrixes collected. We found that, irrespective of dietary regimes, taurine-conjugated bile acids were the dominant species in the liver whereas unconjugated bile acids were in plasma. However, HFD caused slight increases in the total bile acids pool and particularly the increases in the levels of deoxycholic acid (DCA) (138.67 ± 37.225 nmol/L in control group, 242.61 ± 43.16 nmol/L in HFD group, $p = 0.014$) and taurodeoxycholic acid (TDCA) (2.8 ± 0.247 nmol/g in control group, 4.5 ± 0.386 nmol/g in HFD group, $p = 0.0018$) in plasma and liver tissues, respectively, which were consistent with the increased levels of DCA in intestinal tissues and feces. These changes are correlated to an increase in abundance of genera *Blautia*, *Coprococcus*, *Intestinimonas*, *Lactococcus*, *Roseburia*, and *Ruminococcus*. Our investigation revealed the fluxes of bile acids and their association with gut microbiota during obesity development and explicated unfavorable impact of HFD on health. © 2019 American Chemical Society.

An accurate quantitative method for NdFeB magnetism based on laser-induced breakdown spectroscopy

Item Type Journal Article

Author G. Chen

Author J. Chen

Author D. Qu

Author G. Yang

Author H. Sun

Abstract NdFeB magnetic materials are widely used in daily life, such as in permanent magnet motors, loudspeakers and computer disks. The NdFeB magnetic material has excellent magnetic properties, and its magnetic properties are also the key to judge the production quality of NdFeB. Therefore, the precise quantification of the magnetic properties of NdFeB magnetic materials is crucial. Laser induced breakdown spectroscopy (LIBS) is a technique to obtain the spectrum of chemical

elements by excitation of plasma on the surface of a sample with a high energy laser. In this paper, a precise classification and magnetic quantification method for NdFeB magnetic materials based on laser-induced breakdown spectroscopy is designed, which is different from the traditional direct magnetic property detection method and uses element detection to quantitatively analyze the magnetic properties indirectly. A laser-induced breakdown spectroscopy system was used to collect the characteristic spectrum of NdFeB magnetic materials, and the sliding window minimum removal base method was independently designed to further optimize the detection accuracy. A classification model and quantitative analysis method model were further established and optimized. The random forest method was used to preliminarily classify NdFeB magnetic materials, and the GA-ELM method was used to conduct quantitative analysis of magnetic properties. Quantitative magnetic properties include Br, Hcj, Hcb and (BH)max. The error analysis of the final quantitative analysis is as follows: RMSE of Br reaches 0.0001526, RMSE of Hcj reaches 0.0001937, RMSE of Hcb reaches 0.00197, and RMSE of (BH)max reaches 0.00785. It is verified that the magnetic quantification method for NdFeB magnetic materials based on laser-induced breakdown spectroscopy can effectively conduct accurate quantitative analysis of the magnetic properties of NdFeB magnetic materials and provide a fast, convenient, accurate and economical detection method for the quality control of magnetic materials workshops. © 2025 The Royal Society of Chemistry.

Abstract Pancreatic volume and fat fraction are critical prognoses for metabolic diseases like type 2 diabetes (T2D). Magnetic Resonance Imaging (MRI) is a required non-invasive quantification method for the pancreatic fat fraction. The dramatic development of deep learning has enabled the automatic measurement of MR images. Therefore, based on MRI, we intend to develop a deep convolutional neural network (DCNN) that can accurately segment and measure pancreatic volume and fat fraction. This retrospective study involved abdominal MR images from 148 diabetic patients and 246 healthy normoglycemic participants. We randomly separated them into training and testing sets according to the proportion of 80:20. There were 2364 recognizable pancreas images labeled and pre-treated by an upgraded superpixel algorithm for a discernible pancreatic boundary. We then applied them to the novel DCNN model, mimicking the most accurate and latest manual pancreatic segmentation process. Fat phantom and erosion algorithms were employed to increase the accuracy. The results were evaluated by dice similarity coefficient (DSC). External validation datasets included 240 MR images from 10 additional patients. We assessed the pancreas and pancreatic fat volume using the DCNN and compared them with those of specialists. This DCNN employed the cutting-edge idea of manual pancreas segmentation and achieved the highest DSC (91.2%) compared with any reported models. It is the first framework to measure intra-pancreatic fat volume and fat deposition. Performance validation reflected by regression R2 value between manual operation and trained DCNN segmentation on the pancreas and pancreatic fat volume were 0.9764 and 0.9675, respectively. The performance of the novel DCNN enables accurate pancreas segmentation, pancreatic fat volume, fraction measurement, and calculation. It achieves the same segmentation level of experts. With further training, it may well surpass any expert and provide accurate

measurements, which may have significant clinical relevance. © 2022 by the authors.

Abstract We introduce a new and efficient solution to the Positive and Unlabeled (PU) problem which is tailored specifically for a deep learning framework. We demonstrate the merit of this method using image classification. When only positive and unlabeled images are available for training, our custom loss function,

paired with a simple linear transform of the output, results in an inductive classifier where no estimate of the class prior is required. This algorithm, known as the aaPU (Adaptive Asymmetric Positive Unlabeled) algorithm, provides near supervised classification accuracy with very low levels of labeled data on several image benchmark sets. aaPU demonstrates significant performance improvements over current state-of-the-art positive unlabeled learning algorithms. © 2023 SPIE.

Abstract Intelligent Transportation System (ITS) is an integral part for efficiently and effectively managing road-transport network in metros and smart cities. ITS provides several important features including public transportation management, route information, safety and vehicle control, electronic timetable and payment system etc. In this paper, we have designed and developed an adaptive video-based vehicle detection, classification, counting, and speed-measurement tool using Java programming language and OpenCV for real-time traffic data collection. It can be used for traffic flow monitoring, planning, and controlling to manage transport network as part of implementing intelligent transport management system in smart cities. The proposed system can detect, classify, count, and measure the speed of vehicles that pass through on a particular road. It can extract traffic data in csv/xml format from real-time video and recorded video, and then send the data to the central data-server. The proposed system extracts image frames from video and apply a filter based on the user-defined threshold value. We have applied MOG2 background subtraction algorithm for subtracting background from the object, which separates foreground objects from the background in a sequence of image frames. The proposed system can detect, classify, and count vehicles of different types and size as a plug play system. We have tested the proposed system at six locations under different traffic and environmental conditions in Dhaka city, which is the capital of Bangladesh. The overall average accuracy is above 80% for classifying all types of vehicles in Dhaka city. © 2019 IEEE.

Editor Bhatt N.

Editor Kitsing M.

Abstract Obesity is another common health issue that doesn't care about a person's gender and has gained attention in recent years. Future prevalence estimations made by the WHO indicate that threshold levels of obesity and overweight will impact more than 50% of the world's population by 2030. This increasing health issue illustrates the importance of preventive measures and the timely discovery of any possible causes. The present instruments are restricted mainly to simple BMI computation and exclude vital factors such as family history, exercise regimen, genealogy, and other related factors. This work introduces an original computational intelligence model for integrated assessment and prediction of obesity threats. Our method utilizes high-level algorithms, namely SVM, RF, and XGB algorithms, that have been enriched with precise pre-processing strategies such as removing outliers, handling missing and duplicate data, and scaling. In addition, measures such as univariate and multivariate analyses were conducted on the different variables to understand the obesity factors better. Random searches for the hyperparameters further enhanced the capability of the proposed method in optimizing the models with substantial improvements in the spheres of predictive precision. The tuned XGB model achieved the highest accuracy of 97.61%. This research is helpful for the fight against obesity as it employs computerized analyses to shed light on the diverse aspects of obesity and enhance approaches to its early diagnosis. © The Author(s), under exclusive license to Springer Nature Singapore Pte Ltd. 2025.

Abstract The blood and lymphatic vasculature networks are not yet fully understood even in mouse because of the inherent limitations of imaging systems and quantification methods. This study aims to evaluate the usefulness of the tissue-clearing technology for visualizing blood and lymphatic vessels in adult mouse. Clear, unobstructed brain/body imaging cocktails and computational analysis (CUBIC) enables us to capture the high-resolution 3D images of organ- or area-specific vascular structures. To evaluate these 3D structural images, signals are first classified from the original captured images by machine learning at pixel base. Then, these classified target signals are subjected to topological data analysis and non-homogeneous Poisson process model to extract geometric features. Consequently, the structural difference of vasculatures is successfully evaluated in mouse disease models. In conclusion, this study demonstrates the utility of CUBIC for analysis of vascular structures and

presents its feasibility as an analysis modality in combination with 3D images and mathematical frameworks. © 2022, The Author(s).

Abstract Accurate surveillance of the COVID-19 pandemic can be weakened by under-reporting of cases, particularly due to asymptomatic or pre-symptomatic infections, resulting in bias. Quantification of SARS-CoV-2 RNA in wastewater can be used to infer infection prevalence, but uncertainty in sensitivity and considerable variability has meant that accurate measurement remains elusive. Here, we use data from 45 sewage sites in England, covering 31% of the population, and estimate SARS-CoV-2 prevalence to within 1.1% of estimates from representative prevalence surveys (with 95% confidence). Using machine learning and phenomenological models, we show that differences between sampled sites, particularly the wastewater flow rate, influence prevalence estimation and require careful interpretation. We find that SARS-CoV-2 signals in wastewater appear 4–5 days earlier in comparison to clinical testing data but are coincident with prevalence surveys suggesting that wastewater surveillance can be a leading indicator for symptomatic viral infections. Surveillance for viruses in wastewater complements and strengthens clinical surveillance, with significant implications for public health. © 2022, Crown.

Author	J. Zhang
Author	S. Wang
Abstract	Construction and demolition waste (CDW) management remains a pressing challenge in the construction industry, contributing significantly to environmental degradation and resource depletion. Accurate waste measurement is essential for improving resource recovery and circular economy adoption. However, existing research lacks standardised estimation methods, the integration of digital technologies, and comprehensive lifecycle analysis approaches, limiting the effectiveness of waste prediction and management strategies. This study addresses the gap by conducting a scientometric analysis using CiteSpace and SciMAT, examining research trends, thematic clusters, and knowledge evolution in CDW quantification and management from 2014 to 2024. It establishes a conceptual framework for integrating digital systems and sustainable practices in CDW, focusing on waste generation rate, carbon emission, and phase-based waste management analysis. Network cluster analysis

reveals the integral role of estimation tools and modelling techniques in refining waste generation quantification for building constructions. It also examines the interplay of digital tools, their influence on environmental cost reduction, and factors affecting waste production and environmental protection across project phases. This conjugate approach highlights the importance of the successful implementation of waste quantification and the imperative of machine learning for further investigation. This review offers an evidence-based framework to identify key stakeholders, guide future research, and implement sustainable waste management policies. © 2025 by the authors.

An Application-Oriented Process Model for Selecting Uncertainty Quantification Methods in Machine Learning

Item Type Conference Paper

Author N. Holderied

Author S. Hörtling

Author K. Bause

Author T. Düser

Abstract Uncertainty quantification (UQ) is increasingly recognized as essential when machine learning (ML) is employed in domains that are safety-relevant, cost-intensive, or legally binding, such as the product engineering of battery electric vehicle (BEV) energy systems. UQ methods aim to estimate the aleatoric, epistemic or both uncertainties associated with the predictions of a machine learning model. However, the landscape of UQ methods is diverse and rapidly evolving, with no single approach proving optimal across all tasks. Consequently, the selection of methods in practice is often driven by experience, constrained by limited comprehensive knowledge, time, and implementation capacity. This paper introduces an application-oriented process model supporting data scientists in selecting UQ methods in ML by adapting the SPALTEN [1] problem-solving methodology and the Algorithm Selection Process Model (ASPM) into an Algorithm Selection Process Model for Uncertainty Quantification (UQ-ASPM). This model can be integrated into the modeling phase of a data mining process, such as the Cross Industry Standard Process for Data Mining (CRISP-DM). Ethnographic observations and expert interviews conducted within the research environment of BEV energy system development were analyzed using inductive qualitative content analysis to identify practical barriers, motivations, and requirements. The resulting process translates task requirements and boundary conditions into UQ-specific criteria, primarily including the source of uncertainty, integration depth, and output type. It employs a funnel-like narrowing from method families to candidate algorithms and utilizes a transparent evaluation matrix with weighted criteria, consequence analysis, and learning through a continuous information pool. An illustrative predictive-maintenance example demonstrates the instantiation of the process when an existing deterministic ML model must be retained. The contribution is made at a meta-level, facilitating structured navigation of the method space rather than providing a direct comparison of individual UQ algorithms. © 2026 SAE International. An assessment of adding value of traffic information and other attributes as part of its classifiers in a data mining tool set for predicting surface ozone levels

Item Type Journal Article

Author A. Nawahda

Abstract This study seeks to examine to what extent traffic information can improve the prediction of surface ozone levels from mobile sources when coupled with a state of the art air quality monitoring system and the application of data mining tools. For the purpose of the experiment an open-path Differential Optical Absorption Spectroscopy (DOAS) instrument is used and 10 min video samples obtained from Sohar's main highway (SHW) (Sultanate of Oman). This traffic information is collated to recognize, classify, and count three types of vehicles passenger car; light duty vehicle; and heavy duty vehicle. The DOAS is deployed to measure the following gases; ambient nitrogen dioxide (NO₂); ozone (O₃); sulfur dioxide (SO₂); and BTX (benzene, toluene, xylene) across SHW. The ambient concentrations of these gases are measured in situ at time resolutions that vary from 30 s to 1 min along with simultaneous measurements of meteorological parameters. The Waikato Environment for Knowledge Analysis (WEKA) (Witten and Frank, 2005) software was used for the data mining part of the study. To identify which classifiers in WEKA would be the most suitable in predicting surface O₃ levels the following five indexes were used: correlation coefficient (CC); mean absolute error (MAE); root mean square error (RMSE); relative absolute error (RAE); and root relative squared error (RRSE). It was found that the Bagging and M5P classifiers were the most robust when compared to others within the software when measured against the five indexes. It was identified that with the additions of time and day of the week as well as changing of the parameters as part of the classifiers in WEKA the robustness of the predictions was not enhanced significantly. However, the findings did illustrate that the analysis of traffic information does improve the robustness of the prediction of surface O₃ levels. © 2015 The Institution of Chemical Engineers. An automatic segmentation and quantification method for austenite and ferrite phases in duplex stainless steel based on deep learning

Item Type Journal Article

Author L. Che

Author Z. He

Author K. Zheng

Author X. Xu

Author F. Zhao

Abstract Traditional microstructural analysis and phase identification largely rely on manual efforts, inevitably affecting the consistency and accuracy of the results. Historically, the identification of ferrite and retained austenite phases and the extraction of grain information have predominantly been conducted by experts based on their experience. This process is not only time-consuming and labor-intensive but also prone to discrepancies due to the subjective nature of expert judgment. With the continuous advancement of deep learning technologies, new solutions for the classification and analysis of microstructures have emerged. This study proposes a microstructural segmentation method for dual-phase steel based on the Mask R-CNN deep learning model, which can quickly and accurately segment ferrite and retained austenite phases in dual-phase steel subjected to different heat treatment temperatures, enabling quantitative analysis of grain information. First, lightweight dual-phase steel is subjected to heat treatments at five different temperatures, and electron microscope images are obtained as training and testing data for the network. Through data preprocessing, annotation, and augmentation, a microstructural image dataset is constructed. Subsequently, the Mask R-CNN deep learning model is employed to recognize and segment the microstructural dataset of dual-phase steel. From the mask images output by the model, quantitative parameters such as the volume fraction and average grain size of ferrite and retained austenite are successfully extracted. Furthermore, the approach demonstrates high portability and

applicability, particularly relying on a small sample dataset. © 2025 The Royal Society of Chemistry.

An Efficient Arrhythmia Classifier Using Convolutional Neural Network with Incremental Quantification

Item Type Conference Paper

Author J. Huang

Author Z. Liu

Author H. Liu

Abstract Cardiovascular disease (CVD) is a dangerous disease, which can be effectively prevented by detecting arrhythmia early. In order to detect arrhythmia accurately, more and more researches use artificial intelligence methods to realize the classification and detection of electrocardiogram (ECG) signals. However, most of these designs are unfriendly to the hardware design due to too many parameters which lead to large calculation power and data accessing power. In

this paper, we present an efficient arrhythmia classifier based on the convolutional neural network with the incremental quantification. This more efficient design can classify ECG signals accurately with lower capacity of parameters. The simulation results show that the recognition rate of the network with the incremental quantification has reached 92.76% with 39.34KB memory footprint, which is beneficial to hardware design and has better accuracy than other advanced quantification methods. © Published under licence by IOP Publishing Ltd.

An Efficient Framework for Detecting Model Inversion Attacks in Connected Healthcare Systems

Item Type Journal Article

Author A. Malik

Author S.M. Qaisar

Author M.Z. Khan

Author M.N. Khan

Author T.H.H. Aldhyani

Author R.H. Alsisi

Abstract The rapid adoption of artificial intelligence (AI) in healthcare systems and consumer electronics is enhancing clinical decision-making and reshaping patient care. However, these advancements also raise serious security and privacy concerns, particularly model inversion attacks (MIAs), which reconstruct sensitive patient data from trained AI models. Addressing MIAs is essential to ensure trustworthiness and effectiveness of AI-driven healthcare solutions. To address these challenges, a novel four-stage detection framework is proposed to safeguard healthcare AI models against MIAs. Firstly, the data preprocessing and normalization layer eliminates the input noise and stabilizes the incoming query patterns. Onward, the behavioral feature extraction is carried out. It seeks to detect adversarial intent by profiling the temporal patterns as well as the irregularities found in the query behavior. Afterward, statistical anomaly scoring is applied using Mahalanobis distance learning to quantify deviations in query behavior. Lastly, an ensemble-based decision module, built on support vector machine and random forest classifiers, is used for the identification of MIAs. It combines anomaly scores and utilizes a threshold-based decision to accurately separate benign and possible MIA sessions while enhancing robustness against sophisticated attacks. Extensive experimental results on the NIH ChestXray14 and MIT-BIH datasets show that the proposed framework improves best-performing benchmarks in terms of precision by 1.5%, recall by 2.8%, F1-score by 1.18%, and AUROC by 2.23%, while reducing overhead by 9.09%. © 2026 IEEE.

An Efficient Intelligent Edge Diagnosis System Based on WDCNN in the Application of Equipment Fault Classification

Item Type Conference Paper

Author Q. Wu

Author X. Ding

Author Q. He

Author H. Xiang

Author H. Tan

Author Y. Shao

Abstract Edge computing has been extensively used in industries to solve problems such as data explosion. However, in the field of mechanical equipment fault diagnosis, there are still problems such as the large amount of data transmission and storage and the difficulty of applying intelligent algorithms to equipment edge fault diagnosis. Therefore, an intelligent edge diagnosis system (IEDS) is designed and applied to mechanical equipment fault diagnosis, which includes an edge diagnosis unit (EDU) and an edge network model. The EDU uses the STM32F405 chip as the core and acquires vibration signals by MEMS acceleration sensor. Using Deep convolutional neural networks with wide first-layer kernels (WDCNN) as the edge network model. Due to the limitation of hardware resources, this paper uses a fixed-point quantification method to minimize the hardware resource usage of WDCNN. The proposed method can efficiently implement the edge fault diagnosis of mechanical equipment, which is reflected by the fact that IEDS can be deployed directly at the edge of equipment to accomplish efficient data reduction and accurate fault diagnosis results output. The proposed method provides a new solution for intelligent fault diagnosis of mechanical equipment. © 2022 IEEE.

An Efficient Quantification Method Based on Feature Selection for High-Dimensional Uncertainties of Multistage Compressors

Item Type Journal Article**Author** J. Wang**Author** X. Zheng**Author** H. Yang**Author** Z. Sun**Author** Z. Song**Author** Y. Fu

Abstract Multistage compressors are widely used in aero-engines, gas turbines, and industrial compressors. However, many inevitable geometric/condition uncertainties will lead to low manufacturing qualified rate and severe performance degradation of multistage compressors. There might be hundreds of uncertainty variables simultaneously, so the "curse of dimensionality" problem has seriously constrained the uncertainty quantification (UQ) study in multistage compressors. In this paper, a feature selection method based on interpretable machine learning and bidirectional search is developed to reduce the dimensionality in a multistage compressor UQ study. The method is applied to a threestage compressor and reduces the uncertainties dimensionality from 292 to 41 and 66 for mass flow rate and efficiency prediction. Consequently, the required sample size is reduced from 1674 to 160 with the model accuracy almost unchanged. For the first time, this study realizes the UQ modeling study on the high dimensional problem of a multistage compressor. In addition, significant stage-by-

stage uncertainty propagation is found in the compressor. The last stage has the most significant efficiency deviation, which is significantly affected by the geometric uncertainty of the first two stages. Therefore, traditional studies, which usually simplify the multistage compressor UQ problem to a single cascade/row level, may seriously underestimate the uncertainty effect due to the neglect of stage-by-stage propagation. This study not only reveals the necessity for direct UQ study of multistage compressors but also reduces the computational cost, which lays a foundation for the uncertainty control of multistage compressors in engineering practice. © 2023 American Society of Mechanical Engineers (ASME). An Efficient Uncertainty Quantification Method Based on Inter-Blade Decoupling for Compressors

Item Type Journal Article

Author Y. Fu
Author J. Wang
Author D. Shi
Author K. Tang
Author J. Zhao

Abstract A compressor usually contains multiple blade rows, and its uncertainty dimensionality grows proportionally with the number of blade rows, leading to a rapid increase in required sample size for uncertainty quantification analysis. This paper proposes a new model decomposition method based on inter-blade decoupling, by analyzing uncertainty propagation in compressors. Traditionally, a surrogate model with uncertainty variables of all blade rows as input is directly established and the dimensionality is high. To solve this problem, this study decomposes the compressor domain into subdomains, each containing one blade row. For each subdomain, a submodel introduces aerodynamic uncertainties at the interfaces connecting different subdomains. The dimensionality of a submodel is roughly equal to the uncertainty factors in a single row, significantly reducing the required sample size. The uncertainties in the rotor and stator blade rows of a one-stage compressor are investigated to verify this method. Using principal component analysis and machine learning, the projection amplitudes of the interface aerodynamic flow field onto the principal modes are extracted, and submodels are established. Results show that the original 25-dimensional model can be decoupled into a 13-dimensional submodel for the rotor and a 16-dimensional submodel for the stator, reducing the required sample size from 600 to 90 with similar accuracy. This model decomposition method greatly reduces the cost of predicting compressor performance with uncertainty, laying a foundation for comprehensive analysis and effective control of uncertainty factors in engineering applications. © 2025 by ASME.

An Empirical Evaluation of Out-of-Distribution Detection Using Pretrained Language Models

Item Type Conference Paper

Author B. Yoon

Author J. Kim

Abstract In Natural Language Processing (NLP) tasks, detecting out-of-distribution (OOD) samples is essential to safely deploy a language model in real-world problems. Recently, several studies report that pre-trained language models (PLMs) accurately detect OOD data compared to LSTM, but we empirically find that PLMs show sub-par OOD detection performance when (1) OOD samples have similar semantic representation to indistribution (IND) samples and (2) PLMs are finetuned under data scarcity settings. To alleviate above issues, state-of-the-art uncertainty quantification (UQ) methods can be used, but the comprehensive analysis of UQ methods with PLMs has received little consideration. In this work, we investigate seven UQ methods with PLMs and show their effectiveness in the text classification task. © 2023 IEEE.

An Enhanced Fault Diagnosis Method with Uncertainty Quantification Using Bayesian Convolutional Neural Network

Item Type Conference Paper

Author Q. Fang

Author G. Xiong

Author X. Shang

Author S. Liu

Author B. Hu

Author Z. Shen

Abstract Fault diagnosis is a vital technique to pinpoint the machine malfunctions in manufacturing systems. In recent years, the deep learning techniques greatly improve the fault detection accuracy, but there still remain some problems. If one fault is absent in the training data or the fault signal is disturbed by severe noise interference, the fault classifier may misjudge the health state. This problem limits the reliability of the fault diagnosis in real applications. In this paper, we enhance the fault diagnosis method by using Bayesian Convolutional Neural Network (BCNN). A Shannon entropy-based method is presented to quantify the prediction uncertainty. The BCNN turns the deterministic predictions to probabilistic distributions and enhances the robustness of the fault diagnosis. The uncertainty quantification method helps to indicate the wrong predictions, detect unknown faults, and discover the strong disturbances. Then, a fine-tuning strategy is applied to enhance the model performance further. The potential usability of the proposed method in monitoring the motors of 3D printers is studied. And the experiment is conducted on a motor bearing dataset provided by Case Western Reserve University. The proposed BCNN achieves 99.82% fault classification accuracy over nine health conditions. Its robustness is verified by comparing the testing accuracy with three other methods on the noisy datasets. And the uncertainty quantification method successfully detects the outlier inputs. © 2020 IEEE.

An Equivalence Analysis of Binary Quantification Methods

Item Type Conference Paper

Author A. Castaño

Author J. Alonso

Author P. González

Author J.J. del Coz

Editor Williams B.

Editor Chen Y.

Editor Neville J.

Abstract Quantification (or prevalence estimation) algorithms aim at predicting the class distribution of unseen sets (or bags) of examples. These methods are useful for two main tasks: 1) quantification applications, for instance when we need to track the proportions of several groups of interest over time, and 2) domain adaptation problems, in which we usually need to adapt a previously trained classifier to a different –albeit related– target distribution according to the estimated prevalences. This paper analyzes several binary quantification algorithms showing that not only do they share a common framework but are, in fact, equivalent. Inspired by this study, we propose a new method that extends one of the approaches analyzed. After an empirical evaluation of all these methods using synthetic and benchmark datasets, the paper concludes recommending three of them due to their precision, efficiency, and diversity. Author R. Scherer

Author M. Hecht

Abstract Several AI-aided screening tools have emerged to tackle the ever-expanding body of literature. These tools employ active learning, where algorithms sort abstracts based on human feedback. However, researchers using these tools face a crucial dilemma: When should they stop screening without knowing the proportion of relevant studies? Although numerous stopping rules have been proposed to guide users in this decision, they have yet to undergo comprehensive evaluation. In this study, we evaluated the performance of three stopping rules: the knee method, a data-driven heuristic, and a prevalence estimation technique. We measured performance via sensitivity, specificity, and screening cost and explored the influence of the prevalence of relevant studies and the choice of the learning algorithm. We curated a dataset of abstract collections from meta-analyses across five psychological research domains. Our findings revealed performance differences between stopping rules regarding all performance measures and variations in the performance of stopping rules across different prevalence ratios. Moreover, despite the relatively minor impact of the learning algorithm, we found that specific combinations of stopping rules and learning algorithms were most effective for certain prevalence ratios of relevant abstracts. Based on these results, we derived practical recommendations for users of AI-aided screening tools. Furthermore, we discuss possible implications and offer suggestions for future research. © 2024 The Author(s). Research Synthesis Methods published by John Wiley & Sons Ltd.

Abstract Sangiran Early Man Site is a world heritage located in a peri-urban area in Sragen Regency, Central Java, Indonesia. Due to its significance, this 59.21 km² area is recognized as a valuable land. However, landslides persistently threaten its existence. The research intended to evaluate 1) the landslide susceptibility and 2) the vulnerability of the valuable lands in Sangiran Site. It applied the weights-of-evidence method to produce a landslide susceptibility map, which was further validated with field survey. The analysis output included five classes of susceptibility, namely, very low, low, moderate, high, and very high. The classification aimed to generate matrices containing indications of valuable lands in each class. The field survey found no landslides in very-low susceptible areas and several small ones in low susceptible areas. Landslides were found in valuable lands endangered with a moderate degree of landslides. Large but non-risky landslides were detected in highly susceptible areas, while large and risky ones were in very highly susceptible areas. Sangiran consists of 19 valuable lands that help to narrate geological and human evolution through fossils, scarcity, stratigraphy, and other unique features. For each land, a number is assigned to it to mark priority based its importance clues. Priority 13 was included in the low susceptibility class. While priorities 1, 5, 6, 7, 8, 12, 17, and 18 belonged to moderate susceptibility class, priorities 2, 3, 4, 9, 10, 11, 14, 15, 16, and 19 were classified into high susceptibility class. Therefore, Sangiran Site comprises

heterogeneous characteristics that make its valuable lands the subjects of protection against landslide occurrences. © Published under licence by IOP Publishing Ltd.

An extensible software platform for interdisciplinary cardiovascular imaging research

Item Type Journal Article

Author M. Huellebrand

Author D. Messroghli

Author L. Tautz

Author T. Kuehne

Author A. Hennemuth

Abstract Background and objective: Cardiovascular imaging is an exponentially growing field with aspects ranging from image acquisition and analysis to disease characterization, and evaluation of therapy approaches. The transfer of innovative new technological

and algorithmic solutions into clinical practice is still slow. In addition to the verification of solutions, their integration in the clinical processing workflow must be enabled for the assessment of clinical impact and risks. The goal of our software platform for cardiac image processing – CAIPI – is to support researchers from different specialties such as imaging physics, computer science, and medicine by a common extensible platform to address typical challenges and hurdles in interdisciplinary cardiovascular imaging research. It provides an integrated solution for method comparison, integrated analysis, and validation in the clinical context. The interface concept enables a combination with existing frameworks that address specific aspects of the pipeline, such as modeling (e.g., OpenCMISS, CARP) or image reconstruction (Gadgetron). **Methods:** In our platform, we developed a concept for import, integration, and management of cardiac image data. The integration approach considers the spatiotemporal properties of the beating heart through a specific data model. The solution is based on MeVisLab and provides functionalities for data retrieval and storage. Two types of plugins can be added. While ToolPlugins usually provide processing algorithms such as image correction and segmentation, AnalysisPlugins enable interactive data exploration and reporting. GUI integration concepts are presented for both plugin types. We developed domain-specific reporting and visualization tools (e.g., AHA segment model) to enable validation studies by clinical experts. The platform offers plugins for calculating and reporting quantitative parameters such as cardiac function, which can be used to, e.g., evaluate the effect of processing algorithms on clinical parameters. Export functionalities include quantitative measurements to Excel, image data to PACS, and STL models to modeling and simulation tools. **Results:** To demonstrate the applicability of this concept both for method development and clinical application, we present use cases representing different problems along the innovation chain in cardiac MR imaging. Validation of an image reconstruction method (MRI T1 mapping) Validation of an image correction method for real-time 2D-PC MRI Comparison of quantification methods for blood flow analysis Training and integration of machine learning solutions with expert annotations Clinical studies with new imaging techniques (flow measurements in the carotid arteries and peripheral veins as well as cerebral spinal fluid). **Conclusion:** The presented platform can be used in interdisciplinary teams, in which engineers or data scientists perform the method validation, followed by clinical research studies in patient collectives. The demonstrated use cases show how it enables the transfer of innovations through validation in the cardiovascular application context. © 2019

An improved classification scheme for chromosomes with missing data

Item Type Conference Paper

Author E. Poletti

Author A. Ruggeri

Author E. Grisan

Abstract Karyotyping, or the automatic classification of human chromosomes, is mostly based on the analysis of the chromosome specific banding pattern. Unfortunately, the most informative phases of the cell division cycle are composed of long chromosomes that easily overlap: the involved banding pattern information is corrupted, resulting in a drastic increase of the classification error. Assuming the availability of a probabilistic classifier, the improvement of the classification of chromosomes with corrupted data would require the additional estimation of the joint probability density of the observed and missing data for each chromosome class. Given the number of classes, the possible position and extension of the corrupted data within a chromosome, and the dimensionality of the feature space,

a reliable estimation would need an impossible number of training samples. We chose to circumvent the estimation problem by developing a statistical generative model of the pattern of each class, so that the corrupted part can be substituted with a partial pattern synthetically generated from the model. This allows to obtain a Monte Carlo estimate of the maximum a posteriori probability for the class given the observation and the missing data, which reduces to a simple voting scheme if the a priori probability for each class is equal. Moreover, this Monte Carlo classification is superior to the voting scheme based on the simple imputation of the classes mean to the missing data. © 2011 IEEE.

An Improved Method of Automated Nonparametric Content Analysis for Social Science

Item Type Journal Article

Author C.T. Jerzak

Author G. King

Author A. Strezhnev

Abstract Some scholars build models to classify documents into chosen categories. Others, especially social scientists who tend to focus on population characteristics, instead usually estimate the proportion of documents in each category - using either parametric classify-and-count methods or direct nonparametric estimation of proportions without individual classification. Unfortunately, classify-and-count methods can be highly model-dependent or generate more bias in the proportions even as the percent of documents correctly classified increases. Direct estimation avoids these problems, but can suffer when the meaning of language changes between training and test sets or is too similar across categories. We develop an improved direct estimation approach without these issues by including and optimizing continuous text features, along with a form of matching adapted from the causal inference literature. Our approach substantially improves performance in a diverse collection of 73 datasets. We also offer easy-to-use software that implements all ideas discussed herein. © 2022 The Author(s).

An improvement on learning with local and global consistency

Item Type Conference Paper

Author L. Gui

Author D.-S. Huang

Author Z. You

Abstract A modified version for semi-supervised learning algorithm with local and global consistency was proposed in this paper. The new method adds the label information, and adopts the geodesic distance rather than Euclidean distance as the measure of the difference between two data points when conducting calculation. In addition we add class prior knowledge. It was found that the effect of class prior knowledge was different between under high label rate and low label rate. The experimental results show that the changes attain the satisfying classification performance better than the original algorithms. © 2008 IEEE.

An incremental learning framework combining sample confidence and discrimination with an application to automatic image annotation

Item Type Conference Paper

Author B. Byun

Author C.-H. Lee

Abstract We propose an incremental classifier learning framework that starts with a small amount of labeled training data to create an initial set of classifiers, and gradually incorporates unlabeled data into the incremental learning process to improve the models. A key to the effectiveness of the proposed framework is to judiciously select a good incremental learning subset from all remaining unlabeled samples by computing a confidence measure and a margin-like discrimination score that measures potential contributions of the selection set to enhancing the existing models. To further refine the above selection set, class prior densities were also exploited. The proposed framework was tested on an automatic image annotation application using a subset of the Corel image set. When all data, including both initially labeled and incrementally learned samples, were used, the final model was shown to achieve a significant improvement over the initial set of classifiers in terms of micro-averaging F1 even when only a small number of images were initially labeled. Furthermore, when 30% of the images were initially labeled the incrementally learned models achieved comparable results to the case when models were created with all training data labeled. ©2009 IEEE.

An industrial equipment fault diagnosis method based on deep belief rule base fusing indicator uncertainty

Item Type Journal Article

Author X. Liu

Author H. Huang

Author Y. Li

Author X. Xie

Author R. Dai

Abstract Precise fault diagnosis under complex working conditions is critical for ensuring the safety of industrial equipment. The belief rule base (BRB), characterized by its interpretability and capability to handle nonlinear, small-sample data, is inherently suitable for such diagnostic tasks. However, traditional BRB methods are impeded by the combinatorial rule explosion derived from high-dimensional features and the uncertainty introduced by environmental noise. To address structural complexity and environmental uncertainty simultaneously, this paper proposes a deep BRB fault diagnosis method integrated with indicator uncertainty deep BRB uncertainty. First, the extreme gradient boosting algorithm is employed to evaluate feature importance and select key features, constructing a hierarchical deep inference topology. Second, a quantification method based on the average distance of monitoring data is proposed to extract the uncertainty of key indicators, establishing an inference mechanism that fuses this uncertainty. Third, the projected covariance matrix adaptation evolution strategy is utilized to jointly optimize the full parameter set of the model, thereby enhancing generalization performance. Finally, experimental validation is conducted using bearing and gearbox datasets. Results indicate that the proposed method outperforms traditional approaches in terms of comprehensive diagnostic performance, achieving higher fault classification accuracy and stronger robustness, thus validating its superiority in handling interference and uncertain environments. © 2026 IOP Publishing Ltd. An innovative methodology for detection and quantification of cracks through incorporation of depth perception

Item Type Journal Article

Author M.R. Jahanshahi

Author S.F. Masri

Author C.W. Padgett

Author G.S. Sukhatme

Abstract Visual inspection of structures is a highly qualitative method in which inspectors visually assess a structure's condition. If a region is inaccessible, binoculars must be used to detect and characterize defects. Although several Non-Destructive Testing methods have been proposed for inspection purposes, they are nonadaptive and cannot quantify crack thickness reliably. In this paper, a contact-less remote-sensing crack detection and quantification methodology based on 3D scene reconstruction (computer vision), image processing, and pattern recognition concepts is introduced. The proposed approach utilizes depth perception to detect cracks and quantify their thickness, thereby giving a robotic inspection system the ability to analyze images captured from any distance and using any focal length or resolution. This unique adaptive feature is especially useful for incorporating mobile systems, such as unmanned aerial vehicles, into structural inspection methods since it would allow inaccessible regions to be properly inspected for cracks. Guidelines are presented for optimizing the acquisition and processing of images, thereby enhancing the quality and reliability of the damage detection approach and allowing the capture of even the slightest cracks (e.g., detection of 0.1 mm cracks from a distance of 20 m), which are routinely encountered in realistic field applications where the camera-object distance and image contrast are not controllable. © 2011 Springer-Verlag.

An integrated hierarchical Gaussian mixture model to estimate vigilance level based on EEG recordings

Item Type Conference Paper

Author J.-N. Gu

Author H.-J. Liu

Author H.-T. Lu

Author B.-L. Lu

Abstract Effective vigilance level estimation can be used to prevent disastrous accident occurred frequently in high-risk tasks. Brain Computer Interface(BCI) based on ElectroEncephalo-Graph(EEG) is a relatively reliable and convenient mechanism to reflect one's psychological phenomena. In this paper we propose a new integrated approach to predict human vigilance level, which incorporate an automatically artifact removing pre-process, a novel vigilance quantification method and finally a hierarchical Gaussian Mixed Model(hGMM) to discover the underlying pattern of EEG signals. A reasonable high classification performance

(88.46% over 12 data sets) is obtained using this integrated approach. The hGMM is proved to be more powerful against Support Vector Machine(SVM) and Linear Discriminant Analysis(LDA) under complicated probability distributions. © 2011 Springer-Verlag.

An Integrated, Explainable and Uncertainty-Aware Satellite-Based Precipitation Product for the Mediterranean Region

Item Type Conference Paper

Author P. Kossieris

Author I. Tsoukalas

Author L. Brocca

Author H. Mosaffa

Author C. Makropoulos

Author A. Anghelea

Abstract Precipitation is a key variable of earth observation systems, involved in a wide spectrum of applications, from the optimal water resources management to early warning systems for flood/drought events. During the last decade, significant research effort has been given in the development of satellite-based precipitation products (SPPs), with improved accuracy and high spatio-temporal coverage. This work presents a methodological framework that couples machine learning and explainability techniques, along with uncertainty quantification methods, to develop a new SPP for the Mediterranean region. Specifically, the methodology couples: a) ensemble (tree-based) machine learning algorithms to merge multiple satellite-based observations (i.e., both precipitation and soil moisture-based products), b) global and local explainable AI techniques to provide explanations at the model and instance level, respectively, and c) a copula-based approach to quantify the predictive uncertainty of the final integrated product. The new product fuses data from two widely known low-latency SPPs, i.e., the SM2RAIN-ASCAT and GPM Late Run dataset, while its performance is assessed against state-of-art products, i.e., the EMO5, GPM Final Run, ERA5 and PERSIANN CDR. © 2024 IEEE.

Abstract Introduction: In 2011, the St. Gallen Consensus Conference introduced the use of pathology to define the intrinsic breast cancer subtypes by application of immunohistochemical (IHC) surrogate markers ER, PR, HER2 and Ki67 with a specified Ki67 cutoff (>14%) for luminal B-like definition. Reports concerning impaired reproducibility of Ki67 estimation and threshold inconsistency led to the initiation of this quality assurance study (2013–2015). The aim of the study was to investigate inter-observer variation for Ki67 estimation in malignant breast tumors by two different quantification methods (assessment method and count method) including measure of agreement between methods. Material and methods: Fourteen experienced breast pathologists from 12 pathology departments evaluated 118 slides from a consecutive series of malignant breast tumors. The staining interpretation was performed according to both the Danish and Swedish guidelines. Reproducibility was quantified by intra-class correlation coefficient (ICC) and Lights Kappa with dichotomization of observations at the larger than (>) 20% threshold. The agreement between observations by the two quantification methods was evaluated by Bland–Altman plot. Results: For the fourteen raters the median ranged from 20% to 40% by the assessment method and from 22.5% to 36.5% by the count method. Light's Kappa was 0.664 for observation by the assessment method and 0.649 by the count method. The ICC was 0.82 (95% CI: 0.77–0.86) by the assessment method vs. 0.84 (95% CI: 0.80–0.87) by the count method. Conclusion: Although the study in general showed a moderate to good inter-observer agreement according to both ICC and Lights Kappa, still major discrepancies were identified in especially the mid-range of observations. Consequently, for now Ki67 estimation is not implemented in the DBCG treatment algorithm. © 2017 Acta Oncologica Foundation.

An interpretable CNN model for NMR-based whole metabolomic profiling of sepsis

Item Type Journal Article

Author Z. Wang

Author X. Liu

Author Y. Shi

Author R. Wu

Author M. Jiang

Author B. Feng

Author C. Shen

Abstract NMR metabolomics faces critical sensitivity limitations when analyzing whole spectral profiles, particularly in clinical biomarker discovery where weak metabolite signals often elude detection. To address this challenge, we present NMR metabolomics convolutional neural network(NmCNN) as an interpretable 1D-

convolutional neural network framework that innovatively integrates spectral translation invariance with explainable AI. Our approach presents a novel concept distinct from traditional machine learning methods, and the incorporation of an interpreter exhibits a higher sensitivity in detecting differential metabolites. The model incorporates translation invariance from CNN, facilitating efficient processing of spectra and effectively addressing issues pertaining to deviations in spectral peak alignment. Validated on sepsis biomarker discovery for whole blood and blood platelet samples, NmCNN achieved 90–95 % sensitivity, 80 %-85 % specificity and area under curve 0.83–0.96. The interpretability framework with SHapley Additive exPlanations (SHAP) identified previously undetected metabolic features, demonstrating sensitivity improvement over conventional quantification methods through its whole-spectrum utilization. Overall, our NmCNN model offers a distinctive approach that enhances the utilization of raw NMR-based spectral metabolomics profiles in AI-driven clinical research, thereby improving interpretability and sensitivity in metabolomics analysis. © 2025

An Uncertainty Quantitative Method for Cell Image Classification under Label Shift

Item Type Conference Paper

Author L. Zhao

Author J. Yang

Abstract With the development of data-driven deep classification models for cervical cancer diagnosis, results with uncertain cell data are not credible. Uncertainty data limits the application of the deep model in medical scenarios. Cervical cells have the label shift problem between source and target domain images and this uncertainty problem puts forward new requirements for the robustness of the classification model. In this paper, we focus on the label shift uncertainty problem for different cervical cell image classification datasets and propose a control method that performs robust classification under the label shift uncertainty situation. Experiments show that the proposed method cannot reduce the classification performance while improving the robustness of the cell classification model. © 2024 Copyright held by the owner/author(s).

An uncertainty-based decision support tool to evaluate the southern king crab (*Lithodes santolla*) fishery in a scarce information context

Item Type Journal Article**Author** F. Bozzeda**Author** S.L. Marín**Author** L. Nahuelhual

Abstract Decision-making in fishery management depends on the reliable quantification of uncertainty, which emerges from a variety of sources. For small-scale fisheries (SSF) in developing countries, the main sources of uncertainty are the available data, which are often untrustworthy, and poor institutional controls, which allow illegal fishing activities. Despite the global spread of SSF, the management of these socio-ecological resources is usually based on insufficient assessments estimated using scarce data. In this study, we identify and quantify the uncertainty associated with the harvested biomass of southern king crab (SKC) (*Lithodes santolla*), as declared by artisanal fishers of the Magallanes Region, Chile, in order to assess the harvestable biomass under a precautionary (conservative) approach to its exploitation in a scarce information context. This analysis includes the application of (i) fuzzy-Bayesian machine learning to quantify the uncertainty related to the harvested biomass per vessel per fishing cruise (C), and (ii) nonlinear polynomial regression models to project the spatial distribution of C according to the estimated uncertainty limits (minimum and maximum). The uncertainty analysis shows a 2000 kg threshold for C; beyond that, the declared harvest does not follow the estimated relationship between biomass and habitat characteristics (temperature, turbidity). The maps created from this analysis convey crucial information that would allow a more rational exploitation of the SKC stock and could be used to estimate a sustainable fishing quota, i.e., allocating effort according to the harvestable biomass. Our results suggest that the proposed tool can reliably inform management faced with uncertainty in stock exploitation by SSF, particularly when information is scarce. © 2018

An unsupervised multi-class ensemble classifier for identifying equipment failure mechanisms from maintenance records

Item Type Journal Article**Author** A.S. Bhardwaj**Author** D. Veeramani

Abstract Unstructured data in equipment maintenance records contain valuable information regarding failures. The ability to classify failure incidents into contributing failure mechanisms can help in improving equipment design and maintenance plans to achieve higher equipment uptime. Supervised learning approaches for automated extraction of failure mechanisms from unstructured data are impractical due to the manual labeling effort. Further, due to the complexities inherent in unstructured data, it can be beneficial to utilize multiple base classifier algorithms for analyzing the maintenance records from different perspectives. In this paper, we propose a novel unsupervised multi-class ensemble classifier (UMEC) model to automatically extract failure mechanisms from unstructured maintenance records by leveraging continuous scores generated by multiple base classifiers. The model decomposes the unsupervised multi-class classification problem into multiple binary classifiers using error-correcting output codes (ECOC). We encode the multi-class classification problems to multiple binary classes by using maximum as an order statistic to reduce multi-class scores to binary-classes. We also address the issue of unbalanced datasets in unsupervised classification. We study the influence of different types of noise structure (including feature noise and class mislabeling noise) over the classifiers and demonstrate the effectiveness of our approach using simulated and real-world industrial data. © 2025

An unsupervised shapelet-based method for quantification of nanostructured surface imaging

Item Type Journal Article

Author C. Chin

Author M.P. Tino

Author N.M. Abukhdeir

Abstract Computational methods to quantify structure–property relationships of materials are lacking in comparison to the widespread availability of nanostructure image-based characterization techniques. There are several existing quantification methods to characterize self-assembled nanomaterials, however many techniques are infeasible for use in processing large-scale spatial variation and/or require significant manual image pre-processing. The use of shapelet functions to computationally quantify nanostructured materials is a promising approach that is generalized for arbitrary pattern types but the current state of the art, the response distance method, requires user/researcher supervision. This need for supervision, along with the computational complexity of the method, make it infeasible for use in fully-automated large-scale computational analysis of nanostructured surface images. The development of a fully-automated unsupervised method for quantification of nanostructured surfaces would enable the development of broadly applicable structure–property relationships for nanomaterials, leveraging large amounts of previously captured data (so-called meta-analyses). In this work, these issues with the shapelet-based response distance method are resolved through the development and validation of a multi-step machine learning process which enables unsupervised (fully-automated) analysis of nanostructure imaging. The presented method removes the need for any researcher knowledge regarding order symmetries and enables truly large-scale analysis (e.g., meta-analyses) of the vast amount of nanostructure imaging data currently available. The presented unsupervised shapelet-based response distance method also results in at least an order-of-magnitude reduction in computational complexity compared to the existing method, at the cost of some degree of generality. A software implementation of the presented unsupervised method is provided in the open-source shapelets Python package. © 2025 World Scientific Publishing Europe Ltd.

Analysis classes for space exploration reliability assessments

Item Type Conference Paper

Author B.J. Franzini

Author B.F. Putney

Abstract Understanding and effectively communicating the spectrum of risk and reliability analysis classes is critical for an analyst to contribute to a team working on developmental space exploration architecture, mission, vehicle, or technology design. The proper characterization of class prior to the risk and reliability analysis can help calibrate stakeholder expectations with regard to required data inputs as well as anticipated outputs and insights. It can also help in the elicitation of data and cooperative participation from technical experts. This analysis class spectrum is bound on the bottom by low fidelity analyses conducted early in design definition cycles when designers and decision makers are looking for qualitative differences in design options to help discriminate, from a risk standpoint, and incorporate inherent safety into a design. At the other end of this spectrum, classic reliability assessment tools are applied to well defined or even operational hardware. These component level reliability analyses use Probabilistic Risk Assessment (PRA), Failure Mode and Effects Analysis (FMEA), and Hazard Analysis (HA) methodologies to quantify system level reliability values with relatively high confidence. For example, the risk and reliability analysis performed during the early definition of exploration architectures such as the Mars Architecture is significantly different from the analysis performed in support of an existing vehicle such as the Space Shuttle. Levels of design definition, requirement refinement, speed of design iterations,

and available system data determine where on this spectrum an analysis will fall as shown in Figure 1. The proper classification and corresponding analysis type is critical to successfully adding value to design iterations. While most R&M practitioners are familiar with reliability assessment techniques for existing hardware, analysis methodologies at the other end of the analysis spectrum are not as defined. This paper explores two examples representative of the range of analysis classes and associated insights proffered by each class in an attempt to establish a framework of analysis classes with associated inputs and anticipated outputs. Examinations of the risk and reliability assessments performed for NASA's Lunar Surface System Reliability Study and Mars Architecture Study provide a perspective of the unique insights each of these varied assessments can provide. © 2009 IEEE.

Analysis of Interacting Factors Contributing to the Onset of Diabetes Type 2 in the Female Pima Population: A Step towards Understanding the Links

Item Type Conference Paper

Author V.I. Dobromyslin

Author D.B. Megherbi

Abstract One of the biggest challenges in building predictive models relates to proper feature selection. As it is well known, good feature selection will result in accurate prediction independently of the classifier. We propose a novel processing pipeline consisting of unsupervised clustering to balance the class prevalence in the training set, which enables the development of stable models with less overfitting. In this paper, we use the proposed pipeline to predict the onset of Type 2 Diabetes (T2D) in the female Pima American Indian population. The Pima population, living near Phoenix, Arizona in the United States, has been known to have the highest T2D prevalence. While it generally remains unclear how various physiological variables and interacting risk factors contribute to the onset of T2D, here for the first time, we quantify the contribution of each of the physiological variables and their interactions to the predicted probability of developing T2D. Our findings in the adult Pima female T2D cohort point to the existence of two distinct population sub-groups, separated primarily by age and the number of pregnancies. For the first time in this dataset, we show several factor interactions: a) subjects with lower BMI (26.0 ± 2.2 vs. 41.5 ± 4.9) experienced a 57-78% reduction in T2D conversion rate at the high plasma glucose (>133.7 mg/dL) and high serum insulin (>168.0 pmol/L) levels respectively, and b) low serum insulin (70.1 ± 16.7 vs. 294.7 ± 136.6 pmol/L) was associated with a 90% lower risk of T2D conversion rate in individuals with high triceps skin thickness (>34 mm), and interestingly c) non-hypotensive (85.6 ± 7.2 vs. 54.3 ± 7.7 mm Hg) women with ≤ 1 pregnancy had 81% lower risk of T2D conversion. With an increasing number of pregnancies, the trend reversed, and non-hypotensive women experienced a 41% higher rate of T2D conversion. Through the evaluation of multiple feature selection methods and classifiers, we show the potential value of the proposed methodology for feature selection and analysis of interacting factors contributing to the onset of T2D in the female Pima Population. © 2020 IEEE.

Editor Weinberger K.Q.

Abstract Learning a classifier from positive and unlabeled data is an important class of classification problems that are conceivable in many practical applications. In this paper, we first show that this problem can be solved by cost-sensitive learning between positive and unlabeled data. We then show that convex surrogate loss functions such as the hinge loss may lead to a wrong classification boundary due to an intrinsic bias, but the problem can be avoided by using non-convex loss functions such as the ramp loss. We next analyze the excess risk when the class prior is estimated from data, and show that the classification accuracy is not sensitive to class prior estimation if the unlabeled data is dominated by the positive data (this is naturally satisfied in inlier-based outlier detection because inliers are dominant in the unlabeled dataset). Finally, we provide generalization error bounds and show that, for an equal number of labeled and unlabeled samples, the generalization error of learning only from positive and unlabeled samples is no worse than $2\sqrt{2}$ times the fully supervised case. These theoretical findings are also validated through experiments.

Abstract The chemistry of natural products has been achieved through the improvement of physical and chemical techniques for the isolation and purification of secondary metabolism products such as carotenoids. Carotenoids, also called tetraterpenoids, produce the particular pigmentation found in nature such as red, yellow, and orange colors. These pigments have gained attention due their physiological and ecological roles. Several challenges in carotenoid analysis have promoted news techniques of extraction and purification considering chemical and physical properties of these

compounds. In this chapter, the phytochemistry, classification, and biosynthesis of carotenoids were addressed, including their recent analytical advances. Throughout this chapter, their chemistry is also presented in detail and intrinsically related to the several health benefits and different industrial applications. Thus, the need to further develop the identification and quantification methods of such molecules as well as novel and green analytical techniques was emphasized. © 2020 Elsevier Inc. Analysis of Vegetables

Item Type Journal Article

Author W. He

Author B. Xu

Abstract Vegetables serve an important role in human nutrition. The flavor quality of vegetables determines consumers' preferences, consumer acceptance, and repeat purchases. Aroma compounds (volatile compounds) and flavor compounds (non-volatile) both are essential to create the sensory perception of vegetables. The aroma and flavor compounds will be influenced by the species of vegetables, the biosynthesis pathways in vegetables, and the combined response of olfaction and taste perceptions. Therefore, this chapter presents a description of the factors that influence the flavor profile of vegetables, including the classification of vegetables, primary and secondary metabolites of vegetables, and primary and secondary flavor compounds of vegetables, the key flavor compounds, and their biosynthesis pathways in vegetables. In addition, the identification and quantification methods of both

volatile and non-volatile compounds in vegetables using both instrumental analysis and sensory evaluation methods will be discussed. © 2024 selection and editorial matter, Leo M. L. Nollet and Matteo Bordiga; individual chapters, the contributors.

Analytical model for performance-evaluation of multistage interconnection networks supporting multi-class priority service

Item Type Journal Article

Author J. Garofalakis

Author E. Stergiou

Abstract In this paper, a discrete-time, single server with parallel multi-buffers, switching element (SE) is presented and analysed. This SE is used in the construction of multistage interconnection networks which have the ability to service the multi-priority traffic-supporting good quality of service. Through a queuing analysis and under various values of multi-traffic classifications, a performance evaluation is determined. This analytical model is based on the steady-state description of the system behaviour. An utilisation's formula is extracted by considering the steady state of the discrete-time multistage network. Consequently, we estimated the rest of the performance metrics. The results are validated using simulation. Apart from that our multi-priority architecture, validated in marginal cases, is compared to some existing single and two class priority models of multistage networks. This comparison is made by gathering metrics and comparing the total packet throughput. Also, the gain of the high-priority packets against the lower-priority packets under different configuration schemas is demonstrated. Eventually, this proposed analytical model is very accurate for various network sizes, with various values of offered multi-priority traffic on fabric's inputs and, therefore, can be used in performance prediction of multistage networks which supports quality of service. © 2011 Taylor & Francis.

Analyzing infant cries using a committee of neural networks in order to detect hypoxia related disorder

Item Type Journal Article

Author M. Poel

Author T. Ekkel

Abstract Based on the hypothesis that the sound of the infant cry contains information on the infant's health status, research has been done on how to improve classification of neonate crying sounds into categories called 'normal' and 'abnormal' - the latter referring to some hypoxia-related disorder. Research in this field is hindered by lack of test cases and limited understanding of feature relevance. The research described here combines various ways of dealing with the small data set problem. First, feature pre-selection is done using sequential backwards elimination of possible combinations where the performance of the set of features is tested by a Probabilistic Neural Network which has the advantage of fast learning. Using these features a neural network committee, consisting of Radial Basis Function Neural Networks, was trained on the data, using bootstrapping. This construction yields a multi-classifier system with an overall classification performance of 85% on the so-called "All Cry Units" (ACU) data set, an increase of 34% with respect to the a priori probability of 51%. Several leave-1-out experiments for Linear Discriminant Analysis (LDA), Support Vector Machines (SVM) and Neural Networks (NN) have been conducted in

order to compare the performance of the multi-classifier system. © World Scientific Publishing Company.

Analyzing Uncertainty Quantification in Statistical and Deep Learning Models for Probabilistic Electricity Price Forecasting

Item Type Journal Article

Author A. Lebedev

Author A. Das

Author S. Pappert

Author S. Schlüter

Abstract Precise probabilistic forecasts are fundamental for energy risk management, and there is a wide range of both statistical and machine learning models for this purpose. Inherent to these probabilistic models is some form of uncertainty quantification. However, most models do not capture the full extent of uncertainty, which arises not only from the data itself but also from model and distributional choices. In this study, we examine uncertainty quantification in state-of-the-art statistical and deep learning probabilistic forecasting models for electricity price forecasting in the German market. In particular, we consider distributional deep neural networks (DDNNs) and augment them with an ensemble approach, Monte Carlo (MC) dropout, deep evidential regression (DER), and conformal prediction to account for model uncertainty. Additionally, we consider the extreme gradient boosting (XGBoost) and

the LASSO-estimated autoregressive (LEAR) model, each combined with quantile regression averaging (QRA), generalized autoregressive conditional heteroskedasticity (GARCH), and conformal prediction. Across a range of performance metrics, we find that the XGBoost-based models perform well in terms of probabilistic forecasting, irrespective of the uncertainty quantification method. Furthermore, we find that DDNNs benefit from incorporating both data and model uncertainty, improving accuracy of both point and probabilistic forecasts by 7.4% and 7.7% in terms of MAE and CRPS. Uncertainty itself appears to be best captured by the models using conformal prediction. Overall, our extensive study shows that all models under consideration perform competitively. However, their relative performance depends on the choice of metrics for point and probabilistic forecasting. © 2013 IEEE.

Anchoring Public Health Forecasts: High-Precision Obesity Prevalence
Estimation Via Hybrid Geodemographic Ensemble Regression

Item Type Journal Article**Author** T. Ward**Author** I. Osunmakinde

Abstract Obesity remains a major driver of chronic disease and rising healthcare costs in the United States. Yet, most existing predictive models rely on single-model classifiers and rarely incorporate spatial structure or ensemble-based regression, thereby limiting their ability to capture geodemographic variation. This study introduces a hybrid unsupervised–supervised ensemble framework that integrates K-Means spatial profiling with a Stacking Regressor to address these limitations. A geodemographic cluster feature is engineered from latitude, longitude, and population density to capture latent regional health patterns. The supervised ensemble, comprising HistGradientBoosting, Random Forest, and Multi-Layer Perceptron base learners with a RidgeCV meta learner, is trained on CDC BRFSS data cleaned to 19,078 detailed records to forecast obesity prevalence as a continuous regression target. The final ensemble achieves an R^2 of 0.8045, an accuracy of 91.95%, a correlation (r) of 0.897, and a Mean Absolute Error of 2.20%, outperforming all individual models and related literature. To evaluate robustness, the framework is stress-tested on secondary datasets, where it consistently maintains superior accuracy. These findings demonstrate the value of hybrid spatial ensemble modeling for high-precision public health forecasting. © 2026 Trenton Ward and Isaac Osunmakinde. Author W. Bäumer

Abstract The use of antibiotics in companion animals is a key One Health concern, as antimicrobial-resistant bacteria can be transmitted between animals and humans, limiting treatment options in both veterinary and human medicine. This study aimed to assess whether routine data from veterinary practices are suitable for establishing an antibiotic monitoring system for dogs, cats, and horses. We analyzed over 3.7 million consultation records from 106 practices (2018–2023) and compared three quantification methods: (a) the proportion of consultations involving antibiotic treatment, (b) the number of Used Daily Doses (nUDD), and (c) the number of Defined Daily Doses (nDDD). Cats had the highest median proportion of antibiotic-treated consultations, while horses had the lowest. Overall, practice classifications into low, medium, or high antibiotic use were largely consistent across the three indicators. The nDDD could be calculated for most cases but required numerous assumptions regarding dosage and standard animal weights. The nUDD relied on standard treatment durations due to the lack of documented therapy lengths. In contrast, the proportion of antibiotic-treated consultations was fully calculable from routine data and closely aligned with the other indicators. Given its simplicity, transparency, and full data availability, this indicator appears most suitable – at least during the implementation phase of a monitoring system. However, for comprehensive surveillance and antimicrobial stewardship, future systems should also integrate diagnostic information and antimicrobial classes to support prudent use and resistance prevention more effectively. © 2025 Schlütersche Fachmedien GmbH, ein Unternehmen der Schlüterschen Mediengruppe

Antibody-supervised deep learning for quantification of tumor-infiltrating immune cells in hematoxylin and eosin stained breast cancer samples

Item Type Journal Article

Author R. Turkki

Abstract Background: Immune cell infiltration in tumor is an emerging prognostic biomarker in breast cancer. The gold standard for quantification of immune cells in tissue sections is visual assessment through a microscope, which is subjective and semi-quantitative. In this study, we propose and evaluate an approach based on antibody-guided annotation and deep learning to quantify immune cell-rich areas in hematoxylin and eosin (H&E) stained samples. Methods: Consecutive sections of formalin-fixed paraffin-embedded samples obtained from the primary tumor of twenty breast cancer patients were cut and stained with H&E and the pan-leukocyte CD45 antibody. The stained slides were digitally scanned, and a training set of immune cell-rich and cell-poor tissue regions was annotated in H&E whole-slide images using the CD45-expression as a guide. In analysis, the images were divided into small homogenous regions, superpixels, from which features were extracted using a pretrained convolutional neural network (CNN) and classified with a support of vector machine. The CNN approach was compared to texture-based classification and to visual assessments performed by two pathologists. Results: In a set of 123,442 labeled superpixels, the CNN approach achieved an F-score of 0.94 (range: 0.92-0.94) in discrimination of immune cell-rich and cell-poor regions, as compared to an F-score of 0.88 (range: 0.87-0.89) obtained with the texture-based classification. When compared to visual assessment of 200 images, an agreement of 90% ($k = 0.79$) to quantify immune infiltration with the CNN approach was achieved while the inter-observer agreement between pathologists was 90% ($k = 0.78$). Conclusions: Our findings indicate that deep learning can be applied to quantify immune cell infiltration in breast cancer samples using a basic morphology staining only. A good discrimination of immune cell-rich areas was achieved, well in concordance with both leukocyte antigen expression and pathologists' visual assessment. © 2016 Journal of Pathology Informatics | Published by Wolters Kluwer -Medknow.

Anticipative Bayesian classification for data streams with verification latency

Item Type Journal Article

Author V. Hofer

Author G. Kreml

Author D. Lang

Abstract Most of the existing adaptive classification algorithms in non-stationary data streams require recent labelled data for their updates. Such recent labels are often missing. For stream classification under verification latency only few approaches exist. Most of them assume clustered data or homogeneous drift in all features, which limits their applicability. We address this by proposing Anticipative Bayesian stream Classifier (ABClass), an approach that is capable of integrating and automatically selecting from different components. In its Bayesian classification framework, ABClass combines density estimation techniques, extended to extrapolate drift patterns over time, with unsupervised parameter tuning and unsupervised model selection. ABClass allows for multivariate density estimation and extrapolation techniques. In this work, we assume conditional independence between features given the class label for modelling feature-specific drift patterns. ABClass is generative and can also be used for explaining and visualising concept drift patterns. It is generic, making it easy to include further types of drift models, both for the class-conditional feature distribution and for the class prior distribution. The experimental evaluation on several real-world data streams shows its competitiveness compared to other state-of-the-art approaches. ABClass is in most cases ten- to hundred-times faster than its competitors, both for model fitting and for prediction. © 2024 The Author(s).

Abstract To address the issues of insufficient rigor in existing methods for quantifying apple watercore severity and the complexity and low accuracy of traditional classification models, this study proposes a method for watercore quantification and a classification model based on a deep convolutional neural network. Initially, visible/near-infrared transmission spectral data of apple samples were collected. The apples were then sliced into 4.5 mm thick sections using a specialized tool, and image data of each slice were captured. Using BiSeNet and RIFE algorithms, a three-dimensional model of the watercore regions was constructed from the apple slices to calculate the watercore severity, which was subsequently categorized into five distinct levels. Next, methods such as the Gramian Angular Summation Field (GASF), Gram Angular Difference Field (GADF), and Markov Transition Field (MTF) were applied to transform the one-dimensional spectral data into two-dimensional images. These images served as input for training and prediction using the ConvNeXt deep convolutional neural network. The results indicated that the GADF method yielded the best performance, achieving a test set accuracy of 98.73%. Furthermore, the study contrasted the classification and prediction of watercore apples using traditional methods with the existing quantification approaches for watercore levels. The comparative results demonstrated that the proposed GADF-ConvNeXt model is more straightforward and efficient, achieving superior performance in classifying watercore grades. Furthermore, the newly proposed quantification method for watercore levels proved to be more effective. © 2025 by the authors.

Application and comparison of geomorphological and hydrological pool and riffle quantification methods

Item Type Journal Article

Author A.M. Krueger

Author K.M. Frothingham

Abstract Pools and riffles have long been recognized as fundamental geomorphological elements of meandering streams. As such, the quantification of pool and riffle characteristics and development of techniques to identify these bed forms has been an important research field for decades. The definition and identification of pools and riffles, however, can vary amongst disciplines. This research compares methods used in two different disciplines, geomorphology and hydrology, and determines the level of agreement between them. Initially, we identified pools and riffles using the bed differencing technique (bdt) in fifteen reaches of Ransom Creek, Clarence, New York. We then calculated the hydrological index, using the Froude Number (Fr) method, for each bed form identified by the bdt, and investigated the agreement between the two indices. Eleven bed forms were identified using the bdt and eight showed agreement geomorphologically (bdt) and hydrologically (Fr). In the three cases where the classifications did not agree, the bdt appeared to be a more appropriate technique to use to identify pools and riffles. © 2007 by Gamma Theta Upsilon.

Application of Artificial Intelligence in Hydrological Modeling for Streamflow Prediction in Ungauged Watersheds: A Review

Item Type Journal Article

Author J.G. Gacu

Author C.E.F. Monjardin

Author R.G.T. Mangulabnan

Author J.C.F. Mendez

Abstract Streamflow prediction in ungauged watersheds remains a critical challenge in hydrological science due to the absence of in situ measurements, particularly in remote, data-scarce, and developing regions. This review synthesizes recent advancements in artificial intelligence (AI) for streamflow modeling, focusing on machine learning (ML), deep learning (DL), and hybrid modeling frameworks. Three core methodological domains are examined: regionalization techniques that transfer models from gauged to ungauged basins using physiographic similarity and transfer learning; synthetic data generation through proxy variables such as NDVI, soil moisture, and digital elevation models; and model performance evaluation using both deterministic and probabilistic metrics. Findings from recent literature consistently demonstrate that AI-based models, especially Long Short-Term Memory (LSTM) networks and hybrid attention-based architectures, outperform traditional conceptual and physically based models in capturing nonlinear hydrological responses across diverse climatic and physiographic settings. The integration of AI with remote sensing enhances generalizability, particularly in ungauged and human-impacted basins. This review also addresses several persistent research gaps, including inconsistencies in model evaluation protocols, limited transferability across heterogeneous regions, a lack of reproducibility and open-source tools, and insufficient integration of physical hydrological knowledge into AI models. To bridge these gaps, future research should prioritize the development of physics-informed AI frameworks, standardized benchmarking datasets, uncertainty quantification methods, and interpretable modeling tools to support robust, scalable, and operational streamflow forecasting in ungauged watersheds. © 2025 by the authors.

Application of chemometric methods for classification of atmospheric particles based on thin-window electron probe microanalysis data

Item Type Conference Paper

Author J. Osán

Author J. De Hoog

Author A. Worobiec

Author C.-U. Ro

Author K.-Y. Oh

Author I. Szalóki

Author R. Van Grieken

Abstract Conventional single-particle electron probe microanalysis (EPMA) is widely used for evaluating the sources of atmospheric aerosol. The method is capable of simultaneously detecting the chemical composition and the morphology of each particle. Computer-controlled automatic EPMA allows the analysis of huge numbers of individual particles. Cluster as well as factor analysis are used for the classification of particles based on the obtained data set. However, the method is not able to detect low-Z elements (C, N, O), therefore, e.g. organic particles can only be identified by their typical inorganic content and high background. Using a thin-window X-ray detector, the capabilities of EPMA can be extended to determine low-Z elements. The recently developed quantification method based

on Monte Carlo simulations is capable to evaluate elemental concentrations in single microscopic particles, including C, N and O. It was shown that also chemical species can be determined from the obtained concentrations. Hierarchical and non-hierarchical cluster analysis, as well as principal component analysis were applied for the classification of particles based on low-Z EPMA data. A mixture of standard particles as well as atmospheric aerosol samples were used to test the classification methods. Different input data (X-ray intensities or elemental concentrations) and scaling functions were used for the chemometric methods. Cluster and factor analysis appear to be efficient tools for classification of particles based on low-Z EPMA data. As an example, atmospheric ammonium sulphate and organic sulphur were classified in separate groups, which was not possible by conventional EPMA. © 2001 Elsevier Science B.V. All rights reserved.

Application of Machine Learning and Multi-Dimensional Perception in Urban Spatial Quality Evaluation: A Case Study of Shanghai Underground Pedestrian Street

Item Type Journal Article

Author T. Yao

Author Y. Xu

Author L. Sun

Author P. Liao

Author J. Wang

Abstract The exploitation of urban subsurface space in urban inventory planning is closely connected to the quality of urban environments. Currently, the construction of underground pedestrian streets is characterised by inefficiency and traffic congestion, making them insufficient for fulfilling the demand for well-designed and human-centred spaces. In the study of spatial quality, traditional evaluation methods, such as satellite remote sensing and street maps, often suffer from low accuracy and slow updating rates, and they frequently overlook human perceptual evaluations. Consequently, there is a pressing need to develop a set of spatial quality evaluation methods incorporating pedestrian perspectives, thereby addressing the neglect of subjective human experiences in spatial quality research. This study first quantifies and clusters the characteristics of underground pedestrian spaces using spatial syntax. It then gathers multidimensional perception data from selected locations and ultimately analyses and predicts the results employing machine learning techniques, specifically Random Forest and XGBoost. The research results indicate variability in pedestrians' evaluations of spatial quality across different functionally oriented spaces. Key factors influencing these evaluations include Gorgeous, Warm, Good Ventilation, and Flavour indicators. The study proposes a comprehensive and applicable spatial quality evaluation model integrating spatial quantification methods, machine learning algorithms, and multidimensional perception measurements. The development of this model offers valuable scientific guidance for the planning and construction of high-quality urban public spaces. © 2024 by the authors.

Application of Machine Learning to Quantify the Role of the Dryline in the Severe Thunderstorm Climatology of the U.S. Southern Great Plains

Item Type Journal Article

Author M.J. Hosek

Author K.A. Hoogewind

Author A.J. Clark

Author A.D. Justin

Abstract The dryline is well understood to be an important mechanism for convection initiation in the U.S. Southern Great Plains (SGP) during its peak severe weather season (March–June). However, the role of the dryline in the severe climatology of the SGP has not yet been quantified. In this study, a machine learning front-identification model (FrontFinder AI) is used to construct a climatology of March–June 0000 UTC drylines over 26 years (1995–2020). Severe storm reports between 2100 and 0300 UTC within the expected region of dryline convection initiation are attributed to the dryline to determine the fraction of the SGP severe climatology associated with drylines. From southwest Texas through western Oklahoma, over 50% of March–June severe storm days are associated with a dryline. During May__the month with the most severe reports__drylines are associated with over 75% of severe thunderstorm days in the Texas Panhandle and northwest Oklahoma. Across the entire SGP, drylines are associated with approximately 41% of severe storm reports and 48% of significant severe storm reports. © 2026 American Meteorological Society.

Application of relative quantification TaqMan real-time polymerase chain reaction technology for the identification and quantification of *Thunnus alalunga* and *Thunnus albacares*

Item Type Journal Article

Author I. Lopez

Author M.A. Pardo

Abstract A novel one-step methodology based on real-time Polymerase Chain Reaction (PCR) technology has been developed for the identification of two of the most valuable tuna species. Nowadays, species identification of seafood products has a major concern due to the importing to Europe of new species from other countries. To achieve this aim, two specific TaqMan systems were devised to identify *Thunnus alalunga* and *Thunnus albacares*. Another system specific to Scombroidei species was devised as a consensus system. In addition, a relative quantification methodology was carried out to quantify *T. alalunga* and *T. albacares* in mixtures after the relative amount of the target was compared with the consensus. This relative quantification methodology does not require a known amount of standard, allowing the analysis of many more samples together and saving costs and time. The utilization of real-time PCR does not require sample handling, preventing contamination and resulting in much faster and higher throughput results. © 2005 American Chemical Society.

Application of supervised learning to quantify uncertainties in turbulence and combustion modeling

Item Type Conference Paper

Author B. Tracey

Author K. Duraisamy

Author J.J. Alonso

Abstract The accuracy of low-fidelity models of turbulent flow such as those based on the Reynolds Averaged Navier-Stokes (RANS) equations can be questionable, especially when these models are applied in situations different from those in which the models were calibrated. At present, there is no general method to quantify structural uncertainties in such models. Greater accuracy and a reliable quantification of modeling errors is much needed to expand the use of affordable simulation models in engineering design and analysis. In this paper, we introduce a methodology aimed at improving low-fidelity models of turbulence and combustion and obtaining error bounds. Towards this end, we first develop a new machine learning algorithm to construct a stochastic model of the error of low-fidelity models using information from higher-fidelity data sets. Then, by applying this error model to the low-fidelity result, we obtain better approximations of uncertain model outputs and generate confidence intervals on

the prediction of simulation outputs. We apply this technique to two representative flow problems. The first application is in flamelet-based simulations to model combustion in a turbulent mixing layer; and the second application is in the prediction of the anisotropy of turbulence in a non-equilibrium boundary layer flow. We demonstrate that our methodology can be used to improve aspects of predictive modeling while offering a route towards obtaining error bounds. © 2013 by Brendan Tracey.

Application of three different methods to determine the prevalence, the abundance and the environmental drivers of culturable *Vibrio cholerae* in fresh and brackish bathing waters

Item Type Journal Article

Author A.K.T. Kirschner

Author A. Indra

Abstract Aims: Three cultivation methods were used to study the prevalence and abundance of *Vibrio cholerae* in Eastern Austrian bathing waters and to elucidate the main factors controlling their distribution. Methods and Results: *Vibrio cholerae* abundance was monitored at 36 inland bathing sites with membrane filtration (MF), a standard most probable number (MPN) approach and direct plating (DP). Membrane filtration yielded the most reliable and sensitive results and allowed *V. cholerae* detection at 22 sites with concentrations up to 39 000 CFU per 100 ml, all belonging to serogroups other than O1 and O139 and not coding for cholera toxin and toxin coregulated pilus. Direct plating turned out as an easy method for environments with high *V. cholerae* abundances, conductivity was the only significant predictor of *V. cholerae* abundance in the bathing waters at warm water temperatures. Conclusions: *Vibrio cholerae* nonO1/nonO139 are widely prevalent in Eastern Austrian bathing waters. Instead of the standard MPN approach, MF and DP are recommended for *V. cholerae* monitoring. Conductivity can be used as a first easy-to-measure parameter to identify potential bathing waters at risk. Significance and Impact of the Study: *Vibrio cholerae* nonO1/nonO139 infections associated with bathing activities are an increasing public health issue in many countries of the northern hemisphere. However, there are only limited data available on the prevalence and abundance of *V. cholerae* in coastal and inland bathing waters. For monitoring *V. cholerae* prevalence and abundance, reliable and simple quantification methods are needed. Moreover, prediction of *V. cholerae* abundance from environmental parameters would be a helpful tool for risk assessment. This study identified the best culture-based quantification methods and a first quick surrogate parameter to attain these aims. © 2018 The Authors. Application of two-step quantitative reverse-transcription PCR to bacterial diagnostics.

Item Type Journal Article

Author B. Glynn

Abstract Use of high copy number bacterial RNA offers several advantages in a diagnostics context compared with current deoxyribonucleic acid-based assays. The opportunity to only detect viable cells by targeting labile RNA transcripts may create an opportunity for "real-time" monitoring of pathogen load in response to a treatment regimen, while the natural amplification provided by the relative abundance of the RNA target compared with its corresponding gene opens a door to potential nonamplified direct detection technologies. In this chapter, a method is described to accurately quantify specific RNA transcripts and thus determine their potential utility as "high-copy" targets. The quantification method described also has application in gene-expression analysis.

Applications of Machine Learning to in Silico Quantification of Chemicals without Analytical Standards

Item Type Journal Article**Author** D. Panagopoulos Abrahamsson**Author** J.-S. Park**Author** R.R. Singh**Author** M. Sirota**Author** T.J. Woodruff

Abstract Non-targeted analysis provides a comprehensive approach to analyze environmental and biological samples for nearly all chemicals present. One of the main shortcomings of current analytical methods and workflows is that they are unable to provide any quantitative information constituting an important obstacle in understanding environmental fate and human exposure. Herein, we present an in silico quantification method using machine-learning for chemicals analyzed using electrospray ionization (ESI). We considered three data sets from different instrumental setups: (i) capillary electrophoresis electrospray ionization-mass spectrometry (CE-MS) in positive ionization mode (ESI+), (ii) liquid chromatography quadrupole time-of-flight mass spectrometry (LC-QTOF/MS) in ESI+ and (iii) LC-QTOF/MS in negative ionization mode (ESI-). We developed and applied two different machine-learning algorithms: A random forest (RF) and an artificial neural network (ANN) to predict the relative response factors (RRFs) of different chemicals based on their physicochemical properties. Chemical concentrations can then be calculated by dividing the measured abundance of a chemical, as peak area or peak height, by its corresponding RRF. We evaluated our models and tested their predictive power using 5-fold cross-validation (CV) and y randomization. Both the RF and the ANN models showed great promise in predicting RRFs. However, the accuracy of the

predictions was dependent on the data set composition and the experimental setup. For the CE-MS ESI+ data set, the best model predicted measured RRFs with a mean absolute error (MAE) of 0.19 log units and a cross-validation coefficient of determination (Q²) of 0.84 for the testing set. For the LC-QTOF/MS ESI+ data set, the best model predicted measured RRFs with an MAE of 0.32 and a Q² of 0.40. For the LC-QTOF/MS ESI-data set, the best model predicted measured RRFs with a MAE of 0.50 and a Q² of 0.20. Our findings suggest that machine-learning algorithms can be used for predicting concentrations of nontargeted chemicals with reasonable uncertainties, especially in ESI+, while the application on ESI-remains a more challenging problem. © 2020 American Chemical Society.

Abstract Osteonecrosis of the femoral head (ONFH) is a disease in which inadequate blood supply to the subchondral bone causes the death of cells in the bone marrow. Decalcified histology and assessment of the percentage of empty lacunae are used to quantify the severity of ONFH. However, the current clinical practice of manually counting cells is a tedious and inefficient process. We utilized the power of artificial intelligence by training an established deep convolutional neural network framework, Faster-RCNN, to automatically classify and quantify osteocytes (healthy and pyknotic) and empty lacunae in 135 histology images. The adjusted correlation coefficient between the trained cell classifier and the ground truth was $R = 0.98$. The methods detailed in this study significantly reduced the manual effort of cell counting in ONFH histological samples and can be translated to other fields of image quantification. © 2021 Orthopaedic Research Society. Applying the Landscape Services Concept in Landscape Research: A Review

Item Type Journal Article

Author S. Zhang

Abstract Considerable attention has been given to the concept of landscape services since the development of research on ecosystem services. However, from the landscape perspective, there are numerous challenges and unanswered issues regarding landscape services. The objective of this paper is to provide a comprehensive review about the state-of-the-art concept of landscape services and its corresponding approaches while trying to set up a foundation for further discussions. First, the definitions and classifications of ecosystem services and landscape services are presented. Second, the relationship between ecosystem services and landscape services, and the studies that integrate ecosystem services into landscape research, are discussed. Finally, an overview is provided concerning research conducted at multiple scales, and the various assessment and quantification methods used for mapping and studying landscape services, even though there are many challenges in establishing a comprehensive approach for such quantification and mapping. © 2022 by author(s).

Approach to an answer to “How dangerous microplastics are to the human body”: A systematic review of the quantification of MPs and simultaneously exposed chemicals

Item Type Journal Article

Author J. Lee

Author S. Jeong

Abstract This review aims to facilitate future research on microplastics (MPs) in the environment using systematic and analytical protocols, ultimately contributing to assessment of the risk to human health due to continuous daily exposure to MPs. Despite extensive studies on MP abundance in environment, identification, and treatment, their negative effects on human health remain unknown due to the lack of proof from clinical studies and limited technology on the MP identification. To assess the risk of MPs to human health, the first step is to estimate MP intake via ingestion, inhalation, and dermal contact under standardized exposure conditions in daily life. Furthermore, rather than focusing on the sole MPs, migrating chemicals from plastic products should be quantified and their health risk be assessed concurrently with MP release. The critical factors influencing MP release and simultaneously exposed chemicals (SECs) must be investigated using a standardized identification method. This review summarises release sources, factors, and possible routes of MPs from the environment to the human body, and the quantification methods used in risk assessment. We also discussed the issues encountered in MP release and SEC migration. Consequently, this review provides directions for future MP studies that can answer questions about MP toxicity to human health. © 2023 Elsevier B.V.

Approaches to improve accuracy of neural network classification of images dominated by mixed pixels

Item Type Conference Paper

Author M.A. Ibrahim

Author M.K. Arora

Author S.K. Ghosh

Author H.-M. Chen

Abstract Often, previous knowledge about the classes on the ground may assist in the improvement of a land cover classification from remote sensing data. There are many ways in which the previous information in the form of a priori probabilities can be included in the training stage of a supervised classification process. The inclusion of a priori probabilities may be useful to classify the images dominated by mixed pixels. In this paper, an approach to incorporate a priori probabilities in back propagation neural network (BPNN) algorithm, by way of replicating the

training data (consisting of pure pixels) of a class according to its proportional area coverage has been implemented. By doing this, the abundant classes are assigned more weights than the other classes in the image. The results show a significant improvement in classification accuracy by 20% over the case when the a priori probabilities are not included. However, the major limitation of this approach is that it depends on the use of pure pixels, which may often be hard to find in images dominated by mixed pixels. We therefore suggest an alternative approach that incorporates mixed pixels in the training stage of BPNN algorithm. The results from this approach also reflect a significant improvement in classification accuracy by 14%. Further, both the approaches produce significantly higher accuracy than the most widely used maximum likelihood classifier (MLC). However, the second approach, which does not depend on identification of pure pixels in the image and their replication, appears more attractive to produce meaningful and accurate land cover classification from remote sensing data.

Abstract A Bayesian network is a tree structure where each branch represents a classification candidate. The leaves of the tree represent observable target features such as frequency or length. An optimized tree groups similar features together, e.g. frequency and pulse width, while collecting dissimilar or disparate information, e.g. spectral and kinematics, all within the same unifying structure. A vehicular track then is a subset of the a priori candidate library and contains only feasible branches. The algorithm for updating the confidence of each feasible candidate according to Bayes' rule is embedded in each track, as is the ability of a track to learn, apply a priori probability distributions, switch modes, switch among kinematics models, apply tracking history to classification and apply classification history to tracking, and support multisensor correlation and sensor fusion. © 2011 SPIE.

Are Cramér-Rao lower bounds an accurate estimate for standard deviations in in vivo magnetic resonance spectroscopy?

Item Type Journal Article

Author K. Landheer

Author C. Juchem

Abstract Due to inherent time constraints for in vivo experiments, it is infeasible to repeat multiple MRS scans to estimate standard deviations on the desired measured parameters. As such, the Cramér-Rao lower bounds (CRLBs) have become the routine method to approximate standard deviations for in vivo experiments. Cramér-Rao lower bounds, however, as the name suggests, are theoretically a lower bound on the standard deviation and it is not clear if and under what circumstances this approximation is valid. Realistic synthetic 3 T spectra were used to investigate the relationship between estimated CRLBs, true CRLBs and standard deviations. Here we demonstrate that, although the CRLBs are theoretically truly a lower bound on the standard deviation (not an equality) for the problem typically encountered in quantification, they are still an adequate approximation to standard deviation as long as the model perfectly characterizes the data. In the case when the macromolecule basis deviates from the measured macromolecules it was shown that the CRLBs can deviate from standard deviations by approximately 50% for N-acetylaspartic acid, creatine and glutamate and of the order of 100% or more for myo-inositol and γ -aminobutyric acid. In the case when the model perfectly reflects the data the CRLBs are within approximately 10% of standard deviations for all metabolites. The result of the CRLB being within 10% of standard deviations means that, for an accurate model, novel quantification methods such as machine learning or deep learning will not be able to obtain substantially more precise estimates for the desired parameters than traditional maximum-likelihood estimation. © 2021 John Wiley & Sons, Ltd.

Are Your Fairness Metrics Accurate? A Semi-Supervised Approach to Improving Fairness Estimates Under Sample Selection Bias

Item Type Conference Paper

Author R. Baeza-Yates

Author P. Radivojac

Author S. Jain

Abstract A key challenge impeding the widespread deployment of machine learning is overcoming the impact of statistical biases in the data. Models trained on unrepresentative data can perform worse than anticipated and differentially affect cross-sections of the population. Therefore, evaluating and vetting models based on an appropriate notion of fairness is often indispensable, making accurate estimation of fairness metrics a critical step to safeguard against deployment of unfair algorithms. It is often assumed that a fairness metric computed from the observed data is accurate. However, in presence of selection bias, also referred to as distributional shifts, fairness metric estimates too can have systematic application-specific errors. In this work, we demonstrate this phenomenon and, relying on access to an unbiased unlabeled data, derive a semi-supervised approach to mitigate estimation errors emerging from the biased labeled data. Specifically, we introduce a novel selection bias model called “sub-class-conditional invariance” (SCC-invariance), that offers a flexible framework to

effectively capture distributional shifts in the real-world data, particularly compared to traditional models such as label shift and covariate shift. Assuming a finite Gaussian mixture form for each class-conditional distribution, we then derive an Expectation-Maximization algorithm to estimate model parameters and correction weights necessary for computing unbiased estimates. We focus on three widely used fairness metrics—equal opportunity, predictive equality, and predictive parity—and demonstrate the effectiveness of our approach in improving their estimates on synthetic data. Finally, we apply our bias mitigation approach to clinical genetics and study the fairness of pathogenicity predictors across ancestral groups. © 2025 Copyright held by the owner/author(s)

Abstract Antibiotic resistance, which is encoded by antibiotic-resistance genes (ARGs), has proliferated to become a growing threat to public health around the world. With technical advances, especially in the popularization of metagenomic sequencing, scientists have gained the ability to decipher the profiles of ARGs in diverse samples with high accuracy at an accelerated speed. To analyze thousands of ARGs in a high-throughput way, standardized and integrated pipelines are needed. The new version (v3.0) of the widely used ARGs online analysis pipeline (ARGs-OAP) has made significant improvements to both the reference database—the structured ARG (SARG) database—and the integrated analysis pipeline. SARG has been enhanced with sequence curation to improve annotation reliability, incorporate emerging resistance genotypes, and determine rigorous mechanism classification. The database has been further organized and visualized online in the format of a tree-like structure with a dictionary. It has also been divided into sub-databases for different application scenarios. In addition, the ARGs-OAP has been improved with adjusted quantification methods, simplified tool implementation, and multiple functions with user-defined reference databases. Moreover, the online platform now provides a diverse biostatistical analysis workflow with visualization packages for the efficient interpretation of ARG profiles. The ARGs-OAP v3.0 with an improved database and analysis pipeline will benefit academia, governmental management, and consultation regarding risk assessment of the environmental prevalence of ARGs. © 2022 THE AUTHORS

Artificial Intelligence (AI) approach for the quantification of C-phycocyanin in *Spirulina platensis*: Hybrid stacking-ensemble model based on machine learning and deep learning

Item Type Journal Article

Author J.W.R. Chong

Author K.S. Khoo

Author H.-Y. Ting

Author I. Koji

Author Z. Ma

Author P.L. Show

Abstract The rising demand for natural pigments in nutraceuticals, pharmaceuticals, and cosmetics has highlighted the need for efficient, non-destructive methods to predict C-phycocyanin (CPC) concentrations in *Spirulina platensis*. Conventional extraction and quantification methods are labour-intensive, environmentally harmful, and time-consuming. This study proposes a hybrid stacking-ensemble model integrating convolutional neural networks (CNN) for automated feature extraction with both Support Vector Machine (SVM) and eXtreme gradient boosting (XGBoost) as base models and multiple meta-regressor models. The meta-regressors include Ridge regression with built-in cross-validation (RidgeCV), Linear Regression (LR), Support Vector Regressor (SVR), Decision Tree (DT), Random Forest (RF), and XGBoost. The datasets comprising 11,000 images of biomass and extracted CPC were captured under varying lighting conditions and device setups to reflect real-world conditions accurately. While digital cameras achieved higher accuracy, smartphones provide competitive results under both covered and light-disturbed conditions, demonstrating smartphones' scalability for real-time applications. While XGBoost as a meta-regressor (standard deviation (Std) = 0.0052, R2Train = 0.9985, R2Val = 0.9983 with 95 % confident interval (CI) [0.9979, 0.9986]), demonstrates marginal improvements over individual models such as SVM (Std = 0.0065, R2Train = 0.9975, R2Val = 0.9973 with 95 % CI [0.9970, 0.9976]) and XGBoost (Std = 0.0053, R2Train = 0.9987, R2Val = 0.9982 with 95 % CI [0.9978, 0.9986]), yet ensemble approach

offers lower variability, reduced overfitting, enhanced stability, and generalisation. CPC datasets delivered better accuracy but were competitive against biomass datasets. Thus, biomass datasets are more feasible in real-world applications by excluding the need for extraction steps, enabling rapid, reliable, and accurate CPC concentration predictions. © 2025 The Authors

Artificial Intelligence and Big Data Analytics for Seismic Hazard Assessment: Methodological Advances and Computational Frameworks for the Marmara Region, Türkiye

Item Type Journal Article

Author P. Lemenkova

Author A.C. Zülfikar

Abstract The Marmara region of Türkiye, situated along the North Anatolian Fault Zone (NAFZ), constitutes one of the most seismically active and densely monitored zones globally. Given the region's high vulnerability and the catastrophic impacts of historical events—notably the 1999 İzmit and 2023 Kahramanmaraş sequences—there is a critical need for advanced seismic hazard risk assessment (SHRA) methods that move beyond static models. This review examines the paradigm shift from traditional geophysics to big data seismology, characterized by the “Five Vs”: volume, velocity, variety, veracity, and value. Critically, we distinguish between two fundamentally different problems: Earthquake Early Warning (EEW), which operates on sub-second timescales after rupture initiation, and probabilistic earthquake forecasting, which operates on timescales of years to decades. The study discusses how cloud-native platforms such as Azure Databricks, combined with data pipelines using Apache Kafka (version 3.5.1) and Apache Spark (version 4.1.2), enable the real-time processing of petabyte-scale seismic sensor streams. Key technological tools, including Physics-Informed Neural Networks (PINNs) and deep learning models such as PhaseNet, are analyzed for their demonstrated ability to enhance EEW systems through sub-second phase picking and automated event detection. Seismic tomography is also undergoing AI-enabled transformation, yielding higher-resolution subsurface imaging. We present statistical validation metrics and uncertainty quantification methods essential for credible hazard assessment. By addressing computational bottlenecks through hybrid computing architectures and edge computing, this framework aims to improve the warning lead time for Istanbul's critical infrastructure. This work provides a structured roadmap for bridging the gap between traditional seismic data analysis and operational predictive analytics in the Marmara region. © 2026 by the authors.

Abstract Background: We aimed to develop an artificial intelligence algorithm able to assess Raynaud's phenomenon (RP) from mobile phone photography, ensuring as a patient-centered, image-based method for RP quantification. Methods: ARTIX (artificial intelligence-based Raynaud's quantification index) score was developed as a multi-step process of segmentation, decomposition and filters application to mobile phone pictures of the hand. ARTIX was validated by the ability to assess finger response to standardised cold challenge in patients with primary and secondary RP and healthy controls (HC) and compared with thermography as a reference. Results: Forty-five RP patients (91.1% female, mean age 52.2 years, 75.5% secondary RP) were enrolled, along with 22 HC comparable for age and gender. RP patients presented significantly lower ARTIX values than HC both at baseline ($p < 0.001$) and across all timepoints of the cold challenge ($p < 0.01$ for all), paralleling a similarly significant difference observed by thermography. ARTIX score was higher in males and in patients taking vasoactive drugs, whereas lower values were obtained in patients with late capillaroscopic pattern, diffuse cutaneous skin subset, or negative for anti-centromere antibodies. ARTIX showed also good ability to discriminate between RP and HC response to cold challenge. Conclusion: We developed and validated ARTIX, a novel machine learning-driven method for the objective quantification of RP. Real-life longitudinal studies in patients with RP will determine the value of ARTIX to complement patient self-assessment surrogate measures of RP activity and severity. © The Author(s) 2025.

Artificial neural networks for classifying olfactory signals

Item Type Conference Paper
Author R. Linder
Author S.J. Pöppel

Abstract For practical applications, artificial neural networks have to meet several requirements: Mainly they should learn quick, classify accurate and behave robust. Programs should be user-friendly and should not need the presence of an expert for fine tuning diverse learning parameters. The present paper demonstrates an approach using an oversized network topology, adaptive propagation (APROP), a modified error function, and averaging outputs of four networks described for the first time. As an example, signals from different semiconductor gas sensors of an electronic nose were classified. The electronic nose smelt different types of edible oil with extremely different a-priori-probabilities. The fully-specified neural network classifier fulfilled the above mentioned demands. The new approach will be helpful not only for classifying olfactory signals automatically but also in many other fields in medicine, e.g. in data mining from medical databases.

ASAP: Unsupervised Post-training with Label Distribution Shift Adaptive Learning Rate

Item Type Conference Paper

Author H. Park

Author M. Joe

Author M. Kim

Author M. Kwon

Abstract In real-world applications, machine learning models face online label shift, where label distributions change over time. Effective adaptation requires careful learning rate selection: too low slows adaptation and too high causes instability. We propose ASAP (Adaptive Shift Aware Post-training), which dynamically adjusts the learning rate by computing the cosine distance between current and previous unlabeled outputs and mapping it within a bounded range. ASAP requires no labels, model ensembles, or past inputs, using only the previous softmax output for fast, lightweight adaptation. Experiments across multiple datasets and shift scenarios show ASAP consistently improves accuracy and efficiency, making it practical for unsupervised model adaptation. © 2025 Copyright held by the owner/author(s).

Aspect-Based Sentiment Quantification

Item Type Journal Article

Author V. Matsiako

Author F. Frasincar

Author D. Boekestijn

Abstract In the current literature, many methods have been devised for sentiment quantification. In this work, we propose AspEntQuaNet, one of the first methods for aspect-based sentiment quantification. It extends the state-of-the-art QuaNet deep learning method for sentiment quantification in two ways. First, it considers aspects and ternary sentiment quantification concerning these aspects instead of binary sentiment quantification. Second, it improves on the results of QuaNet with an entropy-based sorting procedure instead of multisorting. Other sentiment quantification methods have also been adapted for ternary sentiment quantification instead of binary sentiment quantification. Using the modified version of the SemEval 2016 dataset for aspect-based sentiment quantification, we show that AspEntQuaNet is superior to all other considered existing methods based on obtained results for various aspect categories. In particular, AspEntQuaNet outperforms QuaNet often by a factor of 2 on all considered evaluation measures. © 2010-2012 IEEE.

Assessing cropland disagreement in Tanzania using machine learning methods with Sentinel-2 and Planet Scope imagery

Item Type Journal Article

Author V.W. Ogwen

Author N. Moore

Author D. Wanyama

Abstract East Africa faces major land use pressures arising from the harsh effects of climate change and fast-increasing human populations. Recent efforts to increase food production in this region have focused on cropland mapping and approaches to improve yield. Generating accurate cropland maps provides critical support to inform policy, investment, and logistical decisions that address food security, but cropland disagreement assessment studies are lacking mostly due to the unavailability of fine-scale data. Understanding the inconsistent nature of pre-existing global cropland mapping products necessitates disagreement assessment as the most valuable urgent tool to align agricultural resource allocation and policy realignment to tackle food security challenges. This study evaluates cropland disagreement in Kilombero and Ulanga districts in Morogoro, Tanzania based on land use land cover (LULC) maps generated using machine learning methods and high-resolution PlanetScope and Sentinel-2 data sets acquired from 1 January 2017 to 31 December 2018. We created time-variant median composites and performed a three-step assessment; (i) generating multi-class LULC maps in Google Earth Engine, (ii) generating croplands and non-cropland LULC classes from the multi-class images, and (iii) assessing cropland disagreement based on GIS conditional statements. Results show minimal disagreement in mapping cropland based on higher-resolution PlanetScope and Sentinel-2. Results based on the Random Forests and Support Vector Machines relatively outperform those from Classification and Regression Trees achieving 93%, 89%, and 83% with PlanetScope and 91%, 86%, and 76% with Sentinel-2, respectively. On average, 73% of the pixels were consistently classified while 27% were misclassified between cropland and non-cropland classes. Prior unsupervised land cover cluster analysis may substantiate the quality of sampling for accurate land cover classification. Our results indicate that in data-sparse regions where confirmatory ground truth data are lacking, remotely sensed cropland identification

may be more successful using Support Vector Machines on newer high-resolution imagery, thereby improving crop forecasts. © 2023 Informa UK Limited, trading as Taylor & Francis Group.

Assessing Internet Addiction Using the Parsimonious Internet Addiction Components Model-A Preliminary Study

Item Type Journal Article

Author D.J. Kuss

Author G.W. Shorter

Author A.J. van Rooij

Author M.D. Griffiths

Author T.M. Schoenmakers

Abstract Internet usage has grown exponentially over the last decade. Research indicates that excessive Internet use can lead to symptoms associated with addiction. To date, assessment of potential Internet addiction has varied regarding populations studied and instruments used, making reliable prevalence estimations difficult. To overcome the present problems a preliminary study was conducted testing a parsimonious Internet addiction components model based on Griffiths' addiction components (Journal of Substance Use, 10, 191-197, 2005), including salience, mood modification, tolerance, withdrawal, conflict, and relapse. Two validated measures of Internet addiction were used (Compulsive Internet Use Scale [CIUS], Meerkerk et al. in Cyberpsychology & Behavior, 12(1), 1-6, 2009, and Assessment for Internet and Computer Game Addiction Scale [AICA-S], Wölfling et al. 2010) in two independent samples ($n_s = 3,105$ and $2,257$). The fit of the model was analysed using Confirmatory Factor Analysis. Results indicate that the Internet addiction components model fits the data in both samples well. The two sample/two instrument approach provides converging evidence concerning the degree to which the components model can organize the self-reported behavioural components of Internet addiction. Recommendations for future research include a more detailed assessment of tolerance as addiction component. © 2013 Springer Science+Business Media New York.

Assessing Membership Inference Attacks under Distribution Shifts

Item Type Conference Paper**Author** S. Yichuan**Author** O. Kotevska**Author** V. Reshniak**Author** A. Sadovnik**Editor** Ding W.**Editor** Lu C.-T.**Editor** Wang F.**Editor** Di L.**Editor** Wu K.**Editor** Huan J.**Editor** Nambiar R.**Editor** Li J.**Editor** Ilievski F.**Editor** Baeza-Yates R.**Editor** Hu X.

Abstract Membership inference attacks (MIAs) exploit machine learning models to infer whether a data point was in the training set, posing significant privacy risks even with limited black-box access. These attacks rely on the attacker approximating the target model's training distribution, yet the impact of distribution shifts between target and shadow models on MIA success remains underexplored. We systematically evaluate five types of distribution shifts - -cutout, jitter, Gaussian noise, label shift, and attribute shift - - at varying intensities. Our results reveal that these shifts affect MIA effectiveness in nuanced ways, with some reducing attack success while others exacerbate vulnerabilities, and the same shift can have opposite effects depending on the type of MIA. This highlights the complex interplay between distributional differences and attack performance, offering critical insights for improving model defenses against MIAs. © 2024 IEEE.

Assessing operational accuracy of CNN-based image classifiers using an oracle surrogate

Item Type Journal Article

Author A. Guerriero

Author M.R. Lyu

Author R. Pietrantuono

Author S. Russo

Abstract Context: Assessing the accuracy in operation of a Machine Learning (ML) system for image classification on arbitrary (unlabeled) inputs is hard. This is due to the oracle problem, which impacts the ability of automatically judging the output of the classification, thus hindering the accuracy of the assessment when unlabeled previously unseen inputs are submitted to the system. Objective: We propose the Image Classification Oracle Surrogate (ICOS), a technique to automatically evaluate the accuracy in operation of image classifiers based on Convolutional Neural Networks (CNNs). Method: To establish whether the classification of an arbitrary image is correct or not, ICOS leverages three knowledge sources: operational input data, training data, and the ML algorithm. Knowledge is expressed through likely invariants - properties which should not be violated by correct classifications. ICOS infers and filters invariants to improve the correct detection of misclassifications, reducing the number of false positives. We evaluate ICOS experimentally on twelve CNNs – using the popular MNIST, CIFAR10, CIFAR100, and ImageNet datasets. We compare it to two alternative strategies, namely cross-referencing and self-checking. Results: Experimental results show that ICOS exhibits performance comparable to the other strategies in terms of accuracy, showing higher stability over a variety of CNNs and datasets with different complexity and size. Conclusions: ICOS likely invariants are shown to be effective in automatically detecting misclassifications by CNNs used in image classification tasks when the expected output is unknown; ICOS ultimately yields faithful assessments of their accuracy in operation. Knowledge about input data can also be manually incorporated into ICOS, to increase robustness against unexpected phenomena in operation, like label shift. © 2022 The Author(s)

Assessing rare diseases prevalence using literature quantification

Item Type Journal Article

Author S. Jason

Author W. Maxime

Author J. Anne-Sophie

Abstract Introduction: Estimating the prevalence of diseases is crucial for the organization of healthcare. The amount of literature on a rare pathology could help differentiate between rare and very rare diseases. The objective of this work was to evaluate to what extent the number of publications can be used to predict the prevalence of a given pathology. Methods: We queried Orphanet for the global prevalence class for all conditions for which it was available. For these pathologies, we cross-referenced the Orphanet, MeSH, and OMIM vocabularies to assess the number of publication available on Pubmed using three different query strategies (one proposed in the literature, and two built specifically for this study). We first studied the association of the number of publications obtained by each of these query strategies with the prevalence class, then their predictive ability. Results: Class prevalence was available for 3128 conditions, 2970 had a prevalence class < 1/1,000,000, 41 of 1–9/1,000,000, 84 of 1–9/100,000, and 33 of 1–9/10,000. We show a significant association and

excellent predictive performance of the number of publication, with an AUC over 94% for the best query strategy. Conclusion: Our study highlights the link and the excellent predictive performance of the number of publications on the prevalence of rare diseases provided by Orphanet. © 2021, The Author(s).

Assessing the Impact of the COVID-19 Pandemic on Electricity Consumption: A Machine Learning Approach

Item Type Journal Article

Author X. Qian

Author H. Hong

Author X. Zhan

Author Y. Wang

Author Y. Chen

Author K. Xiao

Author Y. Huang

Abstract This study aims to quantitatively assess the impact of the COVID-19 pandemic on societal electricity consumption behavior, particularly considering the interference of special events. Currently, there is insufficient quantitative analysis of the extent to which the COVID-19 pandemic affects electricity consumption behavior. Therefore, we endeavor to introduce new theories and methods to comprehensively understand the potential impact of the pandemic on electricity usage in this field. Our proposed machine learning methods demonstrate significant results and advantages in two key aspects. Firstly, we innovatively introduce an abnormality detection algorithm based on the lunar calendar, thereby establishing a detection system capable of accurately identifying abnormal fluctuations in electricity consumption, to precisely determine the onset of the pandemic. Secondly, we design an evaluation system that integrates CNN-LSTM predictive models and controlled variable strategies, enabling us to reconstruct electricity usage patterns less affected by the pandemic. By comparing actual electricity consumption with reconstructed patterns, we deeply evaluate the impact of the pandemic on different regions and industries and introduce the pandemic impact percentage as a quantification method to precisely assess the extent of the impact. The findings indicate a significant impact of the COVID-19 pandemic on commercial and industrial electricity consumption. Furthermore, our methods are not limited to pandemic research but can also be applied to investigate the effects of other events such as holidays, typhoons, and special production schedules on electricity consumption. In summary, by delving into the complex associations underlying electricity consumption, this study provides a solid theoretical and methodological foundation for future similar research and offers crucial decision support for the electricity industry and emergency management. © 2024 The Authors.

Assessing the Performance of Remaining Time Prediction Methods for Business Processes

Item Type Journal Article

Author J. Roider

Author A. Nguyen

Author D. Zanca

Author B.M. Eskofier

Abstract The prediction of the remaining time for business processes is a major task in predictive process monitoring (PPM). In the last years, various machine learning methods were introduced which reduced error levels steadily. However, the commonly applied metric for optimization and evaluation, the Mean Absolute Error (MAE), has limitations regarding its interpretability. In this work we introduce and evaluate the normalized Mean Absolute Error (nMAE) as an interpretable metric for model evaluation. It accounts for different kinds of label shifts, which are a special type of concept drift that can distort remaining time results. We investigate these concepts in a thorough benchmark study and use them to assess the current state of remaining time prediction for business processes. This includes the evaluation of four different baseline models, identifying the most accurate one. Furthermore, our study compares three different state-of-the-art methods, namely XGBoost, DA-LSTM, and PGT-Net. In contrary to prior studies we find that there is no significant difference in the performance between these models. Additionally, using the nMAE as evaluation metric we find that these models do not perform reasonably well on a range of event logs. Initial ideas for this behaviour are discussed and consolidated along with other findings from the case study into a comprehensive list motivating future research directions. © 2013 IEEE.

Assessing Uncertainty in Machine Learning for Polymer Property Prediction: A Benchmark Study

Item Type Journal Article

Author H. Tang

Author T. Yue

Author Y. Li

Abstract Machine learning (ML) has emerged as a transformative tool in material science, enabling accelerated discovery and design of novel molecules while reducing experimental costs. Uncertainty quantification (UQ) is crucial for enhancing the reliability of ML predictions, particularly in high-stakes applications, such as functional polymer discovery. In this study, we present a comprehensive evaluation of nine UQ methods in ML—ensemble, Gaussian Process Regression (GPR), Monte Carlo Dropout (MCD), mean-variance estimation (MVE), Bayesian Neural Network based on Variational Inference (BNN-VI) and Markov Chain Monte Carlo (BNN-MCMC), evidential deep learning (EDL), quantile regression (QR), natural gradient boosting (NGBoost)—for predicting key polymer properties, including glass transition temperature (T_g), band gap (E_g), melting temperature (T_m) and decomposition temperature (T_d). The models are assessed using three independent metrics, including prediction accuracy (R^2), Spearman's rank correlation coefficient and calibration area, offering a robust framework for evaluating both mean predictions and uncertainty estimates. Our analysis spans data sets of four properties, out-of-distribution (OOD) experimental and molecular dynamics (MD)-derived data, high- T_g polymers and diverse polymer types, providing a holistic perspective on model performance. Our findings reveal that optimal UQ method selection is highly context-dependent. Ensemble method consistently excelled for general in-distribution predictions across four properties. For challenging OOD scenarios, BNN-MCMC offered a strong balance of predictive accuracy and reliable UQ. NGBoost emerged as the top-performing method for high- T_g polymers, effectively balancing accuracy and uncertainty characterization, with Ensemble method also providing excellent accuracy in this case. Furthermore, BNN-VI demonstrated superior and consistent performance across the nine distinct polymer classes evaluated. This comprehensive benchmark underscores the critical importance of selecting tailored UQ strategies to enhance the trustworthiness of ML predictions, optimize experimental validation efforts, and ultimately accelerate the discovery of advanced functional polymers. ©

Assessment and quantification methods of urbanization patterns using geospatial techniques and spatial metrics in Tirunelveli city, Tamil Nadu, India

Item Type Journal Article

Author A.V.T. Annamalai

Author S.R. Kolanuvada

Author N. Radhakrishnan

Abstract Urban expansion has become a major challenge in recent years, threatening environmental sustainability and urban planning. Methods to quantify urban growth are limited, but the combination of geospatial techniques and spatial metrics offers significant advantages in quantifying growth and detecting early signs of sprawl for sustainable development. This study evaluated the effectiveness of the entropy model, landscape metrics, and urban metrics in quantifying urban growth. We focused on Tirunelveli City, the sixth-largest corporation in Tamil Nadu, India, by its evolution, spatial patterns and urban expansion trends. Landsat images and the CART classifier were used to prepare LULC maps for the years 1997, 2005, 2015 and 2022. Built-up areas of the city were extracted, and Shannon Entropy, five landscape metrics, four urban metrics, and the urban sprawl matrix were applied. Landscape metrics and Shannon Entropy methods indicated that the city was experiencing sprawl. Urban metrics were applied to five concentric rings, each with a 2 km radius from the city center, revealing a moderate growth rate. The urban sprawl matrix analyzed the city's spatial pattern, confirming the presence of a multi-nuclei structure and development along major roads, known as ribbon development. We conclude that the urban sprawl matrix is an effective method for analyzing city spatial patterns. Shannon Entropy and landscape metrics provide robust results for quantifying sprawl, and urban metrics are reliable for assessing growth rate. Therefore, local planners should focus on Concentric Ring 04, where significant growth has occurred, to ensure sustainable urban development. © The Japan Section of the Regional Science Association International 2025.

Assessment of Classified Regulation Capability of New Energy Storage for Urban Grid Flexibility Demands

Item Type Conference Paper

Author S. Wang

Author J. Yu

Author S. Chen

Author J. Yang

Author X. Dai

Author X. Yuan

Abstract With the increasing proportion of external power supply and the high penetration of renewable energy in Shanghai's power system, the demand for flexibility resources in urban grids continues to grow. Novel energy storage systems (NESS) feature fast response and high precision; however, systematic evaluation methods for their adjustable capability across diverse scenarios, such as peak-shaving and frequency regulation, are currently lacking. To address this gap, this paper proposes a flexibility demand quantification method based on load variation to characterize the grid's requirements. On this basis, an operational and economic model for energy storage is established, incorporating round-trip efficiency and battery degradation costs. Furthermore, a multi-dimensional evaluation framework is constructed, encompassing energy-oriented, power/ramp-rate-oriented, and economic indicators to enable standardized scoring and classification of various configurations. Using a 50 MW/200 MWh energy storage station as a case study, simulation results demonstrate that the integration of energy storage significantly reduces the peak-valley difference and ramp rate of the urban grid, effectively meeting flexibility requirements. These findings provide a robust foundation for optimizing energy storage configurations and assessing adjustable capabilities in different application contexts. © 2026 IEEE.

Assessment of multiresolution segmentation for delimiting drumlins in digital elevation models

Item Type Journal Article**Author** C. Eisan**Author** M. Smith**Author** J. Hillier

Abstract Mapping or "delimiting" landforms is one of geomorphology's primary tools. Computer-based techniques such as land-surface segmentation allow the emulation of the process of manual landform delineation. Land-surface segmentation exhaustively subdivides a digital elevation model (DEM) into morphometrically-homogeneous irregularly-shaped regions, called terrain segments. Terrain segments can be created from various land-surface parameters (LSP) at multiple scales, and may therefore potentially correspond to the spatial extents of landforms such as drumlins. However, this depends on the segmentation algorithm, the parameterization, and the LSPs. In the present study we assess the widely used multiresolution segmentation (MRS) algorithm for its potential in providing terrain segments which delimit drumlins. Supervised testing was based on five 5-m DEMs that represented a set of 173 synthetic drumlins at random but representative positions in the same landscape. Five LSPs were tested, and four variants were computed for each LSP to assess the impact of median filtering of DEMs, and logarithmic transformation of LSPs. The testing scheme (1) employs MRS to partition each LSP exhaustively into 200 coarser scales of terrain segments by increasing the scale parameter (SP), (2) identifies the spatially best matching terrain segment for each reference drumlin, and (3) computes four segmentation accuracy metrics for quantifying the overall spatial match between drumlin segments and reference drumlins. Results of 100 tests showed that MRS tends to perform best on LSPs that are regionally derived from filtered DEMs, and then log-transformed. MRS delineated 97% of the detected drumlins at SP values between 1 and 50. Drumlin delimitation rates with values up to 50% are in line with the success of manual interpretations. Synthetic DEMs are well-suited for assessing landform quantification methods such as MRS, since subjectivity in the reference data is avoided which increases the reliability, validity and applicability of results. © 2014 The Authors.

Abstract Background: Cognitive impairments induced by substance use disorders (SUDs) are broadly documented. Evidence for these effects ought to be considered with regard to the new classification of neurocognitive disorders (NCDs). Failing to assess diagnostic criteria for NCD could be a limitation of studies addressing the effects of SUDs on cognition, resulting in misdiagnosis and inaccurate prevalence estimation. Methods: A systematic search of original articles (2000–2016) was conducted in Web of Knowledge and Science Direct. Key terms were: NCD and associated terms, and SUDs or alcohol, marijuana, cocaine and inhalants. Results: 59 cross-sectional and five prospective studies were reviewed. Criterion A.1 (evaluation of subjective concern of cognitive decline relative to a baseline), and criterion B (evaluation of impairment in daily life activities due to cognitive impairment) were not effectively evaluated in any of the studies. All studies addressed criterion A.2 (objective evidence of cognitive decline) via heterogeneous neuropsychological testing. Criteria C (absence of delirium) and D (absence of other possible etiologies) were frequently

considered for control of confounding effects, mostly via methodological procedures (e.g. abstinence before evaluation, and exclusion of participants with comorbid disorders). Conclusion: These findings highlight the need to develop and disseminate standard procedures for assessment of substance-induced NCD. © 2017, © 2017 Taylor & Francis Group, LLC.

Abstract This study aims to analyze psychometric properties and validity of the Compulsive Internet Use Scale (CIUS) and the Internet Addiction Test (IAT) and, second, to determine a threshold for the CIUS which matches the IAT cut-off for detecting problematic Internet use. A total of 292 subjects with problematic or pathological gambling (237 men, 55 women) aged 14-63 years and with private Internet use for at least 1 h per working or weekend day were recruited via different recruitment channels. Results include that both scales were internally consistent (Cronbach's = 0.9) and had satisfactory convergent validity ($r = 0.75$; 95% CI 0.70-0.80). The correlation with duration of private Internet use per week was significantly higher for the CIUS ($r = 0.54$) compared to the IAT ($r = 0.40$). Among all participants, 25.3% were classified as problematic Internet users based on the IAT with a cut-off ≥ 40 . The highest proportion of congruent classified cases results from a CIUS cut-off ≥ 18 (sensitivity 79.7%, specificity 79.4%). However, a higher cut-off (≥ 21) seems to be more appropriate for prevalence estimation of problematic Internet use. © 2013 S. Karger AG, Basel.

Assessment of simplified methods for quantification of [18F]-DPA-714 using 3D whole-brain TSPO immunohistochemistry in a non-human primate

Item Type Journal Article**Author** N. Van Camp**Author** Y. Balbastre**Author** A.-S. Herard**Author** S. Lavisse**Author** C. Tauber**Author** C. Wimberley**Author** M. Guillermier**Author** A. Abstract The 18 kDa translocator protein (TSPO) is the main molecular target to image neuroinflammation by positron emission tomography (PET). However, TSPO-PET quantification is complex and none of the kinetic modelling approaches has been validated using a voxel-by-voxel comparison of TSPO-PET data with the actual TSPO levels of expression. Here, we present a single case study of binary classification of in vivo PET data to evaluate the statistical performance of different TSPO-PET quantification methods. To that end, we induced a localized and adjustable increase of TSPO levels in a non-human primate brain through a viral-vector strategy. We then performed a voxel-wise comparison of the different TSPO-PET quantification approaches providing parametric [18F]-DPA-714 PET images, with co-registered in vitro three-dimensional TSPO immunohistochemistry (3D-IHC) data. A data matrix was extracted from each brain hemisphere, containing the TSPO-IHC and TSPO-PET data for each voxel position. Each voxel was then classified as false or true, positive or negative after comparison of the TSPO-PET measure to the reference 3D-IHC method. Finally, receiver operating characteristic curves (ROC) were calculated for each TSPO-PET quantification method. Our results show that standard uptake value ratios using cerebellum as a reference region (SUVCBL) has the most optimal ROC score amongst all non-invasive approaches. © The Author(s) 2019.

Assessment of spatiotemporal dynamics of diurnal fog occurrence in
subtropical montane cloud forests

Item Type Journal Article**Author** H.-J. Li**Author** M.-H. Lo**Author** J.-Y. Juang**Author** J. Wang**Author** C.-Y. Huang

Abstract Montane cloud forests (MCFs) are frequently immersed in low-altitude clouds or fog. The diurnal (defined as 07:00–16:50 local time) cycle of fog is particularly important for regulating the carbon, water and energy cycles of these ecosystems. Elevated temperatures may alter the spatiotemporal dynamics of fog and have cascading impacts on MCFs. Therefore, systematic monitoring of fog occurrence is essential for understanding the ramifications of climate change on these unique forests. This study aims to quantify three years (2018–2020) of diurnal fog occurrence with high spatiotemporal (5 km, 10 minutes) resolutions in subtropical MCF in northeast Taiwan. Four open-sky observation stations were installed along an elevation gradient (1151, 1514, 1670 and 1811 m a.s.l.) within the cloud band to record meteorological data including rainfall, air temperature and relative humidity. We also acquired spatiotemporally-corresponding photosynthetic photon flux density from the geostationary Himawari-8 satellite and derived solar zenith angle for each station. We utilized these ground and satellite meteorological attributes to model fog occurrence using seven machine learning methods. By referring to time-lapse images, the performance of random forests was determined to be superior compared to other approaches and was therefore selected to quantify spatiotemporal dynamics of fog occurrence. Fog was determined to be more abundant in terms of probability, frequency and duration in mid-elevations when compared to the lower and higher ends. Temporal analysis demonstrated that overall seasonality was pronounced with higher fog abundance in the afternoons and cold months but varied from station to station. In addition, three-year fog duration and event variability for each month were notable for all stations; the foggiest station was at 1670 m a.s.l. This study demonstrates the feasibility of using machine learning to quantify spatiotemporal dynamics of fog using cross-scale meteorological attributes, which may facilitate monitoring the impact of climate change on MCFs. © 2022 Elsevier B.V.

Assigning Test Priority to Modules Using Code-Content and Bug History

Item Type Journal Article

Author E. Daka

Author E. Mustafa

Abstract Regression testing is a process that is repeated after every change in the program. Prioritization of test cases is an important process during regression test execution. Nowadays, there exist several techniques that decide which of the test cases will run first as per their priority levels, while increasing the probability of finding bugs earlier in the test life cycle. However, sometimes algorithms used to select important test cases may stop searching in local minima while missing the rest of the tests that might be important for a given change. To address this limitation further, we propose a domain-specific model that assigns testing priority to classes in applications based on developers' judgments for priority. Moreover, our technique which takes into consideration applications' code content and bug history, relates these features to overall class priority for testing. In the end, we test the proposed approach with a new (unknown) dataset of 20 instances. The predicted results are compared with developers' priority score and saw that this metric can prioritize correctly 70% of classes under test. © 2022 CCIS

AUC Optimization from Multiple Unlabeled Datasets

Item Type Conference Paper

Editor Dy J.
Editor Natarajan S.
Abstract Weakly supervised learning aims to make machine learning more powerful when the perfect supervision is unavailable, and has attracted much attention from researchers. Among the various scenarios of weak supervision, one of the most challenging cases is learning from multiple unlabeled (U) datasets with only a little knowledge of the class priors, or Um learning for short. In this paper, we study the problem of building an AUC (area under ROC curve) optimal model from multiple unlabeled datasets, which maximizes the pairwise ranking ability of the classifier. We propose Um-AUC, an AUC optimization approach that converts the Um data into a multi-label AUC optimization problem, and can be trained efficiently. We show that the proposed Um-AUC is effective theoretically and empirically. Copyright © 2024, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

AUC_μ: A performance metric for multi-class machine learning models

Item Type Conference Paper**Author** R.S. Kleiman**Author** D. Page

Abstract The area under the receiver operating characteristic curve (AUC) is arguably the most common metric in machine learning for assessing the quality of a two-class classification model. As the number and complexity of machine learning applications grows, so too does the need for measures that can gracefully extend to classification models trained for more than two classes. Prior work in this area has proven computationally intractable and/or inconsistent with known properties of AUC, and thus there is still a need for an improved multi-class efficacy metric. We provide in this work a multi-class extension of AUC that we call AUC_μ that is derived from first principles of the binary class AUC. AUC_μ has similar computational complexity to AUC and maintains the properties of AUC critical to its interpretation and use. Copyright © 2019 ASME

Abstract *Dendrobium officinale* is a valuable medicinal and edible homologous health food. It has immunomodulatory, antioxidant, and metabolism-regulating properties. However, its adulteration is widespread, seriously compromising product quality and safety. Traditional adulteration detection methods are complex, costly, and time-consuming, making it urgent to establish a rapid and non-destructive detection approach. This study developed a rapid identification and quantification method for adulterated *D. officinale*. The method combined near-infrared (NIR) spectroscopy with data-driven soft independent modeling of class analogy (DD-SIMCA) and partial least squares regression (PLSR) models. PCA, PLS-DA, and OPLS-DA were first used to visualize sample clustering and group differences. DT, SVM, ANN, and NB were used for classification. DD-SIMCA and PLSR were used for one-class modeling and quantitative analysis. Raw spectral data were preprocessed using multiplicative scatter correction (MSC), the standard normal variate (SNV), the first derivative, and

Savitzky–Golay smoothing. In the identification analysis, the DD-SIMCA model achieved 100% sensitivity and 100% specificity in the validation set. Its overall accuracy in the independent test set was 99.2%, demonstrating excellent discrimination performance. In addition, SVM combined with NIR also achieved good accuracy. In the quantitative analysis of adulteration, the PLSR model predicted different adulteration levels. Most calibration and validation sets showed R^2 values above 0.99 and RMSE values below 0.05, indicating excellent predictive performance. The results indicate that NIR combined with DD-SIMCA and PLSR can achieve rapid identification and accurate quantification of adulterated *D. officinale* samples. This approach provides strong support for quality control and regulatory supervision of high-value health foods. © 2026 by the authors.

Author B. Drossel
Author M. Löbrich

Abstract Double-strand breaks (DSBs) are the most lethal DNA damages induced by ionising radiation (IR) and their efficient repair is crucial to limit genomic instability. The cellular DSB response after low IR doses is of particular interest but its examination requires the analysis of high cell numbers. Here, we present an automated DSB quantification method based on the analysis of γ H2AX and 53BP1 foci as markers for DSBs. We establish a combination of object properties, combined in the object evaluation parameter (OEP), which correlates with manual object classification. Strikingly, OEP histograms show a bi-modal distribution with two maxima and a minimum in between, which correlates with the manually determined transition between background signals and foci. We used algorithms to detect the minimum, thus separating foci from background signals and automatically assessing DSB levels. To demonstrate the validity of this method, we analyzed over 600.000 cells to verify results of previous studies showing that DSBs induced by low doses are less efficiently repaired compared with DSBs induced by higher doses. Thus, the automated foci counting method, called AutoFoci, provides a valuable tool for high-throughput image analysis of thousands of cells which will prove useful for many biological screening approaches. © 2018, The Author(s).

Automated classification of local patches in colon histopathology

Item Type	Conference Paper
Author	H. Kalkan
Author	M. Nap
Author	R.P.W. Duin
Author	M. Loog
Abstract	An automated histology analysis is proposed for classification of local image patches of colon histopathology images into four principle classes: normal, cancer, adenomatous and inflamed classes. Shape features based on stroma, lumen and imperfectly segmented nuclei are combined with texture features for classification. The classification is analyzed under the three scenarios: normal vs. abnormal, cancer vs. non-cancer and four-class classification on a labeled dataset consisting of 2000 patches per class which were collected from 55 different slices. The proposed method achieves 79.28% mean accuracy between normal and abnormal; 87.67% accuracy between cancer and non-cancer and 75.15% between the four classes with equal class priories. © 2012 ICPR Org Committee.

Abstract Background Manual analysis of behavior is labor intensive and subject to inter-rater variability. Although considerable progress in automation of analysis has been made, complex behavior such as grooming still lacks satisfactory automated quantification. New method We trained a freely available, automated classifier, Janelia Automatic Animal Behavior Annotator (JAABA), to quantify self-grooming duration and number of bouts based on video recordings of SAPAP3 knockout mice (a mouse line that self-grooms excessively) and wild-type animals. Results We compared the JAABA classifier with human expert observers to test its ability to measure self-grooming in three scenarios: mice in an open field, mice on an elevated plus-maze, and tethered mice in an open field. In each scenario, the classifier identified both grooming and non-grooming with great accuracy and correlated highly with results obtained by human observers. Consistently, the JAABA classifier confirmed previous reports of excessive grooming in SAPAP3 knockout mice. Comparison with existing methods Thus far, manual analysis was regarded as the only valid quantification method for self-grooming. We demonstrate that the JAABA classifier is a valid and reliable scoring tool, more cost-efficient than manual scoring, easy to use, requires minimal effort, provides high throughput, and prevents inter-rater variability. Conclusion We introduce the JAABA classifier as an efficient analysis tool for the assessment of rodent self-grooming with expert quality. In our “how-to” instructions, we provide all information necessary to implement behavioral classification with JAABA. © 2017 Elsevier B.V.

Abstract INTRODUCTION: – Emerging evidence implicates eosinophils as important modulators of disease activity and therapeutic response in ulcerative colitis (UC). Automated image analysis provides a scalable and reproducible approach to their evaluation, overcoming the limitations of manual quantification. METHODS: – We developed a U-Net-based deep learning model to automate eosinophil detection, using whole-slide images from 2 pediatric sites. Pathologist-annotated 500×500 -pixel patches served as training data; model performance was evaluated using area under the receiver operator curve (AUROC), precision, recall, and F1 score and benchmarked against SAU-Net, YOLO-v8, and HoVer-Next. The validated algorithm was applied to rectal biopsies from treatment-naïve children with moderate-to-severe UC in the PROTECT inception cohort ($n = 221$). Eosinophil metrics (density in cells/mm² and peak high-power field counts) were analyzed for associations with baseline clinical, histologic, and endoscopic features and 1-year clinical outcomes including anti-tumor necrosis factor α (TNF α) escalation and corticosteroid-free clinical remission. Predictive models were evaluated with logistic regression and machine learning approaches using 5-fold cross-validation. RESULTS: – The segmentation model achieved high accuracy (test AUROC = 0.94, F1 score = 0.86) and strong concordance with expert counts ($p = 0.87$ – 0.89). Higher eosinophil density and counts correlated with basal lymphoid aggregates ($P < 0.001$) and predicted week 4 and corticosteroid-free remission ($P = 0.03$ and $P = 0.01$, respectively). Lower eosinophil counts predicted escalation to anti-TNF α therapy ($P = 0.04$). Incorporation of eosinophil metrics into Predicting Response to Standardized Pediatric Colitis Therapy (PROTECT) clinical models maintained predictive accuracy for anti-TNF α escalation (AUROC = 0.79; accuracy = 0.76). DISCUSSION: – Deep learning-based eosinophil quantification has the potential to transform pediatric UC care by serving as a reproducible biomarker that informs risk stratification and to guide therapy. © 2026 The Author(s). Abstract Background: Accurate mortality risk quantification is crucial for the management of hepatocellular carcinoma (HCC); however, most scoring systems are subjective. Purpose: To develop and independently validate a machine learning mortality risk quantification method for HCC patients using standard-of-care clinical data and liver

radiomics on baseline magnetic resonance imaging (MRI). Methods: This retrospective study included all patients with multiphasic contrast-enhanced MRI at the time of diagnosis treated at our institution. Patients were censored at their last date of follow-up, end-of-observation, or liver transplantation date. The data were randomly sampled into independent cohorts, with 85% for development and 15% for independent validation. An automated liver segmentation framework was adopted for radiomic feature extraction. A random survival forest combined clinical and radiomic variables to predict overall survival (OS), and performance was evaluated using Harrell's C-index. Results: A total of 555 treatment-naïve HCC patients (mean age, 63.8 years $\pm$ 8.9 [standard deviation]; 118 females) with MRI at the time of diagnosis were included, of which 287 (51.7%) died after a median time of 14.40 (interquartile range, 22.23) months, and had median followed up of 32.47 (interquartile range, 61.5) months. The developed risk prediction framework required 1.11 min on average and yielded C-indices of 0.8503 and 0.8234 in the development and independent validation cohorts, respectively, outperforming conventional clinical staging systems. Predicted risk scores were significantly associated with OS ($p < .00001$ in both cohorts). Conclusions: Machine learning reliably, rapidly, and reproducibly predicts mortality risk in patients with hepatocellular carcinoma from data routinely acquired in clinical practice. Clinical relevance statement: Precision mortality risk prediction using routinely available standard-of-care clinical data and automated MRI radiomic features could enable personalized follow-up strategies, guide management decisions, and improve clinical workflow efficiency in tumor boards. Key Points: • Machine learning enables hepatocellular carcinoma mortality risk prediction using standard-of-care clinical data and automated radiomic features from multiphasic contrast-enhanced MRI. • Automated mortality risk prediction achieved state-of-the-art performances for mortality risk quantification and outperformed conventional clinical staging systems. • Patients were stratified into low, intermediate, and high-risk groups with significantly different survival times, generalizable to an independent evaluation cohort. © The Author(s) 2024.

Automated measurement of penile curvature using deep learning-based novel quantification method

Item Type Journal Article

Abstract Objective: Develop a reliable, automated deep learning-based method for accurate measurement of penile curvature (PC) using 2-dimensional images. Materials and methods: A set of nine 3D-printed models was used to generate a batch of 913 images of penile curvature (PC) with varying configurations (curvature range 18° to 86°). The penile region was initially localized and cropped using a YOLOv5 model, after which the shaft area was extracted using a UNet-based segmentation model. The penile shaft was then divided into three distinct predefined regions: the distal zone, curvature zone, and proximal zone. To measure PC, we identified four distinct locations on the shaft that reflected the mid-axes of proximal and distal segments, then trained an HRNet model to predict these landmarks and calculate curvature

angle in both the 3D-printed models and masked segmented images derived from these. Finally, the optimized HRNet model was applied to quantify PC in medical images of real human patients and the accuracy of this novel method was determined. Results: We obtained a mean absolute error (MAE) of angle measurement $<5^\circ$ for both penile model images and their derivative masks. For real patient images, AI prediction varied between 1.7° (for cases of $\sim 30^\circ$ PC) and approximately 6° (for cases of 70° PC) compared with assessment by a clinical expert. Discussion: This study demonstrates a novel approach to the automated, accurate measurement of PC that could significantly improve patient assessment by surgeons and hypospadiology researchers. This method may overcome current limitations encountered when applying conventional methods of measuring arc-type PC. 2023 Baray, Abdelmoniem, Mahmud, Kabir, Faisal, Chowdhury and Abbas.

Automated Morphological Classification of Neural Cells growing in Culture

Item Type Conference Paper

Author J. Kim

Author D.F. Gillies

Abstract Studies of developing neural cells are widely used in fundamental research into the mechanisms of nervous diseases, such as multiple sclerosis. These studies normally require researchers to estimate the populations of different classes of cells in microscope images of either tissue or cultures. The estimation process is carried out by human visual inspection, and is time consuming and subjective in nature. As an attack on this problem, we have been investigating the use of computer vision to classify and count the neural cells automatically. We apply various image processing techniques and then use measures such as the fractal dimension and 2nd moment to classify cells according to their spatial growth characteristics seen during their development. The measures are then combined using a Bayesian classifier, and a decision is taken as to which class a cell belongs. The results on isolated cell images showed that more than 80% agreement between the computer analysis and human judgement. Our latest work concerns the problems to be tackled on mixed cell images where dendrites of different cells overlap. We have been investigating how to apply the shape measures in this case and results are promising.

Automated MPI segmentation in X-space and calibration to quantify iron concentration in a tracer distribution

Item Type Journal Article**Author** Z. Sun**Author** J. Tian**Author** Y. Du

Abstract Magnetic particle imaging (MPI) is a new, radiation-free medical imaging modality that relies on the non-linear magnetization response of superparamagnetic iron oxide nanoparticles (SPIONs) to reconstruct their concentration distribution with high sensitivity and medical safety. Current quantification methods for region of interest (ROI) are inadequate and are usually outlined manually or using deep learning methods. We propose two new models for ROI selection based on machine learning, one is the K-means++-based threshold-inflated image segmentation model and the other is the image segmentation model based on MPI simulation and SVM. We have developed an accurate quantification of 2D MPI images and established the calibration curve to predict the corresponding iron content based on the MPI image. © 2023 Infinite Science Publishing.

Automated MRI assessment confirms cartilage thickness modification in patients with knee osteoarthritis: post-hoc analysis from a phase II sprifermin study

Item Type Journal Article**Author** A. Brett**Author** M.A. Bowes**Author** P.G. Conaghan

Author C. Ladel

Author H. Guehring

Author F. Moreau

Author F. Eckstein

Abstract Background: Sprifermin is under investigation as a potential disease-modifying osteoarthritis drug. Previously, 2-year results from the FORWARD study showed significant dose-dependent modification of cartilage thickness in the total femorotibial joint (TFTJ), medial and lateral femorotibial compartments (MFTC, LFTC), and central medial and lateral TFTJ subregions, by quantitative magnetic resonance imaging (qMRI) using manual segmentation. Objective: To determine whether qMRI findings from FORWARD could be reproduced by an independent method of automated segmentation using an identical dataset and similar anatomical regions in a post-hoc analysis. Method: Cartilage thickness was assessed at baseline and 6, 12, 18 and 24 months, using automated cartilage segmentation with active appearance models, a supervised machine learning method. Images were blinded for treatment and timepoint. Treatment effect was assessed by observed and adjusted changes using a linear mixed model for repeated measures. Results: Based on automated segmentation, statistically significant, dose-dependent structural modification of cartilage thickness was observed over 2 years with sprifermin vs placebo for TFTJ (overall treatment effect and dose response, both $P < 0.001$), MFTC ($P = 0.004$ and $P = 0.044$), and LFTC (both $P < 0.001$) regions. For highest dose, in the central medial tibial ($P = 0.008$), central lateral tibial ($P < 0.001$) and central lateral femoral ($P < 0.001$) regions. Conclusions: Cartilage thickness assessed by automated segmentation provided a consistent dose response in structural modification compared with manual segmentation. This is the first time that two independent quantification methods of image analysis have reached the same conclusions in an interventional trial, strengthening the conclusions that sprifermin modifies structural progression in knee osteoarthritis. © 2020 Osteoarthritis Research Society International

Automated multiclass structural damage detection and quantification using augmented reality

Item Type Journal Article

Author O. Awadallah

Author A. Sadhu

Abstract Civil infrastructure worldwide is ageing and enduring increasingly adverse weather conditions. Traditional structural health monitoring (SHM) involves the expensive and time-consuming installation of contact sensors. For example, inspectors use costly large-scale equipment to reach a certain area of the structure and at different heights to inspect it, which can pose a risk to the inspector's safety. Moreover, the inspectors rely only on the batch data acquired during the inspection period, which are analyzed by engineers at a later time due to the limited availability of a real-time visualization approach for structural inspection within the traditional mode of SHM. To address these timely challenges, an Augmented Reality (AR)-based automated multiclass damage identification and quantification methodology is proposed in this paper. The interactive visualization framework of AR is integrated with the autonomous decision-making of Artificial Intelligence (AI) in a unified fashion to incorporate human-sensor interaction. The proposed system uses an AI model that is trained and optimized using the YOLOv5 architecture to detect and classify four different types of anomalies/damages (i.e., cracks, spalls, pittings, and joints). The AI model is then updated to quantify the length, area, and perimeter of any damage using segmentation to further assess its severity. Once the model is developed, the model is embedded with the AR device and tested through its interactive environment for SHM of various structures. The paper concludes that the proposed approach

successfully classifies four types of damage with an accuracy of more than 90% for up to 2 m, and it also quantifies the length, area, and perimeter with less than 2% of error. © 2022 The Author(s)

Abstract Background: Pericardial adipose tissue (PAT) may represent a novel risk marker for cardiovascular disease. However, absence of rapid radiation-free PAT quantification methods has precluded its examination in large cohorts. Objectives: We developed a fully automated quality-controlled tool for cardiovascular magnetic resonance (CMR) PAT quantification in the UK Biobank (UKB). Methods: Image analysis comprised contouring an en-bloc PAT area on four-chamber cine images. We created a ground truth manual analysis dataset randomly split into training and test sets. We built a neural network for automated segmentation using a Multi-residual U-net architecture with incorporation of permanently active dropout layers to facilitate quality control of the model's output using Monte Carlo sampling. We developed an in-built quality control feature, which presents predicted Dice scores. We evaluated model performance against the test set (n = 87), the whole UKB Imaging cohort (n = 45,519), and an external dataset (n = 103). In an independent dataset, we compared automated CMR and cardiac computed tomography (CCT) PAT quantification. Finally, we tested association of CMR PAT with diabetes in the UKB (n = 42,928). Results: Agreement between automated and manual segmentations in the test set was almost identical to inter-observer variability (mean Dice score = 0.8). The quality control method predicted individual Dice scores with Pearson $r = 0.75$. Model performance remained high in the whole UKB Imaging cohort and in the external dataset, with medium–good quality segmentation in 94.3% (mean Dice score = 0.77) and 94.4% (mean Dice score = 0.78), respectively. There was high correlation between CMR and CCT PAT measures (Pearson $r = 0.72$, p -value 5.3×10^{-18}). Larger CMR PAT area was associated with significantly greater odds of diabetes independent of age, sex, and body mass index. Conclusions: We present a novel fully automated method for CMR PAT quantification with good model performance on independent and external datasets, high correlation with reference standard CCT PAT measurement, and expected clinical associations with diabetes. Automated quantification of 18F-flutemetamol PET activity for categorizing scans as negative or positive for brain amyloid: Concordance with visual image reads

Item Type Journal Article

Abstract Clinical trials of the PET amyloid imaging agent 18F-flutemetamol have used visual assessment to classify PET scans as negative or positive for brain amyloid. However, quantification provides additional information about regional and global tracer uptake and may have utility for image assessment over time and across different centers. Using postmortem brain neuritic plaque density data as a truth standard to derive a standardized uptake value ratio (SUVR) threshold, we assessed a fully automated quantification method comparing visual and quantitative scan categorizations. We also compared the histopathology-derived SUVR threshold with one derived from healthy controls.; Methods: Data from 345 consenting subjects enrolled in 8 prior clinical trials of 18F-flutemetamol injection were used. We grouped subjects into 3 cohorts: an autopsy cohort (n = 68) comprising terminally ill patients with postmortem confirmation of brain amyloid status; a test cohort (n = 172) comprising 33 patients with clinically probable Alzheimer disease, 80 patients with mild cognitive impairment, and 59 healthy volunteers; and a healthy cohort of 105 volunteers, used to define a reference range for SUVR. Visual image categorizations for comparison were from a previous study. A fully automated PET-only

quantification method was used to compute regional neocortical SUVRs that were combined into a single composite SUVR. An SUVR threshold for classifying scans as positive or negative was derived by ranking the PET scans from the autopsy cohort based on their composite SUVR and comparing data with the standard of truth based on postmortem brain amyloid status for subjects in the autopsy cohort. The derived threshold was used to categorize the 172 scans in the test cohort as negative or positive, and results were compared with categorization using visual assessment. Different reference and composite region definitions were assessed. Threshold levels were also compared with corresponding thresholds derived from the healthy group.; Results: Automated quantification (using pons as the reference region) demonstrated 91% sensitivity and 88% specificity and gave 3 false-positive and 4 false-negative scans. All 3 false-positive cases were either borderline-normal by standard of truth or had moderate to heavy cortical diffuse plaque burden. In the test cohort, the concordance between quantitative and visual read categorization ranged from 97.1% to 99.4% depending on the selection of reference and composite regions. The threshold derived from the healthy group was close to the histopathology-derived threshold.; Conclusion: Categorization of 18F-flutemetamol amyloid imaging data using an automated PET-only quantification method showed good agreement with histopathologic classification of neuritic plaque density and a strong concordance with visual read results. Abstract Background: Epicardial adipose tissue (EAT) is emerging as a risk factor for coronary artery disease (CAD). Objective: The aim of this study was to determine the applicability and efficiency of automated EAT quantification. Methods: EAT volume was assessed both manually and automatically in 157 patients undergoing coronary CT angiography. Manual assessment consisted of a short-axis-based manual measurement, whereas automated assessment on both contrast and non-contrast-

enhanced data sets was achieved through novel prototype software. Duration of both quantification methods was recorded, and EAT volumes were compared with paired samples t test. Correlation of volumes was determined with intraclass correlation coefficient; agreement was tested with Bland-Altman analysis. The association between EAT and CAD was estimated with logistic regression. Results: Automated quantification was significantly less time consuming than automated quantification (17 ± 2 seconds vs 280 ± 78 seconds; $P < .0001$). Although manual EAT volume differed significantly from automated EAT volume (75 ± 33 cm³ vs 95 ± 45 cm³; $P < .001$), a good correlation between both assessments was found ($r = 0.76$; $P < .001$). For all methods, EAT volume was positively associated with the presence of CAD. Stronger predictive value for the severity of CAD was achieved through automated quantification on both contrast-enhanced and non-contrast-enhanced data sets. Conclusion: Automated EAT quantification is a quick method to estimate EAT and may serve as a predictor for CAD presence and severity. © 2014 Society of Cardiovascular Computed Tomography.

Abstract The functionality of photoreceptors, rods, and cones is highly dependent on their outer segments (POS), a cellular compartment containing highly organized membranous structures that generate biochemical signals from incident light. While POS formation and degeneration are qualitatively assessed on microscopy images, reliable methodology for quantitative analyses is still limited. Here, we developed methods to quantify POS (QuaPOS) maturation and quality on retinal sections using automated image analyses. POS formation was examined during the development and in adulthood of wild-type mice via light microscopy (LM) and transmission electron

microscopy (TEM). To quantify the number, size, shape, and fluorescence intensity of POS, retinal cryosections were immunostained for the cone POS marker S-opsin. Fluorescence images were used to train the robust classifier QuaPOS-LM based on supervised machine learning for automated image segmentation. Characteristic features of segmentation results were extracted to quantify the maturation of cone POS. Subsequently, this quantification method was applied to characterize POS degeneration in “cone photoreceptor function loss 1” mice. TEM images were used to establish the ultrastructural quantification method QuaPOS-TEM for the alignment of POS membranes. Images were analyzed using a custom-written MATLAB code to extract the orientation of membranes from the image gradient and their alignment (coherency). This analysis was used to quantify the POS morphology of wild-type and two inherited retinal degeneration (“retinal degeneration 19” and “rhodopsin knock-out”) mouse lines. Both automated analysis technologies provided robust characterization and quantification of POS based on LM or TEM images. Automated image segmentation by the classifier QuaPOS-LM and analysis of the orientation of membrane stacks by QuaPOS-TEM using fluorescent or TEM images allowed quantitative evaluation of POS formation and quality. The assessments showed an increase in POS number, volume, and membrane coherency during wild-type postnatal development, while a decrease in all three observables was detected in different retinal degeneration mouse models. All the code used for the presented analysis is open source, including example datasets to reproduce the findings. Hence, the QuaPOS quantification methods are useful for in-depth characterization of POS on retinal sections in developmental studies, for disease modeling, or after therapeutic interventions affecting photoreceptors. Automated quantification of spikes**Item Type** Journal Article**Author** V. Chavakula**Author** I. Sánchez Fernández**Author** J.M. Peters**Author** G. Popli**Author** W. Bosl**Author** S. Rakhade**Author** A. Rotenberg**Author** T. Loddenkemper

Abstract Methods for rapid and objective quantification of interictal spikes in raw, unprocessed electroencephalogram (EEG) samples are scarce. We evaluated the accuracy of a tailored automated spike quantification algorithm. The automated quantification was compared with the quantification by two board-certified clinical neurophysiologists (gold-standard) in five steps: 1) accuracy in a single EEG channel (5 EEG samples), 2) accuracy in multiple EEG channels and across different stages of the sleep-wake cycles (75 EEG samples), 3) capacity to detect lateralization of spikes (6 EEG samples), 4) accuracy after application of a machine-learning mechanism (11 EEG samples), and 5) accuracy during wakefulness only (8 EEG samples). Our method was accurate during all stages of the sleep-wake cycle and improved after the application of the machine-learning mechanism. Spikes were correctly lateralized in all cases. Our automated method was accurate in quantifying and detecting the lateralization of interictal spikes in raw unprocessed EEG samples. © 2012 Elsevier Inc.

Automated quantification of vesicoureteral reflux using machine learning with advancing diagnostic precision

Item Type Journal Article

Author M. Alqaraleh

Author M. Al-Batah

Author M. Salem Alzboon

Author E. Alzaghouli

Abstract This article uses machine learning to quantify vesicoureteral reflux (VUR). VCUGs in pediatric urology are used to diagnose VUR. The goal is to increase diagnostic precision. Various machine learning models categorize VUR grades (Grade 1 to Grade 5) and are evaluated using performance metrics and confusion matrices. Study datasets come from internet repositories with repository names and accession numbers. Machine learning models performed well across several measures. KNN, Random Forest, AdaBoost, and CN2 Rule Induction consistently scored 100 % in AUC, CA, F1-score, precision, recall, MCC, and specificity. These models classified grades well individually and collectively. In contrast, the Constant model performed poorly across all criteria, suggesting its inability to categorize VUR grades reliably. With the most excellent average performance ratings, the CN2 Rule Induction model excelled at grade categorization. Confusion matrices demonstrate that machine

learning models predict VUR grades. The large diagonal numbers of the matrices show that the models are regularly predicted effectively. However, the Constant model's constant Grade 5 forecast reduced its differentiation. This study shows that most machine learning methods automate VUR measurement. The findings aid objective pediatric urology grading and radiographic evaluation. The CN2 Rule Induction model accurately classifies VUR grades. Machine learning-based diagnostic techniques may increase diagnostic precision, clinical decision-making, and patient outcomes. © 2025; Los autores.

Abstract Anthropogenic global change is occurring at alarming rates, leading to increased urgency in the ability to monitor wildlife health in real time. Monitoring sentinel marine species, such as bottlenose dolphins, is particularly important due to extensive anthropogenic modifications to their habitats. The most common non-invasive method of monitoring cetacean health is documentation of skin lesions, often associated with poor health or disease, but the current methodology is inefficient and imprecise. Recent advancements in technology, such as machine learning, can provide researchers with more efficient ecological monitoring methods to address health questions at both the population and the individual levels. Our work develops a machine learning model to classify skin lesions on the understudied Tamanend's bottlenose dolphins (*Tursiops erebennus*) of the Chesapeake Bay, using manual estimates of lesion presence in photographs. We assess the model's performance and find that our best model performs with a high mean average precision (65.6 %–86.8 %), and generally increased accuracy with improved photo quality. We also demonstrate the model's ability to address ecological questions across scales by generating model-based estimates of lesion prevalence and testing the effect of gregariousness on health status. At the population level, our model accurately estimates a prevalence of 72.1 % spot and 27.3 % fringe ring lesions, with a slight underprediction compared to manual estimates (82.2 % and 32.1 %). On the other hand, we find that individual-level analyses from the model predictions may be more sensitive to data quality, and thus, some individual scale questions may not be feasible to address if data quality is inconsistent. Manually, we do find that lesion presence in individuals suggests a positive relationship between lesion presence and gregariousness. This work demonstrates that object detection models on photographic data are reasonably successful, highly efficient, and provide initial estimates on the health status of understudied populations of bottlenose dolphins. © 2024 The Authors

- Abstract** According to FreshFruit in the period 2023 the production of Tahitian lemons was 13 515 tons for USD 14 million being one of the most important citrus fruits in the Peruvian economy. This work develops an automated system for the classification of Tahiti lemons by size and maturity grade from green to yellow. For the simulation of the classification of Tahiti lemons by size from 3 to 6 cm, the bottleneck was determined by direct observation and then the mechanical system was programmed for the classification by size and degree of maturity through the detection of color by HSV to classify Tahiti lemons greater than 10% damage or by maturity, and then obtain the simulation in Factory IO and TIA PORTAL with connection to PLC S7-1200 1214 DC/DC/DC and a HMI TP700. Finally, the grading proposal was implemented in which 100% of the Tahiti lemons were recognized and packed for export through the interactive HMI screen, being able to classify and count them automatically, which has a graphical environment for the operator to manipulate them. © 2023 IEEE.

Abstract Abstract: To observe biodiversity, the variety of plant and animal life in the world or in a particular habitat, human observers make the most common examinations, often assisted by technical equipment. Measuring objectively the number of different species of animals, plants, fungi, and microbes that make up the ecosystem can be difficult. In order to monitor changes in biodiversity, data have to be compared across space and time. Cameras are an essential sensor to determine the species range, abundance, and behavior of animals. The millions of recordings from camera traps set up in natural environments can no longer be analyzed by biologists. We started research on doing this analysis automatically without human interaction. The focus of our present sensor is on image capture of wildlife and moths. Special hardware elements for the detection of different species are designed, implemented, tested, and improved, as well as the algorithms for classification and counting of samples from images and image sequences, e.g., to calculate presence, absence, and abundance values or the duration of characteristic activities related to the spatial mobilities. For this purpose, we are developing stereo camera traps that allow spatial reconstruction of the observed animals. This allows three-dimensional coordinates to be recorded and the shape to be characterized. With this additional feature data, species identification and movement detection are facilitated. To classify and count moths, they are attracted to an illuminated screen, which is then photographed at intervals by a high-resolution color camera. To greatly reduce the volume of data, redundant elements and elements that are consistent from image to image are eliminated. All design decisions take into account that at remote sites and in fully autonomous operation, power supply on the one hand and possibilities for data exchange with central servers on the other hand are limited. Installation at hard-to-reach locations requires a sophisticated and demanding system design with an optimal balance

between power requirements, bandwidth for data transmission, required service and operation in all environmental conditions for at least ten years. © 2021, Pleiades Publishing, Ltd.

Automatic 1D 1H NMR metabolite quantification for bioreactor monitoring

Item Type Journal Article

Author R.C.C. Wang

Author D.A. Campbell

Author J.R. Green

Author M. Čuperlović-Culf

Abstract High-throughput metabolomics can be used to optimize cell growth for enhanced production or for monitoring cell health in bioreactors. It has applications in cell and gene therapies, vaccines, biologics, and bioprocessing. NMR metabolomics is a method that allows for fast and reliable experimentation, requires only minimal sample preparation, and can be set up to take online measurements of cell media for bioreactor monitoring. This type of application requires a fully automated metabolite quantification method that can be linked with high-throughput measurements. In this review, we discuss the quantifier requirements in this type of application, the existing methods for NMR metabolomics quantification, and the performance of three existing quantifiers in the context of NMR metabolomics for bioreactor monitoring. © 2021 by the authors. Author P.O. Zingg

Author H. Esfandiari

Author P. Färnstahl

Abstract In clinical practice, image-based postoperative evaluation is still performed without state-of-the-art computer methods, as these are not sufficiently automated. In this study we propose a fully automatic 3D postoperative outcome quantification method for the relevant steps of orthopaedic interventions on the example of Periacetabular Osteotomy of Ganz (PAO). A typical orthopaedic intervention involves cutting bone, anatomy manipulation and repositioning as well as implant placement. Our method includes a segmentation based deep learning approach for detection and quantification of the cuts. Furthermore, anatomy repositioning was quantified through a multi-step registration method, which entailed a coarse alignment of the pre- and postoperative CT images followed by a fine fragment alignment of the repositioned anatomy. Implant (i.e., screw) position was identified by 3D Hough transform for line detection combined with fast voxel traversal based on ray tracing. The feasibility of our approach was investigated on 27 interventions and compared against manually performed 3D outcome evaluations. The results show that our method can accurately assess the quality and accuracy of the surgery. Our evaluation of the fragment repositioning showed a cumulative error for the coarse and fine alignment of 2.1 mm. Our evaluation of screw placement accuracy resulted in a distance error of 1.32 mm for screw head location and an angular deviation of 1.1° for screw axis. As a next step we will explore generalisation capabilities by applying the method to different interventions. © 2023 by the authors.

Automatic Classification and Quantification of Cell Adhesion Locations on the Endothelium

Item Type Journal Article

Author J. Wei

Author B. Cai

Author L. Zhang

Author B.M. Fu

Abstract To target tumor hematogenous metastasis and to understand how leukocytes cross the microvessel wall to perform immune functions, it is necessary to elucidate the adhesion location and transmigration pathway of tumor cells and leukocytes on/ across the endothelial cells forming the microvessel wall. We developed an algorithm to classify and quantify cell adhesion locations from photomicrographs taken from the experiments of tumor cell/leukocyte adhesion in individual microvessels. The first step is to identify the microvessel by a novel gravity-field dynamic programming (DP) procedure. Next, an anisotropic image smoothing suppresses noises without unduly mitigating crucial visual features. After an adaptive thresholding process further tackles uneven lighting conditions during the imaging process, a series of local mathematical morphological operators and eigenanalysis identify tumor cells or leukocytes. Finally, a novel double component labeling procedure categorizes the cell adhesion locations. This algorithm has generated consistently encouraging performances on photomicrographs obtained from in vivo experiments for tumor cell and leukocyte adhesion locations on the endothelium forming the microvessel wall. Compared with human experts, this algorithm used 1/500–1/200 of the time without having the errors due to human subjectivity. Our automatic classification and quantification method provides a reliable and cost effective approach for biomedical image processing. © 2014, Biomedical Engineering Society.

Automatic classified system for customs export cargo

Item Type Conference Paper

Author M.-H. Hsu

Author Y.-F. Wang

Author D.-A. Chiang

Author Y.-L. Chuang

Abstract Test Classification is functioned to categorized the unclassified text documents into the pre-defined category. We can take the customs export cargo for example and we chiefly make the comparison for the subjective cargo description of the texts and terms categorized by the typists. Most of the said fields are composed of free content, namely, the contents categorized by identical typists. During various periods, it will also exist in distinct cargo descriptions for the same cargo commodity. This situation cause poor classification results. It is necessary for users to lots of time and effort for analysis, filter and determination with the categorized data finished. Thus, we propose an improved term algorithm allowable for the notion of multi-classification and class priority. It is helpful to enhance the accuracy of existent classification system with the ultimate goal that it is available for users to perform rapid an accurate information inquiry.

Automatic complex concrete crack detection and quantification based on point clouds and deep learning

Item Type Journal Article

Author S. Chen

Author G. Fan

Author J. Li

Author H. Hao

Abstract The inspection of cracks on structural surface is an essential component of structural condition assessment. Recent advancements in image-based techniques aim to automate this process and reduce the associated costs. However, these methods typically focus on localized planar cracks, neglecting the more severe and complex multi-planar cracks. Moreover, accurate global positioning and quantification of these complex cracks pose challenges due to image distortions. To tackle these challenges, this paper proposes a point cloud-based framework for the automatic detection and quantification of complex cracks on concrete surfaces. The proposed framework involves generating a semantic point cloud for crack positioning and quantification by integrating a pixel-level crack segmentation network with 3D reconstruction algorithms. With the establishment of the semantic point clouds, a crack skeletonization based crack length quantification method and a crack width quantification algorithm are proposed to facilitate the automated and effective crack quantification. Experimental evaluations are conducted on a test beam with five characteristic flexural cracks. The results demonstrate the superior performance of the proposed framework over conventional methods with a mean relative error of merely 1.3 % in length quantification and a median of absolute errors less than 0.15 mm in crack width measurements. The efficacy and precision of the proposed framework enhance the potential applications of vision techniques for crack inspection. © 2025 The Authors

Automatic coronary calcium scoring in low-dose chest computed tomography

Item Type Journal Article**Author** I. Išgum**Author** M. Prokop**Author** M. Niemeijer**Author** M.A. Viergever**Author** B. Van Ginneken

Abstract The calcium burden as estimated from non-ECG-synchronized computed tomography (CT) exams acquired in screening of heavy smokers has been shown to be a strong predictor of cardiovascular events. We present a method for automatic coronary calcium scoring with low-dose, non-contrast-enhanced, non-ECG-synchronized chest CT. First, a probabilistic coronary calcium map was created using multi-atlas segmentation. This map assigned an a priori probability for the presence of coronary calcifications at every location in a scan. Subsequently, a statistical pattern recognition system was designed to identify coronary calcifications by texture, size, and spatial features; the spatial features were computed using the coronary calcium map. The detected calcifications were quantified in terms of volume and Agatston score. The best results were obtained by merging the results of three different supervised classification systems, namely direct classification with a nearest neighbor classifier, and two-stage classification with nearest neighbor and support vector machine classifiers. We used a total of 231 test scans containing 45 674 mm³ of coronary calcifications. The presented method detected on average 157/198 mm³ (sensitivity 79.2%) of coronary calcium volume with on average 4 mm³ false positive volume. Calcium scoring can be performed automatically in low-dose, noncontrast enhanced, non-ECG-synchronized chest CT in screening of heavy smokers to identify subjects who might benefit from preventive treatment. © 2012 IEEE.

Automatic extraction of land cover statistics from satellite imagery by deep learning

Item Type Journal Article**Author** E. Bernasconi**Author** F. De Fausti**Author** F. Pugliese**Author** M. Scannapieco**Author** D. Zardetto

Abstract In this paper, we address the challenge of producing fully automated land cover estimates from satellite imagery through Deep Learning algorithms. We developed our system according to a tile-based, classify-and-count design. To implement the classification engine of the system, we adopted a cutting-edge Convolutional Neural Network model named Inception-V3, which we customized and trained for scene classification on the EuroSAT dataset. We tested and validated our system on two Sentinel-2 images representing quite different Italian territories (with an area of 751

km² and 443 km², respectively). Because no genuine ground-truth is available for the land cover of these sub-regional territories, we built a pseudo ground-truth by integrating land cover information from flagship European projects CORINE and LUCAS. A critical and careful analysis shows that our automatic land cover estimates are in good agreement with the pseudo ground-truth and offers extensive evidence of the remarkable segmentation ability of our system. The limits of our approach are also critically discussed in the paper and possible countermeasures are illustrated. When compared with traditional projects like CORINE and LUCAS, our automatic land cover estimation system exhibits three fundamental advantages: it can dramatically reduce production costs; it can allow delivering very timely and frequent land cover statistics; it can enable land cover estimation for very small territorial areas, well beyond the NUTS-2 level. As an additional outcome of land cover estimation, our system also automatically generates moderate resolution land cover maps that might be used in cartography projects as an agile first-level tool for map update or change detection purposes. © 2022 - IOS Press. Abstract This paper presents a new automatically quantitative facial features classification system for TCM spirit diagnosis based on facial features. Facial diagnosis is an important diagnostic method in TCM (Traditional Chinese Medicine) and has been used for a long time. However, this traditional diagnostic method is mainly based on observation by TCM doctors and their personal experience. To develop quantification methods for TCM is very important. First, we capture facial features from video images through some algorithms, and then we use some classification models to analyze them. Finally, IG (Information Gain) is used to analyse which kind of features has good performance. Experiment results show that our system has high classification accuracy. © 2014 IEEE.

Automatic Monitoring System for Seed Germination Test Based on Deep Learning

Item Type Journal Article

Author Q. Peng

Author L. Tu

Author Y. Wu

Author Z. Yu

Author G. Tang

Author W. Song

Abstract Germination test is an irreplaceable step in seed selection and breeding. The current traditional germination test method must rely on experienced professional technicians to repeatedly classify and count the germination status of seeds and count the germination rate at different moments during the whole test process (usually takes 2 to 10 days). Currently, only the German seed germination detection system (Germination Scanalyzer) can solve this problem, but it is so expensive that it has not been practically promoted. In order to improve breeding efficiency, an automatic monitoring system for seed germination tests based on deep learning was designed. It includes a modified germination thermostat, connected with a three-dimensional movable camera bin with built-in camera; a multifunctional software system capable of online, offline, and sentinel mode monitoring; a dense distributed small target detection algorithm (DDST-CenterNet) for seed germination monitoring systems. The system test results show that the seed germination test automatic monitoring system is low cost, does not depend on the seed background, light, camera model, and other usage environments, and has high scalability. The DDST-CenterNet algorithm proposed in this paper can still maintain high accuracy and good stability in the process of seed target detection and classification as the number and density of seeds increase, which is suitable for a special application scenario of seed germination test. In addition, the algorithm has high computational efficiency and can give detection results at a frame rate of not less than 10fps, which can be used in practical applications. © 2022 Qi Peng et al.

Abstract Aims: We assessed the value of automated MRI quantification methods in the differential diagnosis of behavioral-variant frontotemporal dementia (bvFTD) from Alzheimer disease (AD), Lewy body dementia (LBD), and subjective memory complaints (SMC). We also examined the role of the C9ORF72-related genetic status in the differentiation sensitivity. Methods: The MRI scans of 50 patients with bvFTD (17 C9ORF72 expansion carriers) were analyzed using 6 quantification methods as follows: voxel-based morphometry (VBM), tensor-based morphometry, volumetry (VOL), manifold learning, grading, and white-matter hyperintensities. Each patient was then individually compared to an independent reference group in order to attain diagnostic suggestions. Results: Only VBM and VOL showed utility in correctly identifying bvFTD from our set of data. The overall classification sensitivity of bvFTD with VOL + VBM achieved a total sensitivity of 60%. Using VOL + VBM, 32% were misclassified as having LBD. There was a trend of higher values for classification sensitivity of the C9ORF72 expansion carriers than noncarriers. Conclusion: VOL, VBM, and their combination are effective in differential diagnostics between bvFTD and AD or SMC. However, MRI atrophy profiles for bvFTD and LBD are too similar for a reliable differentiation with the quantification methods tested in this study. © 2018 The Author(s) Published by S. Automatic music mood classification by learning cross-media relevance between audio and lyrics

Item Type Conference Paper

Author Y. Xiong

Author F. Su

Author Q. Wang

Abstract Automatic analysis of the mood of a piece of music is of great value in music searching, understanding, recommendation and some other music-related applications. Different from most of previous methods that adopted a discriminative mood classification scheme, in this paper, we propose a generative multimodal method for automatically classifying the mood of a piece of music based on effective learning of the relevance (i.e. the joint distribution) between the audio and the lyrics modalities of music. We present effective algorithms for computing the word-to-audio and word-to-word relations in the music as well as a priori probability of lyrics words, which altogether form the multimodal joint distribution that distinctively captures the intrinsic characteristic of one specific music mood. A piece of music is then classified to the mood category that maximizes this joint probability of different modalities of music data. The experiment results demonstrated the effectiveness of the proposed method. © 2017 IEEE.

Abstract Human epidermal growth factor receptor 2 (HER2), a transmembrane tyrosine kinase receptor encoded by the ERBB2 gene on chromosome 17q12, is a predictive and prognostic biomarker in invasive breast cancer (BC). Approximately 20% of BC are HER2-positive as a result of ERBB2 gene amplification and overexpression of the HER2 protein. Quantification of HER2 is performed routinely on all invasive BCs, to assist in clinical decision making for prognosis and treatment for HER2-positive BC patients by manually counting gene signals. We propose an automated system to quantify the HER2 gene status from chromogenic in situ hybridization (CISH) whole slide images (WSI) in invasive BC. The proposed method selects untruncated and nonoverlapped singular nuclei from the cancer regions using color unmixing and machine learning techniques. Then, HER2 and chromosome enumeration probe 17 (CEP17) signals are detected based on the RGB intensity and counted per nucleus. Finally, the HER2-to-CEP17 signal ratio is calculated to determine the HER2 amplification status following the ASCO/CAP 2018 guidelines. The proposed method reduced the labor and time for the quantification. In the experiment, the correlation coefficient between the proposed automatic CISH quantification method and pathologist manual enumeration was 0.98. The p-values larger than 0.05 from the one-sided paired t-test ensured that the proposed method yields statistically

indifferent results to the reference method. The method was established on WSI scanned by two different scanners. Through the experiments, the capability of the proposed system has been demonstrated. © 2019 Society of Photo-Optical Instrumentation Engineers (SPIE).

Abstract Several cell quantification techniques including optical and electrochemical methods have been developed. However, these techniques have certain limitations such as the requirement of considerable effort and time or insufficient feasibility and accessibility. Moreover, cell quantification is generally performed in an invasive manner, which makes performing continuous cell experiments difficult and leads to the requirement of large number of samples. In this study, a simple, rapid, and accurate in-situ cell quantification method using an achromatic colorimetric sensor system is proposed. A non-invasive achromatic colorimetric cell quantitation sensor (Ach-CQ sensor) is developed based on the subtractive color model. The color of the sensor changes from black to orange owing to the pH change occurring due to the release of acid molecules such as proton donors and lactate during cellular respiration. The Ach-CQ sensor exhibits a higher color contrast difference and effectively determines the number of cells through color changes within 20 s compared with that of a conventional pH indicator such as bromothymol blue. Moreover, machine learning-assisted, saturation-based image analysis is applied for the facile quantification of living cells to achieve automatic quantification of living cells in a non-invasive manner with a limit of detection of 51×10^4 cells in the case of HeLa cells using a smartphone. Additionally, a 3D-printed Ach-CQ sensor kit is fabricated for on-site cell quantification. © 2022 Elsevier B.V.

Automatic quantification of lymphocyte vacuolization in peripheral blood smears of patients with Batten's disease (CLN3 disease)

Item Type Journal Article**Author** L.J.P. Nonkes**Author** W.F.E. Kuper**Author** K. Berrens-Hogenbirk**Author** R.E.A. Musson**Author** P.M. van Hasselt**Author** A. Huisman

Abstract Quantifying lymphocyte vacuolization in peripheral blood smears (PBSs) serves as a measure for disease severity in CLN3 disease—a lysosomal storage disorder of childhood-onset. However, thus far quantification methods are based on labor-intensive manual assessment of PBSs. As machine learning techniques like convolutional neural networks (CNNs) have been deployed quite successfully in detecting pathological features in PBSs, we explored whether these techniques could be utilized to automate quantification of lymphocyte vacuolization. Here, we present and validate a deep learning pipeline that automates quantification of lymphocyte vacuolization. By using two CNNs in succession, trained for cytoplasm-segmentation and vacuolization-detection, respectively, we obtained an excellent correlation with manual quantification of lymphocyte vacuolization ($r = 0.98$, $n = 40$). These results show that CNNs can be utilized to automate the otherwise cumbersome task of manually quantifying lymphocyte vacuolization, thereby aiding prompt clinical decisions in relation to CLN3 disease, and potentially beyond. © 2021 The Authors. Automatic recognition of mitotic HEp-2 cells

Item Type Conference Paper**Author** G. Percannella**Author** P. Soda**Author** M. Vento

Abstract Indirect immunofluorescence (IIF) is the recommended method to diagnose the presence of antinuclear autoantibodies in patient serum, but it suffers from several issues limiting its reliability and reproducibility. Diagnostic procedure consists of the following four steps: image acquisition, mitosis detection, fluorescence intensity classification and staining pattern recognition. The detection of mitotic cells, which rarely occur in a well in comparison to other cells, permits to assess the correctness of slide preparation process, providing also information on image staining pattern. In order to support IIF diagnostic procedure, recent researches have been directed towards the development of computer-aided-diagnosis systems, focusing on image acquisition, fluorescence intensity classification and staining pattern recognition. In this respect, we first present a set of features specifically tailored for this application and then we propose mitotic cells classification system able to handle their low a priori probability based on a class skew learning method. The approach has been evaluated on an annotated dataset of mitotic cells and successfully compared to five learning methods. Copyright © 2011 ibai-publishing.

Balanced knowledge distillation for long-tailed learning

Item Type Journal Article

Author S. Zhang

Author C. Chen

Author X. Hu

Author S. Peng

Abstract Deep models trained on long-tailed datasets exhibit unsatisfactory performance on tail classes. Existing methods usually modify the classification loss to increase the learning focus on tail classes, which unexpectedly sacrifice the performance on head classes. In fact, this scheme leads to a contradiction between the two goals of long-tailed learning, i.e., learning generalizable representations and facilitating learning for tail classes. In this work, we explore knowledge distillation in long-tailed scenarios and propose a novel distillation framework, named Balanced Knowledge Distillation (BKD), to disentangle the contradiction between the two goals and achieve both simultaneously. Specifically, given a teacher model, we train the student model by minimizing the combination of an instance-balanced classification loss and a class-balanced distillation loss. The former benefits from the sample diversity and learns generalizable representation, while the latter considers the class priors and facilitates learning for tail classes. We conduct extensive experiments on several long-tailed benchmark datasets and demonstrate that the proposed BKD is an effective knowledge distillation framework in long-tailed scenarios, as well as a competitive method for long-tailed learning. Abstract The focus of this paper is to provide a fast and reliable quantification method of bamboo's main chemical components. Therefore, thermogravimetric analysis was used to determine holocellulose and lignin content in different bamboo specimens.

The influence of nitrogen vs. air atmospheres was investigated on the thermal degradation behavior of *Phyllostachys edulis* (Moso), *Bambusa vulgaris* (BV) and Iranian *Phyllostachys* (IR) bamboos. Due to peaks overlapping, the deconvolution process was carried out to resolve hidden peaks and to allow adequate phase quantification. Also, a set of machine learning (ML) algorithms was applied to predict the composition of the studied bamboos within the 200–500 °C range in their TGA-DTG profiles. The ensembles of the ML models at $R^2 > 0.99$ proved a connection between the features in thermogravimetric curves with two concentrations of the main components, which were preliminarily established by means of chemical extraction from the respective samples. © 2022, The Author(s), under exclusive licence to Springer Nature B.V.

Bayes covariant multi-class classification

Item Type Journal Article

Author O. Šuch

Author S. Barreda

Abstract We consider multi-class classification models built from complete sets of pairwise binary classifiers. The Bradley–Terry model is often used to estimate posterior distributions in this setting. We introduce the notion of Bayes covariance, which holds if the multi-class classifier respects multiplicative group action on class priors. As a consequence, a Bayes covariant method yields the same result whether new priors are considered before or after combination of the individual classifiers, which has several practical advantages for systems with feedback. In the paper, we construct a Bayes covariant combining method and compare it with previously published methods in both Monte Carlo simulations as well as on a practical speech frame recognition task. © 2016 Elsevier B.V.

BayesAHDD: A new Bayesian rule-based adaptive hypersphere data description for few-shot one-class classification

Item Type Journal Article**Author** Y. Ren**Author** X. Liu**Author** Y. Pei**Author** Y. Li**Author** Y. Wei

Abstract Few-shot one-class classification (FS-OCC) is a challenging classification problem that involves learning from a very limited number of training samples, all from a single class. Recently, several data description methods have been proposed to address the FS-OCC problem. Unlike conventional one-class classification problems, the few-shot setting requires the model to generalize to novel tasks with previously unseen positive classes. Most existing methods learn decision boundaries in the feature space without explicitly modeling the underlying data distributions, which limits the generalization ability of the learned representations. To address this issue, we propose Bayesian Rule-based Adaptive Hypersphere Data Description (BayesAHDD), a probabilistic framework that represents data with multivariate Gaussian distributions and performs classification according to the Bayes decision rule. Based on the assumption that negative samples are more dispersed in the feature space, BayesAHDD models the negative class by scaling the positive class variance vector element-wise using a learnable vector. To address the challenges of exploding gradients and numerical overflow, we impose a lower bound on the positive class variance vector and introduce a trainable parameter that integrates the class prior probability ratio with the normalization constants of the Gaussian class-conditional densities. Experimental results on both benchmark and domain-specific datasets show that BayesAHDD consistently outperforms existing baselines and state-of-the-art FS-OCC methods. Moreover, quantitative analysis demonstrates that the learned feature representations exhibit superior discriminative ability compared to those produced by previous approaches. © 2025 Published by Elsevier Ltd.

Bayesian classification of the ice cover of the Arctic seas**Item Type** Journal Article**Author** N.Y. Zakhvatkina**Author** I.A. Bychkova

Abstract A classification of sea ice in the Arctic by age (multiyear; first-year; and first-year deformed ice, nilas, etc.) is developed based on the Bayesian approach using satellite radar data and taking into account regional peculiarities of these types of ice for different sectors of the Arctic. Estimations of a priori probabilities for each ice type, which are required for the use of the Bayesian classification, are obtained by the analysis of ice charts in the Arctic seas developed at the AARI in 2008–2013 using satellite data. A posterior probabilities are estimated visually by an expert. Types of sea ice distinguished by the expert on satellite images make it possible to create sample values of the radar-scattering cross section (RSCS). Examples of the proposed Bayesian classification of ice in the Laptev Sea according to Envisat satellite data are given. © 2015, Pleiades Publishing, Ltd.

Bayesian classifier based on the multivariate normal distribution

Item Type Journal Article

Author I.F. Iatan

Abstract The aim of this paper is the Bayesian estimation techniques to obtain the form of the a posteriori density $p(\mu|D)$ and the desired probability density $p(X|D)$ in the case when $p(X|\mu) \sim N(\mu, \Sigma)$. The treatment of the multivariate case in which Σ is known but μ is not represents the generalization of the univariate case (see [5]). This approach is then used in Bayesian classification. Author U. Pal

Author C.L. Tan

Author T. Lu

Abstract Developing an automatic system for recognizing video texts such as signboards, street names, room numbers, building names and hotels names is challenging due to low resolution, complex background, font or font size variations, and multiple orientations of texts. In this paper, we develop a new system to recognize video texts through binarization by introducing a Bayesian classifier. We explore wavelet decomposition and gradient sub-bands to enhance text information in video. The enhanced information is used in different ways to calculate the requirement of Bayesian classifier, such as a priori probability and conditional probabilities of text pixels to estimate the posterior probability automatically, which results in text components. Connected component analysis is then applied to restore missing text information before sending it to an OCR engine if any disconnection exists in the text components. Experimental results on video data, the benchmark ICDAR scene character data (camera images) and arbitrary orientation data (camera images) show that the proposed method outperforms existing baseline methods in terms of recognition rates at both character and pixel levels. ©2015 Elsevier Ltd. Abstract As autonomous decision-making agents move from narrow operating environments to unstructured worlds, learning systems must move from a closed-world formulation to an open-world and few-shot setting in which agents continuously learn new classes from small amounts of information. This stands in stark contrast to modern machine learning systems that are typically designed with a known set of classes and a large number of examples for each class. In this work we extend embedding-based few-shot learning algorithms to the open-world recognition setting. We combine Bayesian non-parametric class priors with an embedding-based pre-training scheme to yield a highly flexible framework which we refer to as few-shot learning for open world recognition (FLOWR). We benchmark our framework on open-world extensions of the common MiniImageNet and TieredImageNet few-shot learning datasets. Our results show, compared to prior methods, strong classification accuracy performance and up to a 12% improvement in H-measure (a measure of novel class detection) from our non-parametric open-world few-shot learning scheme. © 1979-2012 IEEE.

Abstract Scientific Machine Learning (SciML) integrates physics and data into the learning process, offering improved generalization compared with purely data-driven models. Despite its potential, applications of SciML in prognostics remain limited, partly due to the complexity of incorporating partial differential equations (PDEs) for ageing physics and the scarcity of robust uncertainty quantification methods. This work introduces a Bayesian Physics-Informed Neural Network (B-PINN) framework for probabilistic prognostics estimation. By embedding Bayesian Neural Networks into the PINN architecture, the proposed approach produces principled, uncertaintyaware predictions. The method is applied to a transformer ageing case study, where insulation degradation is primarily driven by thermal stress. The heat diffusion PDE is used as the physical residual, and different prior distributions are investigated to examine their impact on predictive posterior distributions and their ability to encode a priori physical knowledge. The framework is validated against a finite element model developed and tested with real measurements from a solar power plant. Results, benchmarked against a dropout-PINN baseline, show that the proposed B-PINN delivers more reliable prognostic predictions by accurately quantifying predictive uncertainty. This capability is crucial for supporting robust and informed maintenance decision-making in critical power assets. © 2025, Prognostics and Health Management Society. All rights reserved.

Abstract Cone dystrophy with supernormal rod responses (CDSRR) is a rare autosomal recessive hereditary retinal dystrophy caused by biallelic KCNV2 variants. Accurate prevalence data remain limited because current estimates rely on clinically ascertained cases. This study aimed to estimate its population prevalence by integrating curated variant evidence and large-scale population genomics resources. The key methodological feature of this study is a multi-tiered pathogenicity framework combined with estimation of a biologically plausible prevalence range: Known pathogenic variants define conservative estimates, whereas probably pathogenic variants and strong variants of uncertain significance define broader estimates. Allele frequencies were analyzed in 807,162 individuals from the gnomAD database and 144,127 Russian genomes from GDB and EvogenDB. A Bayesian framework was applied to calculate disease prevalence from aggregated carrier frequencies across predefined variant tiers. Conservative estimates based on known pathogenic variants, were 1 in 343,926 globally and 1 in 1,911,347 in Russia. Including broader tiers increased estimates to 1 in 14,620 and 1 in 32,764, respectively. Compared to previous clinically ascertained prevalence of 1 in 865,000, these estimates define a wider biologically plausible prevalence range and are consistent with possible clinical underascertainment. This tier-based approach accounts for uncertainty in variant classification when estimating rare disease prevalence. © 2026 by the authors.

Bayesian Quantification with Black-Box Estimators

Item Type Journal Article

Author A. Ziegler

Author P. Czyż

Abstract Understanding how different classes are distributed in an unlabeled data set is important for the calibration of probabilistic classifiers and uncertainty quantification. Methods like adjusted classify and count, black-box shift estimators, and invariant ratio estimators use an auxiliary and potentially biased black-box classifier trained on a different data set to estimate the class distribution on the current data set and yield asymptotic guarantees under weak assumptions. We demonstrate that these algorithms are closely related to the inference in a particular probabilistic graphical model approximating the assumed ground-truth generative process, and we propose a Bayesian estimator. Then, we discuss an efficient Markov chain Monte Carlo sampling scheme for the introduced model and show an asymptotic consistency guarantee in the large-data limit. We compare the introduced model against the established point estimators in a variety of scenarios, and show it is competitive, and in some cases superior, with the non-Bayesian alternatives. © 2024, Transactions on Machine Learning Research. Bayesian statistical analysis for spams

Item Type Conference Paper
Author Y. Begriche
Author A. Serhrouchni
Abstract This paper presents a Bayesian statistical analysis applied to the spam problem. In most anti-spam related research, generally it is assumed that the probability of a spam occurrence is equal to 0.5, which is in our opinion unrealistic. It is also assumed that in the spam message, words are considered as an independent family of words. This makes us look at how the posterior probability behaves when the a priori probability is different from 0.5 and derive the consequences of the assumption of independent words on the posterior probability. The first assumption pushes us to define a prior and find a posterior probability laws to enhance the spam detection and increase the reliability decision. This analysis differs from previous results, that used the Bayesian approach to the anti-spam issue, especially through refinement and enhancement of various probability laws. © 2010 IEEE.

Abstract	Currently, industries and researchers recognize the need for new ways to incorporate prior knowledge into processes. With the increasing accessibility of machine learning techniques through software packages, data-driven modeling applications are becoming more prevalent, incorporating more advanced techniques and analytics. Bayesian methods utilize advanced concepts of conditional probability for their inferences. This is crucial for developing robust and understandable solutions that can be used for prediction, optimization, or decision-making. In this paper, we discuss the implementation of Bayesian modeling in hydrometallurgy, focusing specifically on its application in the leaching process. Bayesian statistics provides the opportunity to incorporate prior knowledge into a model, making it a valuable approach in this field. Therefore, parameters that influence leaching, such as mineralogy, particle size, redox potential (pH), acidity, and oxido-reduction potential (ORP), were included as random variables in the model. This enables the designing of Bayesian networks with precisely defined a priori probability laws. © 2024, Avestia Publishing. All rights reserved.

Bayesian uncertainty quantification with multi-fidelity data and gaussian processes for impedance cardiography of aortic dissection

Item Type Journal Article

Author S. Ranftl

Author G.M. Melito

Author V. Badeli

Author A. Reinbacher-Köstinger

Author K. Ellermann

Author W. von der Linden

Abstract In 2000, Kennedy and O'Hagan proposed a model for uncertainty quantification that combines data of several levels of sophistication, fidelity, quality, or accuracy, e.g., a coarse and a fine mesh in finite-element simulations. They assumed each level to be describable by a Gaussian process, and used low-fidelity simulations to improve inference on costly high-fidelity simulations. Departing from there, we move away from the common non-Bayesian practice of optimization and marginalize the parameters instead. Thus, we avoid the awkward logical dilemma of having to choose parameters and of neglecting that choice's uncertainty. We propagate the parameter uncertainties by averaging the predictions and the prediction uncertainties over all the possible parameters. This is done analytically for all but the nonlinear or inseparable kernel function parameters. What is left is a low-dimensional and feasible numerical integral depending on the choice of kernels, thus allowing for a fully Bayesian treatment. By quantifying the uncertainties of the parameters themselves too, we show that "learning" or optimising those parameters has little meaning when data is little and, thus, justify all our mathematical efforts. The recent hype about machine learning has long spilled over to computational engineering but fails to acknowledge that machine learning is a big data problem and that, in computational engineering, we usually face a little data problem. We devise the fully Bayesian uncertainty quantification method in a notation following the tradition of E.T. Jaynes and find that generalization to an arbitrary number of levels of fidelity and parallelisation becomes rather easy. We scrutinize the method with mock data and demonstrate its advantages in its natural application where high-fidelity data is little but low-fidelity data is not. We then apply the method to quantify the uncertainties in finite element simulations of impedance cardiography of aortic dissection. Aortic dissection is a cardiovascular disease that frequently requires immediate surgical treatment and, thus, a fast diagnosis before. While traditional medical imaging techniques such as computed tomography, magnetic resonance tomography, or echocardiography

certainly do the job, Impedance cardiography too is a clinical standard tool and promises to allow earlier diagnoses as well as to detect patients that otherwise go under the radar for too long. © 2019 by the authors.

BC-DMKDE: Bayesian Classifier Based on Distance-Corrected Multivariate Kernel Density Estimation

Item Type Conference Paper

Author G. Chen

Author X. Wu

Author Z. Li

Author R. Zhao

Author J. Jiang

Author K. Yang

Abstract In practical classification problems, imbalanced class distribution is very common. Traditional classification methods usually aim at optimizing the overall accuracy, which leads to classification decisions biased towards categories with a large number of samples. Similar to most traditional classifiers, Naive Bayes (NB) is sensitive to the class prior distribution and has poor recognition

performance for minority class samples, which restricts its application in imbalanced classification. Therefore, we propose a Bayesian classifier based on distance-corrected multivariate kernel density estimation (BC-DMKDE). BC-DMKDE relaxes the assumptions regarding conditional independence and the normality of continuous variables in NB classifiers, by incorporating the multivariate kernel density estimation (MKDE). We also incorporate a distance-correction mechanism utilizing kernel density estimation, specifically to alleviate the impact of class imbalance and overlapping data samples. Across 18 real-world benchmarks, BC-DMKDE exhibits superior classification performance and robustness, outperforming existing methods at both the algorithm and data levels. © 2025 IEEE.

Author A. Rocha

Abstract The detection of copy-move image tampering is of paramount importance nowadays, mainly due to its potential use for misleading the opinion forming process of the general public. In this paper, we go beyond traditional forgery detectors and aim at combining different properties of copy-move detection approaches by modeling the problem on a multiscale behavior knowledge space, which encodes the output combinations of different techniques as a priori probabilities considering multiple scales of the training data. Afterward, the conditional probabilities missing entries are properly estimated through generative models applied on the existing training data. Finally, we propose different techniques that exploit the multi-directionality of the data to generate the final outcome detection map in a machine learning decision-making fashion. Experimental results on complex data sets, comparing the proposed techniques with a gamut of copy-move detection approaches and other fusion methodologies in the literature, show the effectiveness of the proposed method and its suitability for real-world applications. © 1992-2012 IEEE.

Benchmarking Energy Quantification Methods to Predict Heating Energy Performance of Residential Buildings in Germany

Item Type Journal Article**Author** S. Wenninger**Author** C. Wiethe

Abstract To achieve ambitious climate goals, it is necessary to increase the rate of purposeful retrofit measures in the building sector. As a result, Energy Performance Certificates have been designed as important evaluation and rating criterion to increase the retrofit rate in the EU and Germany. Yet, today's most frequently used and legally required methods to quantify building energy performance show low prediction accuracy, as recent research reveals. To enhance prediction accuracy, the research community introduced data-driven methods which obtained promising results. However, there are no insights in how far Energy Quantification Methods are particularly suited for energy performance prediction. In this research article the data-driven methods Artificial Neural Network, D-vine copula quantile regression, Extreme Gradient Boosting, Random Forest, and Support Vector Regression are compared with and validated by real-world Energy Performance Certificates of German residential buildings issued by qualified auditors using the engineering method required by law. The results, tested for robustness and systematic bias, show that all data-driven methods exceed the engineering method by almost 50% in terms of prediction accuracy. In contrast to existing literature favoring Artificial Neural Networks and Support Vector Regression, all tested methods show similar prediction accuracy with marginal advantages for Extreme Gradient Boosting and Support Vector Regression in terms of prediction accuracy. Given the higher prediction accuracy of data-driven methods, it seems appropriate to revise the current legislation prescribing engineering methods. In addition, data-driven methods could support different organizations, e.g., asset management, in decision-making in order to reduce financial risk and to cut expenses. © 2021, The Author(s).

Abstract Reliable uncertainty quantification is crucial for trustworthy decision-making and the deployment of AI models in medical imaging. While prior work has explored the ability of neural networks to quantify predictive, epistemic, and aleatoric uncertainties using an information-theoretical approach in synthetic or well-defined data settings like natural image classification, its applicability to real-life medical diagnosis tasks remains underexplored. In this study, we provide an extensive uncertainty quantification benchmark for multi-label chest X-ray classification using the MIMIC-CXR-JPG dataset. We evaluate 13 uncertainty quantification methods for convolutional (ResNet) and transformer-based (Vision Transformer) architectures across a wide range of tasks. Additionally, we extend Evidential Deep Learning, HetClass NNs, and Deep Deterministic Uncertainty to the multi-label setting. Our analysis provides insights into uncertainty estimation effectiveness and the ability to disentangle epistemic and aleatoric uncertainties, revealing method- and architecture-specific strengths and limitations. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2026.

Benchmarking uncertainty quantification for protein engineering

Item Type Journal Article**Author** K.P. Greenman**Author** A.P. Amini**Author** K.K. Yang

Abstract Machine learning sequence-function models for proteins could enable significant advances in protein engineering, especially when paired with state-of-the-art methods to select new sequences for property optimization and/or model improvement. Such methods (Bayesian optimization and active learning) require calibrated estimations of model uncertainty. While studies have benchmarked a variety of deep learning uncertainty quantification (UQ) methods on standard and molecular machine-learning

datasets, it is not clear if these results extend to protein datasets. In this work, we implemented a panel of deep learning UQ methods on regression tasks from the Fitness Landscape Inference for Proteins (FLIP) benchmark. We compared results across different degrees of distributional shift using metrics that assess each UQ method's accuracy, calibration, coverage, width, and rank correlation. Additionally, we compared these metrics using one-hot encoding and pretrained language model representations, and we tested the UQ methods in retrospective active learning and Bayesian optimization settings. Our results indicate that there is no single best UQ method across all datasets, splits, and metrics, and that uncertainty-based sampling is often unable to outperform greedy sampling in Bayesian optimization. These benchmarks enable us to provide recommendations for more effective design of biological sequences using machine learning. © 2025 Greenman et al. Abstract The rapid proliferation of large language models (LLMs) has stimulated researchers to seek effective and efficient approaches to deal with LLM hallucinations and low-quality outputs. Uncertainty quantification (UQ) is a key element of machine learning applications in dealing with such challenges. However, research to date on UQ for LLMs has been fragmented in terms of techniques and evaluation methodologies. In this work, we address this issue by introducing a novel benchmark that implements a collection of state-of-the-art UQ baselines and offers an environment for controllable and consistent evaluation of novel UQ techniques over various text generation tasks. Our benchmark also supports the assessment of confidence normalization methods in terms of their ability to provide interpretable scores. Using our benchmark, we conduct a large-scale empirical investigation of UQ and normalization techniques across eleven tasks, identifying the most effective approaches. © 2025 Association for Computational Linguistics.

Benchmarking Uncertainty Quantification on Biosignal Classification Tasks Under Dataset Shift

Item Type Journal Article

Author T. Xia

Author J. Han

Author C. Mascolo

Abstract A biosignal is a signal that can be continuously measured from human bodies, such as respiratory sounds, heart activity (ECG), brain waves (EEG), etc., based on which, machine learning models have been developed with very promising performance for automatic disease detection and health status monitoring. However, dataset shift, i.e., data distribution of inference varies from the distribution of the training, is not uncommon for real biosignal-based applications. To improve the robustness, probabilistic models with uncertainty quantification are adapted to capture how reliable a prediction is. Yet, assessing the quality of the estimated uncertainty remains a challenge. In this work, we propose a framework to evaluate the capability of the estimated uncertainty in capturing different types of biosignal dataset shifts with various degrees. In particular, we use three classification tasks based on respiratory sounds and electrocardiography signals to benchmark five representative uncertainty quantification methods. Extensive experiments show that, although Ensemble and Bayesian models could provide relatively better uncertainty estimations under dataset shifts, all tested models fail to meet the promise in trustworthy prediction and model calibration. Our work serves as a benchmark evaluation for any future biosignal classifiers without requiring additional datasets. © 2023, The Author(s), under exclusive license to Springer Nature Switzerland AG.

Beneficial effects of adjunctive Aripiprazole in major depressive disorder are not dependent on antidepressant therapy history: A post hoc analysis of 3 randomized, double-blind, placebo-controlled trials

Item Type Journal Article

Abstract Objective: To determine whether switching within or between antidepressant therapy (ADT) classes prior to the use of adjunctive antipsychotic treatment is associated with different outcomes in major depressive disorder (MDD). Method: This was a post hoc analysis of pooled data from 3 similar, multicenter, randomized, double-blind, placebo-controlled registrational studies of aripiprazole adjunctive to ADT conducted between September 2004 and April 2008. The trials comprised the following 3 phases: a 7- to 28-day screening phase, an 8-week single-blind prospective treatment phase, and a 6-week double-blind, randomized phase. Patients were aged 18-65 years and met DSM-IV-TR criteria for MDD. Patients with an inadequate response to ADT during the screening phase entered the prospective treatment phase, during which

they were switched to another ADT medication of either the same or a different class. Those patients with an inadequate response were then randomized to double-blind adjunctive aripiprazole or adjunctive placebo and followed for 6 weeks. Results: Mean improvement in Montgomery-Asberg Depression Rating Scale total score was significantly greater with adjunctive aripiprazole versus adjunctive placebo for both between-class (-9.2 vs -6.2, $P < .001$) and within-class (-9.8 vs -6.6, $P < .001$) switch groups. Relative risks for response were 1.6 (95% CI = 1.3-2.1) for those who switched between classes and 1.7 (95% CI = 1.2-2.2) for those who switched within class. Conclusions: Augmentation with aripiprazole, after either a between-class or within-class switch following initial ADT failure, is an effective option for patients with nonresponsive MDD. In contrast to current strategies employed in clinical practice, these results suggest that adjunctive aripiprazole is a logical strategy in patients unresponsive to ADT. Trial Registration: ClinicalTrials.gov identifiers: NCT00105196, NCT00095758, NCT00095823. © 2012 Physicians Postgraduate Press, Inc.

Beyond burden metrics: Wearable photoplethysmography-derived spatiotemporal progression of atrial fibrillation linked to clinical outcomes

Item Type Journal Article

Author Y. Guo

Author H. Wang

Author H. Wang

Author H. Zhang

Author Z. Jin

Abstract Background Traditional atrial fibrillation (AF) classification lacks dynamic quantification. Current AF burden assessment is constrained by intermittent monitoring and simplistic metrics. Objective This study aimed to establish a continuous, multidimensional AF progression model using wearable photoplethysmography (PPG) for real-world, dynamic burden quantification. Methods In this prospective cohort, 110 patients with paroxysmal AF underwent synchronized PPG (Huawei Watch GT3) and 24-hour Holter monitoring. We developed a multiscale fusion AF algorithm and a 5-dimensional spatiotemporal progression model quantifying episode frequency, duration, clustering, circadian rhythm, and tachycardia burden. Results The fusion algorithm achieved an accuracy of 0.97. The 5-dimensional model showed strong concordance with Holter monitoring, with near-perfect correlation for episode duration ($r = 0.97$) and high interchangeability (intraclass correlation coefficient >0.75). It demonstrated excellent diagnostic performance for burden trajectories (area under the curve 0.98). A composite AF burden score of ≥ 0.59 identified patients at high risk of AF-related symptoms or heart rate issues. Clinically, AF burden increased with worsening European Heart Rhythm Association symptoms ($P = .04$), varied by risk profile ($P = .03$), and differed between ablation- and drug-treated patients (episode duration $P < .001$). Conclusion Continuous PPG-based spatiotemporal modeling robustly quantified dynamic AF progression, enabled precise phenotyping, and may support early intervention in high-risk patients. © 2026 Heart Rhythm Society.

Abstract Background: Enhanced Recovery After Surgery (ERAS) protocols improve outcomes after colorectal surgery, but adherence remains variable and may interact with patient risk. Traditional compliance scores lack granularity to explore these dynamics. We

aimed to use interpretable machine learning to quantify the contribution of individual ERAS items and clinical features to postoperative complications, and to identify data-driven ERAS phenotypes. Methods: This was a secondary analysis of the EuroPOWER cohort (NCT04889798), a prospective European study including 2,841 adults undergoing elective colorectal surgery. Two Extreme Gradient Boosting models were trained to predict in-hospital complications: a complete model (clinical variables + 23 ERAS items) and an ERAS-only model. Both were interpreted using Shapley Additive Explanations (SHAP). In the complete model, SHAP matrices were clustered to derive phenotypes. Feature importance, adherence, and complication rates were compared descriptively. Results: The complete model achieved an AUC of 0.627. SHAP analysis identified frailty, ASA class, BMI, and age as leading predictors, followed by early mobilisation, nutritional care, and thromboprophylaxis. Three phenotypes were identified, with complication rates of 17.7%, 27.1%, and 41.1%, corresponding to robust, intermediate, and frail profiles. The ERAS-only model showed similar discrimination (area under the curve 0.642), but reduced interpretability. SHAP redundancy analysis supported inclusion of all ERAS items. Conclusions: The clinical effect of ERAS adherence appears to be modulated by baseline vulnerability and implementation patterns. SHAP-based models enable transparent risk attribution and phenotype identification, supporting more targeted ERAS strategies and future development of automated quality monitoring tools. © 2025 Sociedad Española de Anestesiología, Reanimación y Terapéutica del Dolor

Beyond engagement: an EEG-based methodology for assessing user's confusion in an educational game

Item Type Journal Article

Author Y. Zhou

Author T. Xu

Author S. Li

Author R. Shi

Abstract Confusion is an emotion, which may occur when the learner is confronting inconsistency between new knowledge and existing cognitive structure, or reasoning for solving the puzzle and problem. Although confusion is not pleasant, it is necessary for the learner to engage in understanding and deep learning. Consequently, confusion assessment has attracted increased interest in e-learning. However, current studies have targeted no further than engagement detection and measurement, while there is lack of studies in investigating cognitive and emotional aspects beyond engagement in the context of game-based learning. To quantify confused states in logic reasoning in game-based learning, we propose an EEG-based methodology for assessing the user's confusion using the OpenBCI device with 8 channels. In the complicated context of game play, it is difficult, and sometimes impossible, to collect the ground truth of the data in real tasks. To solve this issue, this work leverages cross-task and cross-subject methods to build a classifier, that is, training on the data of one standardized cognitive test paradigm (Raven's test) and testing on the data of real tasks in game play (Sokoban Game). It provides a new possibility to create a classifier based on a small dataset. We also employ the end-to-end algorithm of deep learning in machine learning. Results showed the feasibility of this proposal in the task variation of the classifier, with an accuracy of 91.04%. The proposed EEG-based methodology is suitable to analyze learners' confusion on the long game-play duration and has a good adaption in real tasks. © 2019, Springer-Verlag GmbH Germany, part of Springer Nature.

Abstract In this study, we have developed a framework to propagate the uncertainty from the sorption experiments to the THC model, and then to the PA model. To quantify the uncertainty in SCM parameters, we developed a Python package for the Bayesian inference and general UQ. In addition, we developed a surrogate model for the THC model to quantify the buffer-averaged Kd. The Kd values were then transferred to the PA model (PFLOTRAN) for UQ. Although the results are preliminary, they demonstrate multi-model connections and associated uncertainty quantification methodology to maximize the use of existing experimental datasets as well as more complex geochemical models than Kd-based retardation coefficients. © 2022 Proceedings of the International High-Level Radioactive Waste Management Conference, IHLRWM 2022, Embedded with the 2022 ANS Winter Meeting. Author P. Emiliano

Author F. Valero

Author H. Monclús

Abstract Machine learning regression models are increasingly used to improve management, decision-making, and monitoring of drinking water quality, leveraging growing data from real-time sensors and laboratory analyses. However, most models provide only point predictions, ignoring inherent uncertainty caused by unobserved factors that can produce varying outcomes under similar conditions. This study benchmarks state-of-the-art regression algorithms and uncertainty quantification methods for predicting E. coli concentrations in a drinking water catchment. Gradient-boosted decision trees (GBDT) proved effective for real-time tracking, with CatBoost achieving the lowest error (RMSLE = 0.877), improving on the naïve baseline (1.160) and outperforming Random Forest by 5 %. Uncertainty quantification techniques successfully generated

valid prediction intervals to identify high-risk contamination events, with Conformalized Quantile Regression emerging as the most reliable method. By combining accurate GBDT predictions with well-calibrated uncertainty estimates, this approach enhances microbial water quality forecasting, offering improved risk assessment and supporting more robust decision-making in drinking water management. © 2025 The Author(s)

Beyond pointwise supervision: A pairwise-augmented approach for positive-unlabeled learning

Item Type Journal Article

Author L. Tang

Author J. Wang

Author Y. Tian

Author P.M. Pardalos

Abstract Positive-unlabeled (PU) learning trains binary classifiers using a limited subset of labeled positives alongside vast unlabeled data. Existing methods predominantly rely on pointwise supervision, thereby neglecting the rich latent supervisory signals inherent in the unlabeled data. To address this, we propose a novel paradigm that

augments traditional instance-level supervision with a pairwise comparison (Pcomp) perspective. By constructing positive-unlabeled sample pairs, this paradigm learns ranking relationships where a labeled positive instance is expected to exhibit a higher positive confidence than an unlabeled one. This formulates PU learning as a Pcomp classification problem subject to one-sided noise from hidden positives. To render the Pcomp loss tractable under unknown class priors, we devise a Bayesian strategy that iteratively estimates the prior by explicitly modeling instance-dependent labeling probabilities. Furthermore, to mitigate the noise inherent in constructed sample pairs, we introduce a theoretically grounded loss decomposition mechanism. This strategy decouples the Pcomp loss into cyclically symmetric and asymmetric components, exploiting the intrinsic noise-invariance of the former while applying targeted corrections exclusively to the latter. Consequently, our method achieves strong robustness, even in label-scarce regimes. Extensive benchmark experiments demonstrate that our approach significantly outperforms state-of-the-art algorithms, substantiating both its effectiveness and robustness. © 2026 Elsevier Inc.

Big data driven Cyber-Physical System based Lithium-ion battery modeling method with battery aging considered

Item Type Conference Paper

Author S. Li

Author H. He

Author J. Li

Author H. Wang

Abstract As the bottleneck technology of electric vehicles (EVs), the battery has complex and hardly observable inside chemical reactions. Therefore, a precise mathematical model is crucial for the battery management system to ensure the secure and stable operation of the battery. Aiming at achieving a flexible, self-configuring, reliable Battery Management System (BMS), this paper mainly focuses on the following research points: Firstly, a Cyber-Physical system (CPS) based BMS is presented for a better use of battery data. Next, a data cleaning method based on machine learning algorithm is applied to the big data of batteries in electric vehicles. Finally, a rain-flow cycle counting algorithm-based battery degradation quantification method is proposed and a Stacked Denoising Autoencoders-Extreme Learning Machine (SDAE-ELM) algorithm-based battery modeling method is also built to deal with the influence of battery aging phenomenon. Using the battery data extracted from electric buses, model effectiveness and accuracy are validated. The error of the estimated battery terminal voltage estimator is within 2.5%. © 2019, Scanditale AB. All rights reserved.

Big data driven Internet of Things for credit evaluation and early warning in finance

Item Type Journal Article

Author C. Wen

Author J. Yang

Author L. Gan

Author Y. Pan

Abstract The big data technology framework has been successfully used in the Internet of Things, and the financial industry also hopes to use the advanced technology of big data to integrate and improve internal and external data related to credit risks. Relying on more efficient machine learning algorithms to get a reasonable prediction of credit risk can reduce the self-generated losses of the Internet of Things finance and increase profits. This article uses distributed search engine technology to customize web crawlers to obtain the required bank card and transaction data from the multi-source heterogeneous data of the Internet of Things financial industry, design the corresponding Spark parallel algorithm to preprocess the data, and establish an inverted table and two Level index file provides data source for big data analysis platform. After the data source is determined, the Mutually Exclusive Collectively Exhaustive (MECE) analysis method is combined with the scores of many financial business experts in the industry to obtain a set of candidate indicators and quantification methods for the financial credit risk evaluation of the Internet of Things, and analyze the correlation of indicators and risk grading. The random forest algorithm in the big data machine learning library is used to select the feature of the candidate index set, and a multi-level spatial association rule algorithm based on the Hash structure is designed to mine the financial risk information of the Internet of Things, and build a credit risk assessment and intelligent early warning model. This paper selects 26 indicators of Internet of Things finance as the research objects, uses SPSS26.0 software to perform sample Kaiser–Meyer–Olkin (KMO) test and Bartlett sphere test on the original data, and describes the results of factor analysis in detail. The particle swarm algorithm is introduced into the parameter optimization of random forest, and the financial credit risk assessment model of the Internet of Things is established. The results show that this method can significantly reduce the probability of banks making the first and second error rates when evaluating the credit risk of financing the Internet of Things Finance. This is conducive to the smooth development of the Internet of Things financial business for banks, which enables banks to enhance their own profitability while effectively reducing losses due to incorrect credit provision. © 2021 Elsevier B.V.

Binary Classification from Multiple Unlabeled Datasets via Surrogate Set Classification

Item Type Conference Paper**Author** N. Lu**Author** S. Lei**Author** G. Niu**Author** I. Sato**Author** M. Sugiyama**Abstract** To cope with high annotation costs, training a classifier only from weakly supervised data has attracted a great deal of attention these days. Among various approaches, strengthening supervision from completely unsupervised classification is a promising direction, which typically employs class priors as the

only supervision and trains a binary classifier from unlabeled (U) datasets. While existing risk-consistent methods are theoretically grounded with high flexibility, they can learn only from two U sets. In this paper, we propose a new approach for binary classification from m U sets for $m \geq 2$. Our key idea is to consider an auxiliary classification task called surrogate set classification (SSC), which is aimed at predicting from which U set each observed sample is drawn. SSC can be solved by a standard (multi-class) classification method, and we use the SSC solution to obtain the final binary classifier through a certain linear-fractional transformation. We built our method in a flexible and efficient end-to-end deep learning framework and prove it to be classifier-consistent. Through experiments, we demonstrate the superiority of our proposed method over state-of-the-art methods. Copyright © 2021 by the author(s)

Binary Classification only from Unlabeled Data by Iterative Unlabeled-unlabeled Classification

Item Type Conference Paper

Author H. Kaji

Author M. Sugiyama

Abstract Unlabeled-unlabeled (UU) classification (du Plessis et al. 2013) allows us to train a binary classifier from two sets of unlabeled data with different class priors. In this paper, we go beyond this scenario and try to train a binary classifier only from a single set of unlabeled data. Our key idea is to iteratively perform UU classification: We initially split the original single unlabeled dataset into two disjoint datasets and perform UU classification. We then split the original unlabeled dataset in a different way based on the obtained classifier, perform UU classification, and repeat this process until convergence. We numerically show that the classification accuracy tends to be improved over iterations. Finally, we apply our iterative UU classification method to a realworld drowsiness prediction problem and demonstrate its usefulness. © 2019 IEEE.

Abstract In many real-world pattern recognition scenarios, such as in medical applications, the corresponding classification tasks can be of an imbalanced nature. In the current study, we focus on binary, imbalanced classification tasks, i.e. binary classification tasks in which one of the two classes is under-represented (minority class) in comparison to the other class (majority class). In the literature, many different approaches have been proposed, such as under- or oversampling, to counter class imbalance. In the current work, we introduce a novel method, which addresses the issues of class imbalance. To this end, we first transfer the binary classification task to an equivalent regression task. Subsequently, we generate a set of negative and positive target labels, such that the corresponding regression task becomes balanced, with respect to the redefined target label set. We evaluate our approach on a number of publicly available data sets in combination with Support Vector Machines. Moreover, we compare our proposed method to one of the most popular oversampling techniques (SMOTE). Based on the detailed discussion of the presented outcomes of our experimental evaluation, we provide promising ideas for future research directions. © 2021 by SCITEPRESS - Science and Technology Publications, Lda.

Binary quantification and dataset shift: an experimental investigation

Item Type Journal Article

Author P. González

Author A. Moreo

Author F. Sebastiani

Abstract Quantification is the supervised learning task that consists of training predictors of the class prevalence values of sets of unlabelled data, and is of special interest when the labelled data on which the predictor has been trained and the unlabelled data are not IID, i.e., suffer from dataset shift. To date, quantification methods have mostly been tested only on a special case of dataset shift, i.e., prior probability shift; the relationship between quantification and other types of dataset shift remains, by and large, unexplored. In this work we carry out an experimental analysis of how current quantification algorithms behave under different types of dataset shift, in order to identify limitations of current approaches and hopefully pave the way for the development of more broadly applicable methods. We do this by proposing a fine-grained taxonomy of types of dataset shift, by establishing protocols for the generation of datasets affected by these types of shift, and by testing existing quantification methods on the datasets thus generated. One finding that results from this investigation is that many existing quantification methods that had been found robust to prior probability shift are not necessarily robust to other types of dataset shift. A second finding is that no existing quantification method seems to be robust enough to dealing with all the types of dataset shift we simulate in our experiments. The code needed to reproduce all our experiments is publicly available at https://github.com/pglez82/quant_datasetshift. © The Author(s) 2024.

Binocular Video-Based Automatic Pixel-Level Crack Detection and Quantification Using Deep Convolutional Neural Networks for Concrete Structures

Item Type Journal Article

Author L. Liu

Author B. Shen

Author S. Huang

Author R. Liu

Author W. Liao

Author B. Wang

Author S. Diao

Abstract Crack detection and quantification play crucial roles in assessing the condition of concrete structures. Herein, a novel real-time crack detection and quantification method that leverages binocular vision and a lightweight deep learning model is proposed. In this methodology, the proposed method based on the following four modules is adopted: a lightweight classification algorithm, a high-precision segmentation algorithm, a semi-global block matching algorithm (SGBM), and a crack quantification technique. Based on the crack segmentation results, a framework is developed for quantitative analysis of the major geometric parameters, including crack length, crack width, and crack angle of orientation at the pixel level. Results indicate that, by incorporating channel attention and spatial attention mechanisms in the MBConv module, the detection accuracy of the improved EfficientNetV2 increased by 1.6% compared with the original EfficientNetV2. Results indicate that using the proposed quantification method can achieve low quantification errors of 2%, 4.5%, and 4% for the crack length, width, and angle of orientation, respectively. The proposed method can contribute to crack detection and quantification in practical use by being deployed on smart devices. © 2025 by the authors.

Biosensors in drug discovery and drug analysis

Item Type Journal Article

Author E.B. Aydin

Author M. Aydin

Author M.K. Sezginturk

Abstract Background: The determination of drugs in pharmaceutical formulations and human biologic fluids is important for pharmaceutical and medical sciences. Successful analysis requires low sensitivity, high selectivity and minimum interference effects. Current analytical methods can detect drugs at very low levels but these methods require long sample preparation steps, extraction prior to analysis, highly trained technical staff and high-cost instruments. Biosensors offer several advantages such as short analysis time, high sensitivity, real-time analysis, low-cost instruments, and short pretreatment steps over traditional techniques. Biosensors allow quantification not only of the active component in pharmaceutical formulations, but also the

degradation products and metabolites in biological fluids. The present review gives comprehensive information on the application of biosensors for drug discovery and analysis. Moreover, this review focuses on the fabrication of these biosensors.

Methods: Biosensors can be classified as the utilized bioreceptor and the signal transduction mechanism. The classification based on signal transductions includes electrochemical optical, thermal or acoustic. Electrochemical and optic transducers are mostly utilized transducers used for drug analysis. There are many biological recognition elements, such as enzymes, antibodies, cells that have been used in fabricating of biosensors. Aptamers and antibodies are the most widely used recognition elements for the screening of the drugs. Electrochemical sensors and biosensors have several advantages such as low detection limits, a wide linear response range, good stability and re-productibility. Optical biosensors have several advantages such as direct, real-time and label-free detection of many biological and chemical substances, high specificity, sensitivity, small size and low cost. Modified electrodes enhance sensitivity of the electrodes to develop a new biosensor with desired features. Chemically modified electrodes have gained attention in drug analysis owing to low background current, wide potential window range, simple surface renewal, low detection limit and low cost. Modified electrodes produced by modifying of a solid surface electrode via different materials (carbonaceous materials, metal nanoparticles, polymer, biomolecules) immobilization. Recent advances in nanotechnology offer opportunities to design and construct biosensors. Unique features of nanomaterials provide many advantages in the fabrication of biosensors. Nanomaterials have controllable chemical structures, large surface to volume ratios, functional groups on their surface. To develop protein-inorganic hybrid nanomaterials, four preparation methods have been used. These methods are immobilization, conjugation, crosslinking and self-assembly. In the present manuscript, applications of different biosensors, fabricated by using several materials, for drug analysis are reviewed. The biosensing strategies are investigated and discussed in detail.

Results: Several analytical techniques such as chromatography, spectroscopy, radiometry, immunoassays and electrochemistry have been used for drug analysis and quantification. Methods based on chromatography require time-consuming procedure, long sample-preparation steps, expensive instruments and trained staff. Compared to chromatographic methods, immunoassays have simple protocols and lower cost. Electrochemical measurements have many advantages over traditional chemical analyses and give information about drug quantity, metabolic fate of drugs, and pharmacological activity. Moreover, the electroanalytical methods are useful to determine drugs sensitively and selectivity. Additionally, these methods decrease analysis cost and require low-cost instruments and simple sample pretreatment steps.

Conclusion: In recent years, drug analyses are performed using traditional techniques. These techniques have a good detection limit, but they have some limitations such as long analysis time, expensive device and experienced personnel requirement. Increased demand for practical and low-cost analytical techniques biosensor has gained interest for drug determinations in medical sciences. Biosensors are unique and successful devices when compared to traditional techniques. For drug determination, different electrode modification materials and different biorecognition elements are used for biosensor construction. Several biosensor construction strategies have been developed to enhance the biosensor performance. With the considerable progress in electrode surface modification, promotes the selectivity of the biosensor, decreases the production cost and provides miniaturization. In the next years, advances in technology will provide low cost, sensitive, selective biosensors for drug analysis in drug formulations and biological samples. © 2019 Bentham Science Publishers.

Biospectroscopy, biospectrometry and imaging of: *Ilex paraguariensis*. Basis for non-destructive quality evaluation using artificial vision

Item Type Journal Article

Author T.L. Parapugna

Author G. Petroselli

Author R. Erra-Basells

Author M.G. Lagorio

Abstract Yerba mate (YM) is massively produced and consumed as an infusion in South America and is gaining popularity all over the world. This product is obtained from the dried leaves of *Ilex paraguariensis* Saint Hilaire, mixed with fragments of its dried branches. For its commercialization YM must have a minimum percentage of leaves according to a standard classification. Until now, composition quantification has been mechanically performed, thus development of new methods is still pending. In this work a quantification method using solid-phase molecular fluorescence, alternately

diffuse reflectance spectroscopy and an imaging technique using a scanner have been proposed. Strong differences between the spectroscopic properties of leaves and sticks were observed and in all the cases linear correlations between the processed signals and composition were observed. Interesting differences in chemical composition of YM leaves and sticks were additionally obtained in this work by means of total phenol content quantification, ultraviolet matrix assisted laser-desorption ionization mass spectrometry and ultraviolet laser-desorption ionization mass spectrometry. Abstract We address the problem of large-scale fine-grained visual categorization, describing new methods we have used to produce an online field guide to 500 North American bird species. We focus on the challenges raised when such a system is asked to distinguish between highly similar species of birds. First, we introduce 'one-vs-most classifiers.' By eliminating highly similar species during training, these classifiers achieve more accurate and intuitive results than common one-vs-all classifiers. Second, we show how to estimate spatio-temporal class priors from observations that are sampled at irregular and biased locations. We show how these priors can be used to significantly improve performance. We then show state-of-the-art recognition performance on a new, large dataset that we make publicly available. These recognition methods are integrated into the online field guide, which is also publicly available. © 2014 IEEE.

Black-Box Modeling of Electromagnetic Interference Effects and Key Port Determination Method in Electronic Systems Based on Bayesian Networks

Item Type Conference Paper

Author Z. Han

Author Z. Zhou

Abstract The concept of modeling electromagnetic interference effects in electronic systems with Bayesian networks (BNs) is proposed to transform the complex mapping problem between system port interference response and system effects into a classification problem solved by Bayesian networks. For a specific use case, network structure learning and parameter learning are performed on the basis of discrete processing of raw continuous data. Through the validation of test data, it is demonstrated that the learned network structure meets our expectation of the relationship between electromagnetic environment, ports, and system effects, and has a high accuracy in predicting the system electromagnetic interference effects. Based on this, a Bayesian formula-based port risk quantification method is proposed to assist in identifying critical ports. © 2023 IEEE.

Boosting GNN-Based Link Prediction via PU-AUC Optimization

Item Type Journal Article

Author Y. Mao

Author Y. Hao

Author X. Cao

Author Y. Gao

Author C. Yao

Author X. Lin

Abstract Link prediction, which aims to predict the existence of a link between two nodes in a network, has various applications ranging from friend recommendation to protein interaction prediction. Recently, Graph Neural Network (GNN)-based link prediction has demonstrated its advantages and achieved the state-of-the-art performance. Typically, GNN-based link prediction can be formulated as a binary classification problem. However, in link prediction, we only have positive data (observed links) and unlabeled data (unobserved links), but no negative data. Therefore, Positive Unlabeled (PU) learning naturally fits the link prediction scenario. Unfortunately, the unknown class prior and data imbalance of networks impede the use of PU learning in link prediction. To deal with these issues, this paper proposes a novel model-agnostic PU learning algorithm for GNN-based link prediction by means of Positive-Unlabeled Area Under the Receiver Operating Characteristic Curve (PU-AUC) optimization. The proposed method is free of class prior estimation and able to handle the data imbalance. Moreover, we propose an accelerated method to reduce the operational complexity of PU-AUC optimization from quadratic to approximately linear. Extensive experiments back up our theoretical analysis and validate that the proposed method is capable of boosting the performance of the state-of-the-art GNN-based link prediction models. © 1989-2012 IEEE.

Boosting positive and unlabeled learning for anomaly detection with multi-features

Item Type Journal Article

Author J. Zhang

Author Z. Wang

Author J. Meng

Author Y.-P. Tan

Author J. Yuan

Abstract One of the key challenges of machine learning-based anomaly detection relies on the difficulty of obtaining anomaly data for training, which is usually rare, diversely distributed, and difficult to collect. To address this challenge, we formulate anomaly detection as a Positive and Unlabeled (PU) learning problem where only labeled positive (normal) data and unlabeled (normal and anomaly) data are required for learning an anomaly detector. As a semi-supervised learning method, it does not require providing labeled anomaly data for the training, thus it is easily deployed to various applications. As the unlabeled data can be extremely unbalanced, we introduce a novel PU learning method, which can tackle the situation where an unlabeled data set is mostly composed of positive instances. We start by using a linear model to extract the most reliable negative instances followed by a self-learning process to add reliable negative and positive instances with different speeds based on the estimated positive class prior. Furthermore, when feedback is available, we adopt boosting in the self-learning process to advantageously exploit the instability characteristic of PU learning. The classifiers in the self-learning process are weighted combined based on the estimated error rate to build the final classifier. Extensive experiments on six real datasets and one synthetic dataset show that our methods have better results under different conditions compared to existing methods. © 1999-2012 IEEE.

Bootstrap Latent Prototypes for graph positive-unlabeled learning

Item Type Journal Article

Author C. Liang

Author Y. Tian

Author D. Zhao

Author M. Li

Author S. Pan

Author H. Zhang

Author J. Wei

Abstract Graph positive-unlabeled (GPU) learning aims to learn binary classifiers from only positive and unlabeled (PU) nodes. The state-of-the-art methods rely on provided class prior probabilistic and their performance lags far behind the fully labeled counterparts. To bridge the gap, we propose Bootstrap Latent Prototypes (BLP), a framework that consists of a graph representation learning module and a two-step strategy algorithm. The learning module bootstraps previous versions of node

representations to serve as targets and learns enhanced representations by predicting the latent prototypes respectively for the P set and each individual in the U set. It eliminates the requirement for a class prior, while capturing positive similarity information, as well as the low-level semantic similarity and uniformity information, thereby producing closely aligned and discriminated representations for positive nodes. The algorithm module utilizes the obtained representations to select reliable negative nodes and train a binary classifier with both labeled positives and selected reliable negatives. Experimental results on diverse real-life datasets demonstrate that our proposed BLP method not only outperforms state-of-the-art approaches but also surpasses fully labeled classification models in most cases. The source code is available at <https://github.com/lcq411/BLP>. © 2024 Elsevier B.V.

Bootstrap Your Own Prior: Towards Distribution-Agnostic Novel Class Discovery

Item Type Conference Paper

Author M. Yang

Author L. Wang

Author C. Deng

Author H. Zhang

Abstract Novel Class Discovery (NCD) aims to discover unknown classes without any annotation, by exploiting the transferable knowledge already learned from a base set of known classes. Existing works hold an impractical assumption that the novel class distribution prior is uniform, yet neglect the imbalanced nature of real-world data. In this paper, we relax this assumption by proposing a new challenging task: distribution-agnostic NCD, which allows data drawn from arbitrary unknown class distributions and thus renders existing methods useless or even harmful. We tackle this challenge by proposing a new method, dubbed 'Boot-strapping Your Own Prior (BYOP)', which iteratively estimates the class prior based on the model prediction it-self. At each iteration, we devise a dynamic temperature technique that better estimates the class prior by encouraging sharper predictions for less-confident samples. Thus, BYOP obtains more accurate pseudo-labels for the novel samples, which are beneficial for the next training iteration. Extensive experiments show that existing methods suffer from imbalanced class distributions, while BYOP1 out-performs them by clear margins, demonstrating its effectiveness across various distribution scenarios. © 2023 IEEE.

BottleEdgeNet: A Calibrated Edge-Convolutional Neural Network (CNN) Framework for PET Bottle Quality Inspection in Deposit Return Schemes (DRS)

Item Type Conference Paper

Author L. Duma

Author M.D.C. Mendoza

Abstract Ensuring the cleanliness and structural integrity of PET bottles is a key requirement for the effective operation of Deposit Return Schemes (DRS) in circular economy frameworks. Traditional inspection systems and commercial Reverse Vending Machines (RVMs) often fail to detect subtle defects, leading to high False Acceptance and Rejection Rates. This paper presents BottleEdgeNet, a Calibrated Edge-Convolutional Neural Network (CNN) framework for PET bottle quality inspection that integrates EfficientNet-B0, ResNet-50, and a Google Teachable Machine backbone within a unified, low-power inference pipeline implemented in TensorFlow Lite (FP32/INT8) for CPU-oriented edge inference. The proposed system introduces a class-wise power reweighting calibration layer to stabilize confidence scores and mitigate label-shift effects under heterogeneous lighting and background conditions. A hybrid dataset comprising 7,849 training, 972 validation, and 972 testing images (plus 80 real-world samples) was used to evaluate performance across four operational classes: Clean Intact, Clean Damaged, Dirty Intact, and Dirty Damaged. Internal tests revealed that EfficientNetB0 (FP32) achieved the best accuracy (87.96%), outperforming ResNet-50 (84.47%) and Teachable Machine (67.45%), with negligible degradation after INT8 quantization. External validation confirmed EfficientNet-B0's generalization stability (87.5%), while ResNet-50 prioritized contamination detection and Teachable Machine provided a lightweight, no-code alternative for rapid deployment. To enhance field robustness, improvements should focus on data diversity and controlled illumination rather than model complexity. We report operational decision metrics (FAR/FRR) under argmax decision logic to connect model-level classification behavior with accept/reject decisions. In addition, edge-oriented efficiency is discussed through proxy-based considerations across FP32 and INT8 inference. Together, these analyses strengthen the practical relevance of the proposed framework by linking accuracy and confidence stabilization to DRS throughput, quality control, and deployment feasibility. The results demonstrate that calibrated Edge-CNNs can enable accurate, efficient, and scalable inspection of returnable PET bottles, supporting sustainable and decentralized DRS operations. © 2026 IEEE.

Bound on the probability of HMM misclassification

Item Type Conference Paper

Author C. Keroglou

Author C.N. Hadjicostis

Abstract In this paper we consider the problem of classifying a sequence of observations among two known hidden Markov models (HMMs). We use a classifier that minimizes the probability of error (i.e., the probability of misclassification), and we are interested in assessing its performance by computing the a priori probability of error (before any observations are made). This probability (that the classifier makes an incorrect decision) can be obtained, as a function of the length of the sequence of observations, by summing up the probability of misclassification over all possible observation sequences, weighted by their corresponding probabilities. In an effort to avoid the high complexity associated with the computation of the exact probability of error, we establish an upper bound on the probability of error, and we find the necessary and sufficient conditions for this bound to tend to zero exponentially with the number of observation steps. We focus on classification among two HMMs that have the same language, which is the most difficult case to characterize; our approach can easily be applied to classification among any two arbitrary HMMs. The bound we obtain can also be used to approximate the dissimilarity between the two given HMMs. © 2011 IEEE.

Bounds on the probability of misclassification among hidden Markov models

Item Type Conference Paper**Author** C. Keroglou**Author** C.N. Hadjicostis

Abstract Given a sequence of observations, classification among two known hidden Markov models (HMMs) can be accomplished with a classifier that minimizes the probability of error (i.e., the probability of misclassification) by enforcing the maximum a posteriori probability (MAP) rule. For this MAP classifier, we are interested in assessing the a priori probability of error (before any observations are made), something that can be obtained (as a function of the length of the sequence of observations) by summing up the probability of error over all possible observation sequences of the given length. To avoid the high complexity of computing the exact probability of error, we devise techniques for merging different observation sequences, and obtain corresponding upper bounds by summing up the probabilities of error over the merged sequences. We show that if one employs a deterministic finite automaton (DFA) to capture the merging of different sequences of observations (of the same length), then Markov chain theory can be used to efficiently determine a corresponding upper bound on the probability of misclassification. The result is a class of upper bounds that can be computed with polynomial complexity in the size of the two HMMs and the size of the DFA. © 2011 IEEE.

Brain tissue segmentation in neurosurgery: a systematic analysis for quantitative tractography approaches

Item Type Journal Article**Author** P.R. Kumar**Author** R.K. Jha**Author** A. Katti

Abstract Diffusion magnetic resonance imaging (dMRI) is a cutting-edge imaging method that provides a macro-scale in vivo map of the white matter pathways in the brain. The measurement of brain microstructure and the enhancement of tractography rely heavily on dMRI tissue segmentation. Anatomical MRI technique (e.g., T1- and T2-weighted imaging) is the most widely used method for segmentation in dMRI. In comparison to anatomical MRI, dMRI suffers from higher image distortions, lower image quality, and making inter-modality registration more difficult. The dMRI tractography study of brain connectivity has become a major part of the neuroimaging landscape in recent years. In this research, we provide a high-level overview of the methods used to segment several brain tissues types, including grey and white matter and cerebrospinal fluid, to enable quantitative studies of structural connectivity in the

brain in health and illness. In the first part of our review, we discuss the three main phases in the quantitative analysis of tractography, which are correction, segmentation, and quantification. Methodological possibilities are described for each phase, along with their popularity and potential benefits and drawbacks. After that, we will look at research that used quantitative tractography approaches to examine the white and grey matter of the brain, with an emphasis on neurodevelopment, ageing, neurological illnesses, mental disorders, and neurosurgery as possible applications. Even though there have been substantial advancements in methodological technology and the spectrum of applications, there is still no consensus regarding the "optimal" approach in the quantitative analysis of tractography. As a result, researchers should tread carefully when interpreting the findings of quantitative analysis of tractography. © The Author(s) under exclusive licence to Belgian Neurological Society 2023.

Abstract The Early Neolithic site Göbekli Tepe which has delivered the largest corpus of grinding stones known by now in Northern Mesopotamia is used as a case study to test the possibility of wear classification and the application of quantification methods in use-wear caused by the processing of cereals. The research design is based on combined optical and tactile analyses as well as geometric analyses of shape deformation and 3D-modelling of surface roughness on original grinding stones and experimentally used replicas. This approach can be used to differentiate between fine and coarse flour as products of cereal processing as they produce different wear markers. Also, it can be applied to quantify use-lives of handstones. At Göbekli Tepe, handstones with markers for fine flour production, which can be possibly linked to bread-like products, are in the minority while handstones with markers for coarse flour clearly predominate. The social implications of these results have to be discussed with a view towards Göbekli Tepe's interpretation as a ritual site. We propose fine flour as a special product within feasting, in accordance with previous interpretations of the site. © 2020 Elsevier Ltd

Breast cancer classification by a new approach to assessing deep neural network-based uncertainty quantification methods

Item Type Journal Article**Author** F. Hamedani-KarAzmoodehFar**Author** R. Tavakkoli-Moghaddam**Author** A.R. Tajally**Author** S.S. Aria

Abstract Deep learning-based approaches have become widespread in medical fields and have achieved profound success in recent years. Nonetheless, most of these approaches cannot provide the certainty of their output numerically, and their output often has too many confidence levels. Therefore, they cannot be efficient and may even lead to irreparable damage. Accordingly, to tackle such a challenge, the Bayesian approximation and Ensemble learning techniques are deliberated as uncertainty quantification (UQ) methods. We apply and evaluate three UQ models regarding the classification of breast tumor tissue types. These methods are Mont Carlo-dropout (MCD), Bayesian Ensemble, and MCD Ensemble. Furthermore, to increase the classification's precision and eliminate the adverse effects of the smallness of the data collection in Wisconsin Diagnostic Breast Cancer (WDBC) used in the present research, transfer learning technique and pre-trained Convolutional Neural Network (DenseNet121) are considered. Three proposed models are compared based on their ability to quantify the reliability of classification according to novel performance metrics employed to assess estimated uncertainty. Our quantitative and qualitative examinations in the study demonstrate that models show high uncertainty in misclassifications, which is vital in determining the rate of medical diagnosis risks. As a result, by using these new assessment criteria, we intend to ascertain when can trust the output of the deep neural network. Moreover, in the examination, we witness more reliability in uncertainty quantification of the Bayesian Ensemble model. © 2022 Elsevier Ltd

Bridging expert knowledge and machine intelligence: a hybrid spatial indicator framework for ecotourism suitability

Item Type Journal Article

Author E. Karadeniz

Author S. Er

Author M. Aydogdu

Author F. Sunbul

Abstract Ecotourism suitability assessments increasingly rely on ecological indicators that capture spatial heterogeneity, ecosystem sensitivity, and biodiversity value. This study develops a hybrid indicator-based framework that combines fuzzy expert knowledge with ensemble machine learning to quantify ecotourism suitability in Malatya Province, Türkiye. Fifteen ecological and socio-environmental predictors, including elevation, slope, climate variables, river proximity, biodiversity richness, endemic species distributions, and land-cover patterns, were incorporated into a GIS-based analytical environment. Expert-derived fuzzy weights were computed using the Fuzzy Logarithmic Methodology of Additive Weights (F-LMAW) to generate an Ecological Suitability Indicator (ESI). Complementarily, K-Means clustering was used to derive data-driven suitability classes, which were modeled using Random Forest and XGBoost with spatial-block cross-validation. XGBoost demonstrated superior classification performance (accuracy = 66.8%; $\kappa = 0.585$). Across all models, biodiversity richness, endemic species presence, slope gradients, and river corridors consistently emerged as key ecological determinants. While the ESI

produced conservative suitability zones, ensemble learning identified broader high-quality ecological landscapes, including the Levent Valley corridor, Nemrut foothills, and river-based habitats. The convergence between expert- and data-driven indicators demonstrates the reliability of hybrid ecological assessment. The proposed framework offers a transparent and transferable approach for constructing ecological suitability indicators in data-scarce, biodiversity-rich regions. Copyright © 2026. Abstract The increasing frequency of cyber threats poses substantial challenges for organizations in both the private and public sectors. This systematic literature review evaluates and categorizes current cyber risk assessment methodologies and frameworks, supporting the selection of suitable approaches for practical and academic applications. Utilizing the PRISMA framework, 712 relevant studies were filtered from an initial pool of 1900 academic publications and subsequently analyzed and organized into a structured database, providing an overview of the advantages and limitations of widely cited approaches in this domain. The findings indicate a strong preference for established risk management frameworks, including the ISO 27000 family, OCTAVE, and NIST Special Publications, as well as mathematical approaches such as Bayesian networks, fuzzy logic, and multi-criteria decision-making techniques. The 217 approaches identified were grouped into two primary categories: Standards, Frameworks, and Guidelines and Risk Assessment Methods, with further classification by the application sectors addressed in the literature. Analysis suggests that no single approach offers universal applicability. The choice of methodology should therefore be informed by an organization's specific resources, size, and sectoral requirements. A cross-analysis of methods and sectors reveals gaps in sector-specific coverage, particularly for healthcare, finance, and small and medium-sized enterprises. The review identifies a trend toward hybrid approaches that combine organizational frameworks with quantitative methods and documents persistent barriers to adoption, including cost, data scarcity, and insufficient management engagement. Based on these findings, a conceptual framework is developed to evaluate approaches across five dimensions and to derive a typology of governance-oriented, quantitative, and hybrid methods. Implications for practitioners, regulators, and researchers are discussed in relation to current regulatory frameworks, including the NIS-2 Directive and the Digital Operational Resilience Act (DORA). © The Author(s) 2026.

Building a dynamic classifier for large text data collections

Item Type Conference Paper

Author P. Kalinov

Author B. Stantic

Author A. Sattar

Abstract Due to the lack of in-built tools to navigate the web, people have to use external solutions to find information. The most popular of these are search engines and web directories. Search engines allow users to locate specific information about a particular topic, whereas web directories facilitate exploration over a wider topic. In the recent past, statistical machine learning methods have been successfully exploited in search engines. Web directories remained in their primitive state, which resulted in their decline. Exploration however is a task which answers a different information need of the user and should not be neglected. Web directories should provide a user experience of the same quality as search engines. Their development by machine learning methods however is hindered by the noisy nature of the web, which makes text classifiers unreliable when applied to web data. In this paper we propose Stochastic Prior Distribution Adjustment (SPDA) - a variation of the Multinomial Naive Bayes (MNB) classifier which makes it more suitable to classify real-world data. By stochastically adjusting class prior distributions we achieve a better overall success rate, but more importantly we also significantly improve error distribution across classes, making the classifier equally reliable for all classes and therefore more usable. © 2010, Australian Computer Society, Inc.

Building a model to predict classifier accuracy

Item Type Journal Article

Author S.S. Aubakirov

Author P. Trigo

Author D.Z. Ahmed-zaki

Abstract In this paper, we propose an optimization workflow to predict classifiers accuracy based on the exploration of the space composed of different data features and the configurations of the classification algorithms. The overall process is described considering the text classification problem. We take three main features that affect text classification and therefore the accuracy of classifiers. The first feature considers the words that comprise the input text; here we use the N-gram concept with different N values. The second feature considers the adoption of textual pre-processing steps such as the stop-word filtering and stemming techniques. The third feature considers the classification algorithms hyperparameters. In this paper, we take the well-known classifiers K-Nearest Neighbors (KNN) and Naive Bayes (NB) where K (from KNN) and a-priori probabilities (from NB) are hyperparameters that influence accuracy. As a result, we explore the feature space (correlation among textual and classifier aspects) and we present an approximation model that is able to predict classifiers accuracy.

Building carbon emissions (2016–2025): A PRISMA-based systematic review of definitions, quantification methods and policies

Item Type Journal Article

Author X. Gu

Author L. Fan

Author R. Mahabir

Abstract Managing carbon emissions from buildings requires integrated approaches across the entire lifecycle. Establishing such approaches depends on a clear understanding of key definitions for conceptual grounding, reliable quantification methods for measurement frameworks, and well-designed policies to guide effective reduction strategies. This paper analysed 111 publications on building carbon emissions from 2016 to 2025 using the PRISMA method. Key definitions have evolved from emission source perspectives to life cycle frameworks based on ISO 21930, which divides a building's life cycle into standardized stages. Past research has primarily focused on the B1-B7 stage, followed by the A1-A5 stage, while the C1-D remains understudied. Our review covers diverse quantification methods, including traditional estimation methods, data-driven prediction models (statistical, shallow machine learning, deep learning and hybrid), and emerging large language models. Our review reveals significant regional differences in policy approaches: European frameworks emphasize systematic standards, Chinese approaches centre on mandatory requirements, and American strategies focus on economic incentives. Research contributions are concentrated in China (29 %), Europe (14 %), and the United States (12 %). Drawing on the review, we also propose various reduction measures from a life cycle perspective. This review provides critical guidance for researchers, practitioners, and policymakers working to advance carbon neutrality goals. © 2025 Elsevier B.V.

Building feature-based machine learning regression to quantify urban material stocks: A Hong Kong study

Item Type Journal Article

Author L. Yuan

Author W. Lu

Author F. Xue

Author M. Li

Abstract Urban material stock (UMS) represents elegant thinking by perceiving cities as a repository of construction materials that can be reused in the future, rather than a burdensome generator of construction and demolition waste. Many studies have attempted to quantify UMS but they often fall short in accuracy, primarily owing to the lack of proper quantification methods or good data available at a micro level. This research aims to develop a simple but satisfactory model for UMS quantification by focusing on individual buildings. Generally, it is a “bottom-up” approach that uses building features to proximate the material stocks of individual buildings. The research benefits from a set of valuable, “post-mortem” ground truth data related to 71 buildings that have been demolished in Hong Kong. By comparing a series of machine learning-based models, a multiple linear regression model with six building features, namely building type, building year, height, perimeter, total floor area, and total floor number, is found to yield a satisfactory estimate of building material stocks with a mean absolute percentage error of 9.1%, root-mean-square error of 474.13, and R-square of 0.93. The major contribution of this research is to predict a building's material stock based on several easy-to-obtain building features. The methodology of machine learning regression is novel. The model provides a useful reference for quantifying UMS in other regions. Future explorations are recommended to calibrate the model when data in these regions is available. © 2022 by the International Society for Industrial Ecology.

Abstract Realistic simulation is key to enabling safe and scalable development of self-driving vehicles. A core component is simulating the sensors so that the entire autonomy system can be tested in simulation. Sensor simulation involves modeling traffic participants, such as vehicles, with high quality appearance and articulated geometry, and rendering them in real time. The self-driving industry has typically employed artists to build these assets. However, this is expensive, slow, and may not reflect reality. Instead, reconstructing assets automatically from sensor data collected in the wild would provide a better path to generating a diverse and large set with good real-world coverage. Nevertheless, current reconstruction approaches struggle on in-the-wild sensor data, due to its sparsity and noise. To tackle these issues, we present CADSim, which combines part-aware object-class priors via a small set of CAD models with differentiable rendering to automatically reconstruct vehicle geometry, including articulated wheels, with high-quality appearance. Our experiments show our method recovers more accurate shapes from sparse data compared to existing approaches. Importantly, it also trains and renders efficiently. We demonstrate our reconstructed vehicles in several applications, including accurate testing of autonomy perception systems. © 2023 Proceedings of Machine Learning Research. All rights reserved.

Calibrating Pseudo-Labeling with Class Distribution for Semi-supervised Text Classification

Item Type Conference Paper

Author W. Yang

Author J. Sheng

Editor Christodoulopoulos C.

Editor Chakraborty T.

Editor Rose C.

Editor Peng V.

Abstract Semi-supervised text classification (SSTC) aims to train text classification models with few labeled data and massive unlabeled data. Existing studies develop effective pseudo-labeling methods, but they can struggle with unlabeled data that have imbalanced classes mismatched with the labeled data, making the pseudo-labeling biased towards majority classes, resulting in catastrophic error propagation. We believe it is crucial to explicitly estimate the overall class distribution, and use it to calibrate pseudo-labeling to constrain majority classes. To this end, we formulate the pseudo-labeling as an optimal transport (OT) problem, which transports the unlabeled sample distribution to the class distribution. With a memory bank, we dynamically collect both the high-confidence pseudo-labeled data and true labeled data, thus deriving reliable (pseudo-) labels for class distribution estimation. Empirical results on 3 commonly used benchmarks demonstrate that our model is effective and outperforms previous state-of-the-art methods. © 2025 Association for Computational Linguistics.

Can Class-Priors Help Single-Positive Multi-Label Learning?

Item Type Conference Paper**Author** B. Liu**Author** N. Xu**Author** J. Wang**Author** X. Geng

Abstract Single-positive multi-label learning (SPMLL) is a weakly supervised multi-label learning problem, where each training example is annotated with only one positive label. Existing SPMLL methods typically assign pseudo-labels to unannotated labels with the assumption that prior probabilities of all classes are identical. However, the class-prior of each category may differ significantly in real-world scenarios, which makes the predictive model not perform as well as expected due to the unrealistic assumption on real-world application. To alleviate this issue, a novel framework named CRISP, i.e., Class-pRiors Induced Single-Positive multi-label learning, is proposed. Specifically, a class-priors estimator is introduced, which can estimate the class-priors that are theoretically guaranteed to converge to the ground-truth class-priors. In addition, based on the estimated class-priors, an unbiased risk estimator for classification is derived, and the corresponding risk minimizer can be guaranteed to approximately converge to the optimal risk minimizer on fully supervised data. Experimental results on ten MLL benchmark datasets demonstrate the effectiveness and superiority of our method over existing SPMLL approaches. © 2025 Neural information processing systems foundation. Can gut microbiota composition predict response to dietary treatments?

Item Type Journal Article

Author J.R. Biesiekierski

Author J. Jalanka

Author H.M. Staudacher

Abstract Dietary intervention is a challenge in clinical practice because of inter-individual variability in clinical response. Gut microbiota is mechanistically relevant for a number of disease states and consequently has been incorporated as a key variable in personalised nutrition models within the research context. This paper aims to review the evidence related to the predictive capacity of baseline microbiota for clinical response to dietary intervention in two specific health conditions, namely, obesity and irritable bowel syndrome (IBS). Clinical trials and larger predictive modelling studies were identified and critically evaluated. The findings reveal inconsistent evidence to support baseline microbiota as an accurate predictor of weight loss or glycaemic response in obesity, or as a predictor of symptom improvement in irritable bowel syndrome, in dietary intervention trials. Despite advancement in quantification methodologies, research in this area remains challenging and larger scale studies are needed until personalised nutrition is realistically achievable and can be translated to clinical practice. © 2019 by the authors. Can Land Cover Classification Models Benefit From Distance-Aware Architectures?

Item Type Journal Article

Author C. Koller

Author P. Jung

Author X.X. Zhu

Abstract The quantification of predictive uncertainties helps to understand where the existing models struggle to find the correct prediction. A useful quality control tool is the task of detecting out-of-distribution (OOD) data by examining the model's predictive uncertainty. For this task, deterministic single forward pass frameworks have recently been established as deep learning models and have shown competitive performance in certain tasks. The unique combination of spectrally normalized weight matrices and residual connection networks with an approximate Gaussian process (GP) output layer can here offer the best trade-off between performance and complexity. We utilize this framework with a refined version that adds spectral batch normalization and an inducing points approximation of the GP for the task of OOD detection in remote sensing image classification. This is an important task in the field of remote sensing, because it provides an evaluation of how reliable the model's predictive uncertainty estimates are. By performing experiments on the benchmark datasets Eurosat and So2Sat LCZ42, we can show the effectiveness of the proposed adaptations to the residual networks (ResNets). Depending on the chosen dataset, the proposed methodology achieves OOD detection performance up to 16% higher than previously considered distance-aware networks. Compared with other uncertainty quantification methodologies, the results are on the same level and exceed them in certain experiments by up to 2%. In particular, spectral batch normalization, which normalizes the batched data as opposed to normalizing the network weights by the spectral normalization (SN), plays a crucial role and leads to performance gains of up to 3% in every single experiment. For reproducibility, the code can be found here: https://github.com/ChrisKo94/DUE_Land_Cover. © 2004-2012 IEEE.

Can Lymph Transportation Capacity Predict Treatment Efficacy of Lower Extremity Lymphedema by LVA?

Item Type Journal Article

Author Y. Sowa

Author T. Kodama

Author T. Numajiri

Abstract Treatment outcomes for lower extremity lymphedema (LEL) using multiple lymphaticovenular anastomoses (LVA) are still uncertain. Classification of progression of lymphedema by disease staging is a potential preoperative predictor of the efficacy of treatment, but it is difficult to judge progression of lymphedema objectively. Recent studies have indicated that lymph pump dysfunction, which reflects lymph transportation capacity, is associated with lymphedema progression. Indocyanine green (ICG) lymphography, a minimally invasive modality for pathophysiological assessment of lymphedema, can be used for rapid and objective measurement of ICG velocity (ICGv) and transit time to the knee (TTk), which are parameters of lymph transportation capacity, over a certain period. In the current study, we analyzed the relationship between these parameters and outcomes for LEL treated by multiple LVA. Thirty-four consecutive patients who underwent multiple LVA and ICG lymphography were enrolled in the study. The relationship of ICGv and TTk with the efficacy of treatment by LVA (LEL index reduction) was investigated using Pearson correlation coefficient analysis. LEL index reduction was more strongly correlated with ICGv than with TTk, whereas it was weakly correlated with both quantification methods of lymph pump function ($r > 0.6$). Both ICGv and TTk are objective and simple parameters that can measure lymph pump functions quickly. Lymph pump function, especially calculated with ICGv, might help predict the treatment efficacy and objective evaluation after therapeutic intervention using multiple LVA. © 2021 Lippincott Williams and Wilkins. Capturing uncertainty in black-box chromatography modelling using conformal prediction and Gaussian processes

Item Type Journal Article

Author T.D. Pham

Author R. Bassett

Author U. Aickelin

Abstract We demonstrate that conformal predictors – specifically conformalised quantile regression (CQR) and locally adaptive conformal predictors (LACP) – outperform the commonly used Gaussian Process Regression (GPR) in uncertainty quantification of machine learning surrogate models for chromatography modelling. CQR excelled in black-box scenarios, effectively estimating challenging target variable distributions, while LACP provided extremely informative intervals when kinetic parameters were included. Incorporating kinetic data significantly reduced epistemic uncertainty and increased model accuracy, supporting the hypothesis that adding mechanistic data to black-box models improves prediction uncertainty. This study represents the first application of conformal methods in chromatography modelling, indicating high applicability of this new uncertainty quantification methodology. Our findings offer a promising direction for advancing uncertainty quantification methods in data-driven bioprocess modelling and optimisation. © 2025

CASUAL: Conditional Support Alignment for Domain Adaptation with Label Shift

Item Type Conference Paper

Author A.T. Nguyen

Abstract Unsupervised domain adaptation (UDA) refers to a domain adaptation framework in which a learning model is trained based on the labeled samples on the source domain and unlabelled ones in the target domain. The dominant existing methods in the field that rely on the classical covariate shift assumption to learn domain-invariant feature representation have yielded suboptimal performance under label distribution shift. In this paper, we propose a novel Conditional Adversarial SUPport ALignment (CASUAL) whose aim is to minimize the conditional symmetric support divergence between the source's and target domain's feature representation distributions, aiming at a more discriminative representation for the classification task. We also introduce a novel theoretical target risk bound, which justifies the merits of aligning the supports of conditional feature distributions compared to the existing marginal support alignment approach in the UDA settings. We then provide a complete training process for learning in which the objective optimization functions are precisely based on the proposed target risk bound. Our empirical results demonstrate that CASUAL outperforms other state-of-the-art methods on different UDA benchmark tasks under different label shift conditions. Cataract quantification using swept-source optical coherence tomography

Item Type Journal Article

Author J.E.G. Brás

Author W. Sickenberger

Author N. Hirnschall

Author O. Findl

Abstract Purpose: To develop and evaluate a cataract quantification method using a swept-source optical coherence tomography (SS-OCT) device (IOLMaster 700). Setting: Hanusch Hospital, Vienna, Austria. Design: Prospective multicenter case series. Methods: This study included patients with cataract in at least 1 eye. Two independent examiners performed Lens Opacities Classification System II (LOCS II) grading at the slitlamp independently. Corrected distance visual acuity, contrast sensitivity, and SS-OCT measurements were also performed. In addition, the phacoemulsification energy and time were recorded. To develop an objective SS-OCT-based cataract quantification system, all SS-OCT scans were segmented and the local pixel intensity unit of the lens was analyzed using Matlab's grayscale counting. The pixel intensity unit of the lens nucleus (OCT-based cataract quantification system score) was equated to the clinician's subjective nuclear opalescence grading. Results: The study evaluated 186 eyes (113 patients). The correlation between the independent examiners' LOCS grading was good (0.91) ($P < .01$). The correlation between the LOCS grading and OCT-based cataract quantification system score was 0.86 for examiner 1 and 0.76 for examiner 2 (both $P < .01$). In 24 patients, phacoemulsification time, power, and energy; visual acuity; and contrast sensitivity were available and included in the study. The OCT-based cataract quantification system scores correlated significantly with phacoemulsification time (0.71) and energy (0.64) (both $P < .01$). Conclusions: Cataract density could be evaluated using an SS-OCT device, and the OCT-based cataract quantification system values correlated with the conventional LOCS II classification. Swept-source OCT measurements allowed quantification and documentation cataract density. © 2018 ASCRS and ESCRS

Categorization of multiple objects in a scene using a biased sampling strategy

Item Type Journal Article

Author L. Yang

Author N. Zheng

Author M. Chen

Author Y. Yang

Author J. Yang

Abstract Recently, various bag-of-features (BoF) methods show their good resistance to within-class variations and occlusions in object categorization. In this paper, we present a novel approach for multi-object categorization within the BoF framework. The approach addresses two issues in BoF related methods simultaneously: how to avoid scene modeling and how to predict labels of an image when multiple categories of objects are co-existing. We employ a biased sampling strategy which combines the bottom-up, biologically inspired saliency information and loose, top-down class prior information for object class modeling. Then this biased sampling component is further integrated with a multi-instance multi-label learning and classification algorithm. With the proposed biased sampling strategy, we can perform multiobject categorization within an image without semantic segmentation. The experimental results on PASCAL VOC2007 and SUN09 show that the proposed method significantly improves the discriminative ability of BoF methods and achieves good performance in multi-object categorization tasks. © Springer Science+Business Media New York 2013.

Categorizing and mining concept drifting data streams

Item Type Conference Paper

Author P. Zhang

Author X. Zhu

Author Y. Shi

Abstract Mining concept drifting data streams is a defining challenge for data mining research. Recent years have seen a large body of work on detecting changes and building prediction models from stream data, with a vague understanding on the types of the concept drifting and the impact of different types of concept drifting on the mining algorithms. In this paper, we first categorize concept drifting into two scenarios: Loose Concept Drifting (LCD) and Rigorous Concept Drifting (RCD), and then propose solutions to handle each of them separately. For LCD data streams, because concepts in adjacent data chunks are sufficiently close to each other, we apply kernel mean matching (KMM) method to minimize the discrepancy of the data chunks in the kernel space. Such a minimization process will produce weighted instances to build classifier ensemble and handle concept drifting data streams. For RCD data streams, because genuine concepts in adjacent data chunks may randomly and rapidly change, we propose a new Optimal Weights Adjustment (OWA) method to determine the optimum weight values for classifiers trained from the most recent (up-to-date) data chunk, such that those classifiers can form an accurate classifier ensemble to predict instances in the yet-to-come data chunk. Experiments on synthetic and real-world datasets will show that weighted instance approach is preferable when the concept drifting is mainly caused by the changing of the class prior probability; whereas the

weighted classifier approach is preferable when the concept drifting is mainly triggered by the changing of the conditional probability. © 2008 ACM.

Category-specific unlabeled data risk minimization for ultrasound semi-supervised segmentation

Item Type Journal Article

Author L. Xu

Author M. Liu

Author B. Wei

Author Y. He

Author Z. Gao

Author H. Han

Author J. Zhang

Abstract Achieving accurate computer-aided analysis of ultrasound images is challenging, since not only its image artifacts but also the difficulties in collecting large-scale pixel-wise annotations from experts for training. Semi-supervised segmentation is a solution for learning from labeled and unlabeled data, which mainly focuses on generating pseudo annotations for unlabeled data or learning consistent features in enhanced views of images to enhance model generalization. However, anatomically, diverse learning difficulties across tissues are overlooked, and, technically, the estimation and minimization of empirical risk for unlabeled training data are largely ignored. Motivated by them, this work proposes a semi-supervised segmentation model, named CSUDRM, with two modules. The former is called category-specific distribution alignment (CSDA), which learns more consistent feature representations of the same class across labeled and unlabeled data. Moreover, it enhances feature space intra-class compactness and inter-class discrepancy and provides category-specific penalties for more robust learning. The latter one is Unlabeled Data Risk Minimization (UDRM). It minimizes the risk on the entire training data, which distinguishes it from most existing works that merely optimize labels. The risk of unlabeled data is estimated by a novel learnable class prior estimator, with the help of distributional hints from CSDA. This design could reinforce the robustness of the model and achieve stable segmentation. CSUDRM achieves state-of-the-art performances on four ultrasound datasets. Extensive ablation studies, including quantitative comparisons, feature space visualization, and robustness analysis, demonstrate the superiority of our designs. Copyright © 2025. Abstract All-solid-state batteries are increasingly examined to improve the safety of lithium-ion batteries. Considerable efforts are being made to develop solid electrolyte materials with high ionic conductivity to realize such batteries. Recently, materials informatics (MI), which uses machine learning to quantify the relationships between descriptors that represent the composition, structure, and properties of materials, has been increasingly utilized. However, MI has primarily focused on evaluating the correlations between descriptors, with few examples analyzing hierarchical cause-and-effect relationships. This study analyzes the causal relationships among the descriptors of lithium-ion conductivity in olivine-type LiMXO₄ materials using linear non-Gaussian acyclic model (LiNGAM), a method of causal discovery. We previously compiled a data set for these materials using first-principles calculations and performed machine learning regression analyses. A key aspect of this research is the systematization of knowledge regarding the composition, structure, and ionic conductivity of materials. Clarifying the causal relationships can lead to the discovery of factors that truly control ionic conductivity. Therefore, we qualitatively interpret the causal relationship diagram and provide specific guidelines for controlling the lithium-ion conductivity by comparing the results of previous machine learning regression analyses with those of LiNGAM. © 2025 The Authors. Causal Language Model Aided Sequential Decoding With Natural Redundancy

Item Type Journal Article

Author Z. Zhu

Author H. Yu

Author C. Shen

Author J. Du

Author Z. Shen

Author Z. Wang

Abstract A high-performance communication receiver desires a sufficient and accurate recognition of transmitted sources. In this paper, we propose a sequential decoding algorithm for the robust reception of sources with natural redundancy (NR) over the AWGN channel. To fully exploit the abundant NR in the exemplified English text sources, a causal language modeling (CLM) with a powerful Transformer decoder neural network (NN) structure is adopted for modeling the joint probability distribution. For versatility of byte-level tokenization, the UTF-8 encoding scheme is considered for the Wikipedia corpus, namely the English edition of the Wiki-40B dataset. The tree search-based M-algorithm (MA) is integrated with CLM, denoted as CLM-MA algorithm, to synthesize the a priori probability of information sequence and likelihood values of polluted symbols. Both simulation experiments and hardware platform evaluations are conducted to analyze the performance of the CLM-MA algorithm. With an adequately large M value, tremendous performance profit is achievable, especially for high-efficiency modulation levels and extremely noisy conditions. This mechanism of adopting the pre-trained NN model merely desires self-supervised learning architecture and eliminates the requirement of high-cost and accurate labels, which paves a new way for communication receiver design. © 1972-2012 IEEE.

Causation analysis of collision accidents using Chi-squared test and Bayesian network

Item Type Conference Paper**Author** X. Liu**Author** X. Shen**Author** Q. Yu**Editor** Le Sourne H.**Editor** Soares C.G.

Abstract Maritime accident research conducted at conventions often suffers from insufficient quantitative descriptions of the correlations between factors. This paper aims to conduct new research by incorporating maritime accident data from eight coastal areas into a data-driven Bayesian network model (BN) to analyze the relationship between the severity of marine accidents and relevant Accident Influential Factors (AIFs). To achieve this aim, the factors contributing to maritime accidents are identified, and each of them is subjected to a chi-squared test against the severity of the accident. The results of the chi-square test are then compiled into a comparison matrix, which is imported into the Bayesian network as a priori probability. Next, a Bayesian search algorithm is used to establish a data-driven BN model, and the AIFs of the database for eight different coastal areas are analyzed through data training and machine learning based on the prior probability. This study found that “Type of accident,” “Weather,” and “Sea condition” have the highest correlation with accident severity. Additionally, factors such as visibility, ship size, and age significantly impact serious accidents. The research findings are beneficial for the analysis of marine accidents and

provide insights to stakeholders such as safety authorities and ship owners. ©

CDFNet: Cross-Domain Feature Fusion Network for PolSAR Terrain Classification

Item Type Journal Article
Author S. Wang
Author Z. Sun
Author T. Bian
Author Y. Guo
Author L. Dai
Author Y. Guo
Author L. Jiao

Abstract The scarcity of labeled data and domain shift among polarimetric synthetic aperture radar (PolSAR) images degrades the performance of the supervised-learning-based algorithm. Some unsupervised domain adaptation (UDA) algorithms have been proposed to address this problem and achieve good performance. The existing UDA algorithms for PolSAR terrain classification focus on the feature distribution shift problem but ignore the label shift problem in UDA task. In addition, feature alignment-based algorithms generate pseudo labels for target domain which introduce label noise and compromising the UDA performance. To alleviate the problems above, we present a cross-domain feature fusion network (CDFNet) for PolSAR terrain classification. Specifically, a domain-balanced sampling (DBS) module is proposed to obtain a nearly balanced training dataset to alleviate the label shift problem. Then, a cross-domain feature fusion (CDF) module is presented to achieve class-wise feature alignment with no additional label noise introduction. Experimental results on four PolSAR datasets demonstrate that our algorithm outperforms state-of-the-art UDA algorithms in terms of target domain performance. © 1980-2012 IEEE.

Centerline-based quantification of true Lumen helical Morphology in Type B aortic dissection: Unlocking the potential of helicity as a geometric biomarker

Item Type Journal Article

Author F.O. Kolawole

Author J. Bondesson

Author B.W. Ullery

Author C.P. Cheng

Abstract The helical morphology of Type B aortic dissections (TBAD) represents a potentially important geometric biomarker that may influence dissection progression. While three-dimensional surface-based quantification methods provide accurate TBAD helicity assessment, their clinical adoption remains limited by significant processing time. We developed and validated a clinically practical centerline-based helicity quantification method using routine imaging software (TeraRecon) against an extensively validated surface-based method (SimVascular). In 87 TBAD patients, we semi-automatically extracted aortic, true lumen, and branch vessel centerlines from CT imaging. Helical parameters, including true lumen helical angle and peak helical twist, were computed relative to a standardized anatomical reference, enabling classification of patients into four distinct helicity categories: left-chiral, right-chiral, non-helical, and mixed-chiral patterns. The centerline method demonstrated 92% classification accuracy with excellent agreement with surface-based measurements (Cohen's $\kappa=0.88$, $p<0.001$). Wilcoxon signed-rank tests revealed a median difference of -0.4° ($z=-1.08$, $p=0.28$), indicating no statistically significant systematic bias between methods. This centerline approach we have developed provides clinically feasible TBAD helicity classification while maintaining excellent agreement with the gold-standard surface-based method. This technique can integrate seamlessly with existing clinical workflows, enabling practical assessment of TBAD helical

morphology for enhanced risk stratification and personalized treatment planning. ©

centroIDA: Cross-domain class discrepancy minimization based on
accumulative class-centroids for Imbalanced Domain Adaptation

Item Type Journal Article

Author X. Sun
Author Z. Wu
Author Y. Ji
Author Z. Zhan

Abstract Unsupervised Domain Adaptation (UDA) is a critical task in transfer learning, which seeks to apply the knowledge acquired in one domain (the source domain) to a different but related domain (the target domain). In this context, the two domains exhibit Out-Of-Distribution(OOD), and the label information of the target domain is unavailable. Although numerous UDA methods have made significant strides in mitigating the discrepancies in feature distributions across domains, they often neglect a more prevalent real-world scenario. This scenario, referred to as Imbalanced Domain Adaptation (IDA) task, is characterized by the coexistence of differences in both feature and label distributions. Our empirical analysis suggests that overlooking the disparities in label distributions can severely compromise the performance of the model, thereby limiting the generalizability of domain adaptation models. Consequently, our objective is to introduce a model capable of concurrently addressing differences in both feature and label distributions, thereby fostering a broader application of domain adaptation methodologies. In this paper, we propose a cross-domain class discrepancy minimization method based on accumulative class-centroids for IDA, termed as centroIDA. The strategies of accumulative class-centroids alignment and class-wise feature alignment pay heed to the relationship between cross-domain intra-class features and inter-class features, thereby facilitating conditional feature alignment to overcome both feature and label distribution differences simultaneously. Our experimental evaluation on OfficeHome and DomainNet datasets reveals that, in comparison to TIToK (a novel method also designed to tackle the IDA problem), our method enhances the average accuracy by 5.6% and 2.7%, respectively. Furthermore, as the label shift intensifies, our method consistently outperforms other methods, demonstrating a robust resistance to label shift. © 2024 Elsevier Ltd

Abstract Active class selection (ACS) requires the developer of a classifier to actively choose the class proportions of the training data. This freedom of choice puts the trust in the trained classifier at risk if the true class proportions, which occur during deployment, are subject to uncertainties. This issue has recently motivated a certificate for ACS-trained classifiers, which builds trust by proving that a classifier is sufficiently correct within a specific set of class proportions and with a high probability. However, this certificate was only developed in the context of binary classification. In this paper, we employ Hölder's inequality to extend the binary ACS certificate to multi-class settings. We demonstrate that our extension indeed provides correct and tight upper bounds of the classifier's error. We conclude with several directions for future work. © 2022 for this paper by its authors.

Editor Lozano J.A.

Abstract Active class selection provides machine learning practitioners with the freedom to actively choose the class proportions of their training data. While this freedom can improve the model performance and decrease the data acquisition cost, it also puts the practical value of the trained model into question: is this model really appropriate for the class proportions that are handled during deployment? What if the deployment class proportions are uncertain or change over time? We address these questions by certifying supervised models that are trained through active class selection. Specifically, our certificate declares a set of class proportions for which the certified model induces a training-to-deployment gap that is small with a high probability. This declaration is theoretically justified by PAC bounds. We apply our proposed certification method in astro-particle physics, where a simulation generates telescope recordings from actively chosen particle classes. © 2021, Springer Nature Switzerland AG.

Challenge of validation in whole-cell spike-in amplicon sequencing to comprehensively quantify food lactic acid bacteriota

Item Type Journal Article

Author M. Oshiro

Author K. Nakamura

Author Y. Tashiro

Abstract Lactic acid bacteria (LAB) shape diverse communities in fermented foods. Developing comprehensive quantification methods for community structure will revolutionize our understanding of food LAB microbiome. For this purpose, 16S rRNA gene amplicon-based quantification, using spiked exogenous bacterial cells as an internal standard, shows potential for comprehensiveness and accuracy. We validated cell spike-in amplicon sequencing for quantifying LAB communities in food. Low efficiency of LAB DNA extraction underscores the importance of compensating for DNA loss by spiking internal standard cells. Quantitative equations generated using 15 selected LAB mock species showed positive relationships between the ratio of MiSeq read counts and the expected 16S rRNA gene copy numbers, with coefficients of determination (R^2) ≥ 0.6823 . The fold differences between observed and expected 16S copy numbers were within the range of 1/3 to 3-fold. Our validation highlights that accurate preparation of the LAB mock community is crucial for cell spike-in amplicon sequencing accuracy. © The Author(s) 2024. Abstract Background: Gene expression microarray studies for several types of cancer have been reported to identify previously unknown subtypes of tumors. For breast cancer, a molecular classification consisting of five subtypes based on gene expression microarray data has been proposed. These subtypes have been reported to exist across several breast cancer microarray studies, and they have demonstrated some association with clinical outcome. A classification rule based on the method of centroids has been proposed for identifying the subtypes in new collections of breast cancer samples; the method is based on the similarity of the new profiles to the mean expression profile of the previously identified subtypes. Methods: Previously identified centroids of five breast cancer subtypes were used to assign 99 breast cancer samples, including a subset of 65 estrogen receptor-positive (ER+) samples, to five breast cancer subtypes based on microarray data for the samples. The effect of mean centering the genes (i.e., transforming the expression of each gene so that its mean expression is equal to 0) on subtype assignment by method of centroids was assessed. Further studies of the effect of mean centering and of class prevalence in the test set on the accuracy of method of centroids classifications of ER status were carried out using training and test sets for which ER status had been independently determined by ligand-binding assay and for which the proportion of ER+ and ER- samples were systematically varied. Results: When all 99 samples were considered, mean centering before application of the method of centroids appeared to be helpful for correctly assigning samples to subtypes, as evidenced by the expression of genes that had previously been used as markers to identify the subtypes. However, when only the 65 ER+ samples were considered for classification, many samples appeared to be misclassified, as evidenced by an unexpected distribution of ER+ samples among the resultant subtypes. When genes were mean centered before classification of samples for ER status, the accuracy of the ER subgroup assignments was highly dependent on the proportion of ER+ samples in the test set; this effect of subtype prevalence was not seen when gene expression data were not mean centered. Conclusions: Simple corrections such as mean centering of genes aimed at microarray platform or batch effect correction can have undesirable consequences because patient population effects can easily be confused with these assay-related effects. Careful thought should be given to the comparability of the patient populations before attempting to force data comparability for purposes of assigning subtypes to independent subjects. © The Author 2007. Chance-corrected utility-weighted metrics for binary classification and information retrieval: A conceptual and analytical framework

Item Type Journal Article

Author W.-C. Lee

Abstract Standard confusion-matrix metrics (e.g., AUROC, Youden's index, F1, Jaccard) often do not explicitly account for class imbalance, asymmetric utilities, or performance relative to a no-information baseline. These limitations can obscure the utility structure relevant to model choice. We propose a unified utility-weighted evaluation framework for binary classification and information retrieval, together with a kappa-like chance correction. For classification, we define the utility-weighted accuracy rate (UWAR) by normalizing expected utility to the perfect-model utility, yielding a weighted average of sensitivity and specificity controlled by a single utility-weighting parameter that combines positive-class prevalence with the relative benefit of a true positive compared with a true negative. We then introduce the chance-corrected UWAR (ccUWAR) to quantify utility-weighted performance above the no-information baseline, with interpretable special cases that connect to familiar indices such as AUROC and Youden's index. For information retrieval, we develop parallel measures in the positivity-conditioned space: the conditional utility-weighted accuracy rate (CUWAR) and its chance-corrected version (ccCUWAR), parameterized by the relative cost of missed relevant items versus retrieved non-relevant items and the prevalence of relevant items; CUWAR reduces to the Jaccard

index and is directly related to the F1 score when these error costs are equal. We further derive better-than-chance regions, indifference points, and regions of dominance. Through controlled analytical examples, we illustrate that rankings that appear fixed under symmetric metrics can reverse once utility structure and chance correction are made explicit. The framework is intended as a conceptual and analytical tool for utility-aligned evaluation rather than as a universal replacement for existing metrics. © 2026 Elsevier B.V.

Changes in mouse gastrointestinal microbial ecology with ingestion of kale

Item Type Journal Article

Author Y. Uyeno

Author S. Katayama

Author S. Nakamura

Abstract Kale, a cultivar of *Brassica oleracea*, has attracted a great deal of attention because of its health-promoting effects, which are thought to be exerted through modulation of the intestinal microbiota. The present study was performed to investigate the effects of kale ingestion on the gastrointestinal microbial ecology of mice. 21 male

C57BL/6J mice were divided into three groups and housed in a specific pathogen-free facility. The animals were fed either a control diet or experimental diets supplemented with different commercial kale products for 12 weeks. Contents of the caecum and colon of the mice were processed for the determination of active bacterial populations by a bacterial rRNA-based quantification method and short-chain fatty acids by HPLC. rRNAs of *Bacteroides-Prevotella*, the *Clostridium coccoides*-*Eubacterium* rectale group, and *Clostridium leptum* subgroup constituted the major fraction of microbiota regardless of the composition of the diet. The ratio of Firmicutes to Bacteroidetes was higher in the colon samples of one of the kale diet groups than in the control. The colonic butyrate level was also higher with the kale-supplemented diet. Overall, the ingestion of kale tended to either increase or decrease the activity of specific bacterial groups in the mouse gastrointestinal tract, however, the effect might vary depending on the nutritional composition. © 2014 Wageningen Academic Publishers.

Abstract Deep neural networks have useful applications in many different tasks, however their performance can be severely affected by changes in the input distribution. For example, in the biomedical field, their performance can be affected by changes in the data (different machines, populations) between training and test datasets. To ensure robustness and generalization to real-world scenarios, test-time adaptation has been recently studied as an approach to adjust models to a new data distribution during inference. Test-time batch normalization is a simple and popular method that achieved compelling performance on domain shift benchmarks. It is implemented by recalculating batch normalization statistics on test batches. Although initial work focused on analysis with test data that has the same label distribution as the training data, in many practical applications this technique is vulnerable to label distribution shifts, sometimes causing catastrophic failure. This presents a risk in applying test time adaptation methods in deployment. We propose to tackle this challenge by only selectively adapting channels in a deep network, minimizing drastic adaptation that is sensitive to label shifts. Our selection scheme is based on two principles that we empirically motivate: (1) later layers of networks are more sensitive to label shift; (2) individual features can be sensitive to specific classes. We apply the proposed technique to three classification tasks, including CIFAR10-C, Imagenet-C, and diagnosis of fatty liver, where we explore both covariate and label distribution shifts. We find that our method allows to bring the benefits of TTA while significantly reducing the risk of failure common in imbalanced scenarios. © 2024 CoLLAs. All Rights Reserved.

Characterization of Impact Damage Uncertainty of Composite Materials Based on Bayesian Neural Network

Item Type Conference Paper
Author Z. Song
Author Y. Feng
Author C. Lu
Author W. Liu
Author Y. Liu
Author H. Hu
Abstract To solve the problem of multi-source parameter coupling and damage dispersion quantification in the uncertainty characterization of impact damage in composite materials, this paper proposes a confidence interval quantification method based on a Bayesian neural network to realize the propagation analysis of material parameters and impact energy uncertainty to damage state. Firstly, based on Bayesian inference, the probability distribution of weight and threshold parameters was constructed, and the probability distribution of the predicted value was directly output through the weight posterior distribution sampling, and

the traditional point estimation was transformed into probabilistic interval prediction. Secondly, a hierarchical Monte Carlo sampling strategy was designed, and the input material parameters were dispersed to inject the uncertainty of the damage state to generate a probability envelope covering 95% of the measured data points. Finally, the confidence interval curve of pit depth and damage area is predicted, including the confidence interval curve of pit depth and damage area, and the covariant relationship between the two under energy change is revealed, and the results show that the pit depth and damage area increase nonlinearly with the increase of impact energy, but show different sensitivities, the pit depth increases slowly in the low-energy segment (<50J), and the growth rate of the high-energy segment increases significantly, while the damage area expands exponentially before 50J. © 2025 IEEE.

Characterization of spatio-temporal patterns of grassland utilization intensity in the Selinco watershed of the Qinghai-Tibetan Plateau from 2001 to 2019 based on multisource remote sensing and artificial intelligence algorithms

Abstract Due to the limitations of spatial quantification methods, the spatio-temporal patterns of grassland utilization intensity (GUI) in the Selinco watershed (SLCW), the core region of ecological security on the Qinghai-Tibetan Plateau, is unclear under multiple utilization modes. This paper quantified GUI by constructing the association between the potential and actual Enhanced Vegetation Index (EVI) of grasslands in terms of interannual variability. To obtain an accurate spatio-temporal dataset of potential EVI, the following two components were considered on. Firstly, the temporal lag effects of each raw climate factor were investigated to determine the optimal climate variables affecting vegetation productivity. Secondly, four machine learning (ML) algorithms, including an artificial neural network, random forest, support vector machine, and gradient boosting regression tree combined with the Bayesian model average, were used to construct grassland potential EVI models involving EVI, grassland type, and environmental factors (topography, soil, raw climate, and bioclimatic). Meanwhile, to maximize the performance of ML models, variable selection, variable transformation, and hyperparameter optimization were systematically implemented, where the hyperparameter optimization algorithms employ the grid search algorithm, Bayesian optimization, genetic algorithm, and particle swarm optimization. Then, the spatio-temporal dataset of GUI in the SLCW from 2001 to 2019 was established by using the above quantification method based on multisource remote sensing and artificial intelligence algorithms. The analysis of spatio-temporal variation in GUI showed that the implementation of ecological restoration projects leads to a significant and rapid decline in the overall GUI of the SLCW after 2010 (declining by 4.8%), which is more obvious in the non-nature reserve (declining by 9.3%). In the Qiangtang Nature Reserve within the SLCW, although the GUI shows a declining trend after 2010 because of the implementation of ecological restoration projects, it shows an insignificant increase from 2001 to 2019 due to the recovery increase of wildlife populations in recent decades. Besides, by exploring the effects of elevation and slope on the GUI, it is found that grasslands on higher slopes at lower elevations are at a greater risk of degradation due to more intensive grassland utilization. © 2022 The Author(s). Abstract Harmful algal bloom (HAB) formation leads to the eutrophication of water ecosystems and may render recreational lakes unsuitable for human use. We evaluated the applicability and comparison of metabarcoding, metagenomics, qPCR, and ELISA-based methods for cyanobacteria/cyanotoxin detection in bloom and non-bloom sites for the Great Lakes region. DNA sequencing-based methods robustly identified differences between bloom and non-bloom samples (e.g., the relative prominence of *Anabaena* and *Planktothrix*). Shotgun sequencing strategies also identified the enrichment of metabolic genes typical of cyanobacteria in bloom samples, though toxin genes were not detected, suggesting deeper sequencing or PCR methods may be needed to detect low-abundance toxin genes. PCR and ELISA indicated microcystin levels and microcystin gene copies were significantly more abundant in bloom sites. However, not all bloom samples were positive for microcystin, possibly due to bloom development by non-toxin-producing species. Additionally, microcystin levels were significantly correlated (positively) with microcystin gene copy number but not with total cyanobacterial 16S gene copies. In summary, next-generation sequencing-based methods can identify specific taxonomic and functional targets, which can be used for absolute quantification methods (qPCR and ELISA) to augment conventional water monitoring strategies. © 2024 by the authors.

Characterizing forecastability of wind sites in the United States

Item Type Journal Article

Author J. Zhang

Abstract With the rapid growth of wind power, managing its uncertainty and variability becomes critical in power system operations. Wind forecasting is one of the enablers to partially tackle challenges associated with wind power uncertainty. To improve the 'forecasting ability' defined as forecastability, different forecasting methods have been developed to assist grid integration of wind energy. However, forecasting performance not only relies on the power of forecasting models, but is also related to local weather conditions and (known as wind characteristics) wind farm properties. In this study, geospatial and instance spatial distributions of six wind characteristics and two forecasting error metrics are first analyzed based on 126,000 + wind sites in the United States. Forecasts in different look-ahead times are generated by using a machine learning based multi-model forecasting framework and the Weather Research and Forecasting model. A forecastability quantification method is developed by characterizing the relationship between forecastability and wind series entropy using three regression methods, i.e., linear approximation, locally weighted scatterplot smoother nonlinear nonparametric regression, and quantile regression. It is found that the forecastability of a wind site can be successfully characterized by wind series characteristics, thereby providing valuable information at different stages of wind energy projects. © 2018 Elsevier Ltd

Characterizing Neural Radiance Field Models for 3D Scene Understanding of Hyperspectral Imagery

Item Type Conference Paper

Author S. Jarman

Author S. Zorek

Author K. Moon

Author A. Carr

Author Z. Hampel-Arias

Abstract Hyperspectral imaging (HSI) is crucial for remote detection of various targets. However, detection becomes challenging when targets are obscured by other objects in the scene. To address this, we apply 3D scene understanding methods to create spatially-relevant representations of HSI data. 3D scene understanding with hyperspectral data has the ability to improve target characterization, as it allows for differentiation between materials that may appear similar in standard visual imagery and provide better spatial discrimination compared to single-image captures of a scene. Our approach enables the incorporation of multiple observations from different angles, enhancing the ability to 'look around' targets or obstructions by rendering new views of a scene. We apply the 3D methods of neural radiance fields (NeRFs) to Long Wave IR hyperspectral imagery. We will present results from our analysis pipeline applying machine learning 3D scene understanding methods to physics-driven synthetic images from DIRSIG to quantify accuracy tradeoffs with number of collected view angles, view geometry, and material composition of the scene. We demonstrate the capability of scaling the spectral dimensionality of NeRF models from data comprising single channel to multi-channel imagery, while also including uncertainty quantification methods to measure associated confidence in modeling spatial-spectral components of the scene. © 2026 IEEE.

Abstract Out-of-distribution (OOD) data poses serious challenges in deployed machine learning models, so methods of predicting a model's performance on OOD data without labels are important for machine learning safety. While a number of methods have been proposed by prior work, they often underestimate the actual error, sometimes by a large margin, which greatly impacts their applicability to real tasks. In this work, we identify pseudo-label shift, or the difference between the predicted and true OOD label distributions, as a key indicator of this underestimation. Based on this observation, we introduce a novel method for estimating model performance by leveraging optimal transport theory, Confidence Optimal Transport (COT), and show that it provably provides more robust error estimates in the presence of pseudo label shift. Additionally, we introduce an empirically-motivated variant of COT, Confidence Optimal Transport with Thresholding (COTT), which applies thresholding to the individual transport costs and further improves the accuracy of COT's error estimates. We evaluate COT and COTT on a variety of standard benchmarks that induce various types of distribution shift - synthetic, novel subpopulation, and natural - and show that our approaches significantly outperform existing state-of-the-art methods with up to 3x lower prediction errors. Our code can be found at <https://github.com/luyuzhe111/COT>. © 2023 Neural information processing systems foundation. All rights reserved.

Author A. Salisu

Author S.S. Yusuf

Abstract Interpretable machine learning approaches to quantitative structure–activity relationship (QSAR) modelling are increasingly applied in drug discovery, yet most studies remain confined to single targets and report feature attributions without translating them into chemically meaningful insights. We introduce a cross-target SHAP entropy framework for quantifying shared versus target-specific structure–activity relationships across protein families, applied to 31 human kinase targets from BindingDB under scaffold-based train-test evaluation. Random Forest classifiers trained on Morgan ECFP4 fingerprints achieved a median AUROC of 0.994, AUPRC of 0.9998, and MCC of 0.674, confirming genuine SAR learning beyond class prevalence exploitation. Pairwise Spearman rank correlation of mean absolute SHAP profiles across targets yielded moderate cross-target consistency (mean $r = 0.332$; 465 pairs). Shannon entropy-based classification of the top 200 fingerprint bits identified 15 consensus features dominated by aromatic N-heterocycles, aliphatic rings, and hydrogen bond environments, and 50 divergent features showing 2.8-fold higher SHAP magnitude than consensus features. SAR validation confirmed genuine enrichment of two top consensus fragments in active compounds. These findings indicate that kinase QSAR models share a low-magnitude consensus descriptor signal across the kinase family, while target-specific features dominate predictive decision boundaries. All SHAP attributions describe model decision behavior and should not be interpreted as causal binding mechanisms. The entropy decomposition framework is generalisable to other protein families and provides a transferable workflow for converting SHAP outputs into chemically actionable insights. All code and data are publicly available. © The Author(s), under exclusive licence to Springer Nature Switzerland AG 2026.

Chemical fingerprinting and quantification of Chinese cinnamomi cortex by ultra high performance liquid chromatography coupled with chemometrics methods

Item Type Journal Article**Author** N. Ma**Author** Y. Ding**Author** Y. Zhang**Author** T. Zhang**Author** Y. Yi**Author** B. Wang

Abstract To rapidly clarify and quantify the chemical profiling of Cinnamomi cortex a reliable and feasible strategy of chromatographic fingerprinting with a suite of chemometrics methods was developed and validated by ultra-high performance liquid chromatography coupled with diode array detection. Furthermore, to identify more meaningful chemical markers, the chemometrics methods including hierarchical cluster analysis (HCA), principal component analysis (PCA) and similarity, which all generate quality evaluations and correlation classifications of Cinnamomi cortex, were used to improve the Cinnamomi cortex quality control standards. A total of 12 characteristic peaks were confirmed, seven of which were identified by comparing their retention times, UV and MS spectra with authentic compounds. Moreover, 11 analytes were accurately determined, as a complementary quantification method of chromatographic fingerprinting. For quantitative analyses, selective detection was performed at 254, 280 and 340 nm. The tested samples were separated and determined using UPLC and a series of methodologies including linearity, precision, accuracy, limit of detection and quantification and extraction recoveries were validated. Meanwhile the method bias for all the analytes did not exceed 5%. A total of 42 samples were acquired in China and analyzed. The results demonstrated that chromatographic fingerprinting in combination with chemometrics methods provides a promising and practical method to more effectively and comprehensively control the quality of Cinnamomi cortex from various sources, which would be a useful

reference for the development and further study of Cinnamomi cortex and related formulations. © 2018 by the authors.

Abstract Samples of olive oils (n = 67) from different qualities and samples of other vegetable edible oils (including soybean, sunflower, rapeseed, corn oil etc; n = 79) were used in this study as pure oils. Previous to spectroscopy analysis, a transesterification step was applied to the pure vegetable oil samples and all the different oil blends were then prepared to create in-house blended samples. Spectral acquisition was performed with typical parameters to collect the FTIR and Raman fingerprints. For the olive/non-olive classification model, three classification strategies have been applied: (i) one input-class (1iC) classification; (ii) two input-class (2iC) classification; and (iii) one input-class plus one 'dummy' class classification (or pseudo two input-class (p2iC) classification). The multivariate classification methods used were k-nearest neighbours (kNN), partial least squared-discriminant analysis (PLS-DA), one-class partial least squares (OCPLS), support vector machine classification (SVM-C), and soft independent modelling of class analogies (SIMCA). The multivariate quantification method used was partial least square-regression (PLS-R). FTIR fingerprints showed excellent classification ability to distinguish pure olive from non-olive oil. When PLS-DA or SVM-C techniques are applied, 100% of olive oil samples and 92% of other vegetable edible oils are correctly classified. In general FTIR fingerprints were more discriminative than Raman's in both classification and regression scenarios. © 2017 Elsevier Ltd

Author J. Yuan

Author W. Yan

Abstract The detection of adulteration of sesame oil with four vegetable oils was investigated by measuring fatty acid composition. Adulteration based fatty acid composition was evaluated with 73 sesame seed samples, 57 rapeseed seed samples, 103 soybean seed samples, 11 brands of sunflower oil and 14 brands of maize oil. Discriminate analysis and principal component analysis were used to study the data distribution patterns based on the fatty acid composition and their ratios obtained from pure sesame oils and blends. Pure vegetable oils were gathered in a tendency in principal component analysis score diagram. Although the parameters calculated by fatty acid composition were simple and effective in detection of oil mixture of single vegetable edible oil or different vegetable edible oil, this method could only be used for qualitative determination. Linear discriminant analysis applied and the obtained overall accuracies were between 97.27% and 100%. Partial least-squares regression, the multivariate quantification method, have been successfully applied and quantitatively recognized the type and the level of extra added vegetable oils into the sesame oils. In general, the fatty acid profile of vegetable oils obtained by GC was useful in both qualitative and quantitative detection of sesame oil blends. © 2019 Elsevier Ltd

Chemometrics and digital image colorimetry approaches applied to paper-based analytical devices: A review

Item Type Journal Article**Author** I. Berasarte**Author** G. Albizu**Author** W.F. Santos**Author** L.F. de Lima**Author** M. Ostra**Author** M. Vidal**Author** W.R. de Araujo

Abstract Colorimetric paper-based analytical devices (CPADs) are cost-efficient and high-throughput technologies that use readily available materials for point-of-need (PON) applications by leveraging color changes in response to target analytes. However, the complexity of samples can limit the precision and accuracy of CPAD applications. Therefore, CPADs have been combined with chemometric approaches to enhance analytical performance and provide simple solutions to complex systems. The integration of formal optimization techniques, such as Design of Experiments (DoE), classification tools, quantification methods, and other advanced algorithms enables optimal experimental analytical conditions and extracting meaningful information from the complex colorimetric data generated by CPADs. These approaches facilitate robust calibration and prediction models, enabling reliable quantifications or sample differentiation. In addition, chemometrics combined with CPADs contributes to Green Analytical Chemistry once they have the potential to minimize the number of experiments, provide optimal designs and consumption of reagents, and decrease waste generation. The synergy between digital colorimetry using CPADs and smart devices with chemometric techniques holds great promise for portable analysis in resource-limited settings, with applications ranging from environmental monitoring to point-of-care diagnostics. Herein, we review recent advances in the development of CPADs, ranging from manufacturing methods to extraction of color patterns and data treatment using several chemometric tools, performance assessment, and potential transfer to onsite applications for relevant analytical problems. © 2024 Elsevier B.V.

Citizen science coupled with machine learning to quantify green-blue infrastructure cooling potential in Maricopa County, Arizona

Item Type Journal Article

Author A. Molla
Author K. Lamer
Author D.J. Sailor

Abstract This study investigates the spatiotemporal cooling performance of green and blue infrastructure (GBI) in the Dobson Ranch urban neighborhood in Phoenix, Arizona. We leveraged citizen science near-surface (2 m) air temperature (T_{air}) measurements to train a highly accurate T_{air} predicting LightGBM machine learning model (R²: 0.986, MAE: 0.251 °C, RMSE: 0.585 °C). On June 16, 2024, the park area exhibited approximately 1 °C cooling effect (relative to the neighborhood mean) during both day and night. In contrast, the nearby artificial lake exhibited a stronger cooling effect of 2.4 °C during the day but a slight warming of 0.3 °C at night. At 00:00, locations 50 m downwind of the park were 0.3 °C warmer than the park, while locations 50 m upwind were 0.8 °C warmer. At 11:00, we observed that the downwind area is 0.8 °C cooler and the upwind area is 0.6 °C warmer—at the same 50 m distances relative to the park. We also observed 1 °C cooler and warmer effects respectively at the same 50 m downwind and upwind locations at 19:00 on June 17, 2024. Our data-driven analysis highlights potential limitations of car-traverse measurements, showing that failure to account for temporal variations during the traverse can lead to overestimation of T_{air} at night and underestimation during the day. Our analysis also showed only a weak correlation (coefficient: 0.48) between Landsat-derived land surface temperature (LST) and model predicted T_{air} at the time of the local Landsat overpass (~11.00). This highlights the potential error of relying solely on LST for human thermal exposure analysis—particularly within the heterogenous built-environment. © 2026

Author Y. Wang

Author B.R. Goldsmith

Abstract It is critical that machine learning (ML) model predictions be trustworthy for high-throughput catalyst discovery approaches. Uncertainty quantification (UQ) methods allow estimation of the trustworthiness of an ML model, but these methods have not been well explored in the field of heterogeneous catalysis. Herein, we investigate different UQ methods applied to a crystal graph convolutional neural network to predict adsorption energies of molecules on alloys from the Open Catalyst 2020 dataset, the largest existing heterogeneous catalyst dataset. We apply three UQ methods to the adsorption energy predictions, namely k-fold ensembling, Monte Carlo dropout, and evidential regression. The effectiveness of each UQ method is assessed based on accuracy, sharpness, dispersion, calibration, and tightness. Evidential regression is demonstrated to be a powerful approach for rapidly obtaining tunable, competitively trustworthy UQ estimates for heterogeneous catalysis applications when using neural networks. Recalibration of model uncertainties is shown to be essential in practical screening applications of catalysts using uncertainties. © 2023 The Author(s). Published by IOP Publishing Ltd.

Class and subclass probability re-estimation to adapt a classifier in the presence of concept drift

Item Type Journal Article

Author R. Alaiz-Rodríguez

Author A. Guerrero-Curieses

Author J. Cid-Sueiro

Abstract We consider the problem of classification in environments where training and test data may come from different probability distributions. When the fundamental stationary distribution assumption made in supervised learning (and often not satisfied in practice) does not hold, the classifier performance may significantly deteriorate. Several proposals have been made to deal with classification problems where the class priors change after training, but they may fail when the class conditional data densities also change. To cope with this problem, we propose an algorithm that uses unlabeled test data to adapt the classifier outputs to new operating conditions, without re-training it. The algorithm is based on a posterior probability model with two main assumptions: (1) the classes may be decomposed in several (unknown) subclasses, and (2) all changes in data distributions arise from changes in prior subclass probabilities. Experimental results with a neural network model on synthetic and remote sensing practical settings show that the adaptation at the subclass level can get a better adjustment to the new operational conditions than the methods based on class prior changes. © 2011 Elsevier B.V.

Class distribution estimation based on the Hellinger distance

Item Type Journal Article

Author V. González-Castro

Author R. Alaiz-Rodríguez

Author E. Alegre

Abstract Class distribution estimation (quantification) plays an important role in many practical classification problems. Firstly, it is important in order to adapt the classifier to the operational conditions when they differ from those assumed in learning. Additionally, there are some real domains where the quantification task is itself valuable due to the high variability of the class prior probabilities. Our novel quantification approach for two-class problems is based on distributional divergence measures. The mismatch between the test data distribution and validation distributions generated in a fully controlled way is measured by the Hellinger distance in order to estimate the prior probability that minimizes this divergence. Experimental results on several binary classification problems show the benefits of this approach when compared to such approaches as counting the predicted class labels and other methods based on the classifier confusion matrix or on posterior probability estimations. We also illustrate these techniques as well as their robustness against the base classifier performance (a neural network) with a boar semen quality

control setting. Empirical results show that the quantification can be conducted with a mean absolute error lower than 0.008, which seems very promising in this field. © 2012 Published by Elsevier Inc.

Class distribution estimation in imprecise domains based on supervised learning

Item Type Journal Article

Author V. González-Castro

Author R. Alaiz-Rodríguez

Author E. Alegre

Abstract Quantification-or proportion estimation-plays an important role in many practi{reversed not sign}cal classification problems. On the one hand, a machine that automatically classifies an element into a group of predefined classes will make suboptimal decisions if the class distribution in the test (real) domain differs from the one assumed in learning. Estimating the new class distribution is necessary in order to adapt the classifier to the new operational conditions. On the other hand, there are some real domains where the quantification task itself is the main goal. Some fields,

such as quality control, direct marketing, tendency study or some textual recognition tasks, require methods that can reliably estimate the proportion of elements within each category without any concerns about how each element has been classified individually. We describe several quantification techniques that rely on supervised learning and provide these estimations based on: (a) the classifier confusion matrix, (b) the posterior probability estimations, and (c) distributional divergence measures. We illustrate these techniques, as well as their robustness against the base classifier performance in a practical seminal quality control setting where the ultimate goal is to quantify the proportion of sperm cells with damaged/intact acrosome. © 2012 by Nova Science Publishers, Inc. Class Information-Guided Reconstruction for Automatic Modulation Open-Set Recognition

Item Type Journal Article

Author Z. Zhang

Author M. Zhu

Author J. Liu

Author Y. Li

Author S. Wang

Abstract Automatic Modulation Recognition (AMR) is vital for radar and communication systems. Traditional AMR operates under closed-set scenarios where all modulation types are pre-defined. However, in practical settings, unknown modulation types may emerge due to technological advancements. Closed-set training poses the risk of misclassifying unknown modulations into existing known classes, leading to serious implications for situation awareness and threat assessment. To tackle this challenge, this paper presents a Class Information guided Reconstruction (CIR) framework that

can simultaneously achieve Known Class Classification (KCC) and Unknown Class Identification (UCI). The CIR leverages reconstruction losses to differentiate between known and unknown classes, utilizing Class Conditional Vectors (CCVs) and a Mutual Information (MI) loss function to fully exploit class information. The CCVs offer class-specific guidance for reconstruction process, ensuring accurate reconstruction for known samples while producing subpar results for unknown ones. Moreover, to enhance distinguishability, an MI loss function is introduced to capture class-discriminative semantics in latent space, enabling closer alignment with CCVs during reconstruction. The synergistic relationship between CCVs and MI facilitates optimal UCI performance without compromising KCC accuracy. The CIR is evaluated on simulated, public and real-world datasets, demonstrating its effectiveness and robustness, particularly in low SNR and high unknown class prevalence scenarios. © 2015 IEEE.

Class prior estimation from positive and unlabeled data

Item Type Journal Article

Author M.C. Du Plessis

Author M. Sugiyama

Abstract We consider the problem of learning a classifier using only positive and unlabeled samples. In this setting, it is known that a classifier can be successfully learned if the class prior is available. However, in practice, the class prior is unknown and thus must be estimated from data. In this paper, we propose a new method to estimate the class prior by partially matching the class-conditional density of the positive class to the input density. By performing this partial matching in terms of the Pearson divergence, which we estimate directly without density estimation via lower-bound maximization, we can obtain an analytical estimator of the class prior. We further show that an existing class prior estimation method can also be interpreted as performing partial matching under the Pearson divergence, but in an indirect manner. The superiority of our direct class prior estimation method is illustrated on several benchmark datasets. © 2014 The Institute of Electronics, Information and Communication Engineers.

Class prior estimation in active positive and unlabeled learning

Item Type Conference Paper

Author L. Perini

Author V. Vercruyssen

Author J. Davis

Editor Bessiere C.

Abstract Estimating the proportion of positive examples (i.e., the class prior) from positive and unlabeled (PU) data is an important task that facilitates learning a classifier from such data. In this paper, we explore how to tackle this problem when the observed labels were acquired via active learning. This introduces the challenge that the observed labels were not selected completely at random, which is the primary assumption underpinning existing approaches to estimating the class prior from PU data. We analyze this new setting and design an algorithm that is able to estimate the class prior for a given active learning strategy. Empirically, we show that our approach accurately recovers the true class prior on a benchmark of anomaly detection datasets and that it does so more accurately than existing methods. © 2020 Inst. Class prior estimation with biased positives and unlabeled examples

Item Type Conference Paper

Author S. Jain

Author J.D. Delano

Author H. Sharma

Author P. Radivojac

Abstract Positive-unlabeled learning is often studied under the assumption that the labeled positive sample is drawn randomly from the true distribution of positives. In many application domains, however, certain regions in the support of the positive class-conditional distribution are over-represented while others are under-represented in the positive sample. Although this introduces problems in all aspects of positive-unlabeled learning, we begin to address this challenge by focusing on the estimation of class priors, quantities central to the estimation of posterior probabilities and the recovery of true classification performance. We start by making a set of assumptions to model the sampling bias. We then extend the identifiability theory of class priors from the unbiased to the biased setting. Finally, we derive an algorithm for estimating the class priors that relies on clustering to decompose the original problem into subproblems of unbiased positive-unlabeled learning. Our empirical investigation suggests feasibility of the correction strategy and overall good performance. © 2020, Association for the Advancement of Artificial Intelligence.

Class Prior-Free Positive-Unlabeled Learning with Taylor Variational Loss for Hyperspectral Remote Sensing Imagery

Item Type Conference Paper

Author H. Zhao

Author X. Wang

Author J. Li

Author Y. Zhong

Abstract Positive-unlabeled learning (PU learning) in hyperspectral remote sensing imagery (HSI) is aimed at learning a binary classifier from positive and unlabeled data, which has broad prospects in various earth vision applications. However, when PU learning meets limited labeled HSI, the unlabeled data may dominate the optimization process, which makes the neural networks overfit the unlabeled data. In this paper, a Taylor variational loss is proposed for HSI PU learning, which reduces the weight of the gradient of the unlabeled data by Taylor series expansion to enable the network to find a balance between overfitting and underfitting. In addition, the self-calibrated optimization strategy is designed to stabilize the training process. Experiments on 7 benchmark datasets (21 tasks in total) validate the effectiveness of the proposed method. Code is at: <https://github.com/Hengwei-Zhao96/T-HOneCls>. © 2023 IEEE.

Class prioritization and server dedication in queueing systems: Discrimination and fairness aspects

Item Type Journal Article

Author D. Raz

Author H. Levy

Author B. Avi-Itzhak

Abstract Customer classification and prioritization are commonly utilized in applications to provide queue preferential service. Their fairness aspects, which are inherent to any preferential system and highly important to customers, have not been fully studied and quantified to date. We use the recently proposed Resource Allocation Queueing Fairness Measure (RAQFM), and a newly introduced metric called Class Discrimination, which is based on RAQFM, to analyze such systems and derive their relative fairness values as well as the discrimination experienced by the various classes. Specifically, we study two practices, commonly used in public facilities as well as in computer systems: class prioritization and dedication of servers to classes. © 2009 Elsevier B.V. CLASS PROBABILITY MATCHING WITH CALIBRATED NETWORKS FOR LABEL SHIFT ADAPTATION

Item Type Conference Paper

Author H. Wen

Author A. Betken

Author H. Hang

Abstract We consider the domain adaptation problem in the context of label shift, where the label distributions between source and target domain differ, but the conditional distributions of features given the label are the same. To solve the label shift adaptation problem, we develop a novel matching framework named class probability matching (CPM). It is inspired by a new understanding of the source domain's class probability, as well as a specific relationship between class probability ratios and feature probability ratios between the source and target domains. CPM is able to maintain the same theoretical guarantees as the existing feature probability matching framework, while significantly improving the computational efficiency due to directly matching the probabilities of the label variable. Within the CPM framework, we propose an algorithm named class probability matching with calibrated networks (CPMCN) for target domain classification. From the theoretical perspective, we establish a generalization bound of the CPMCN method in order to explain the benefits of introducing calibrated networks. From the experimental perspective, real data comparisons show that CPMCN outperforms existing matching-based and EM-based algorithms. © 2024 12th International Conference on Learning Representations, ICLR 2024. Abstract Class quantification of aerial images plays a vital role in remote sensing. One of the class quantification method is discussed in this paper. Proposed method uses Maximum Likelihood Estimation based classifier for class quantification. Algorithm is trained by the sample classes derived from parent image. Feature space is estimated from each training sample. Different classes are labeled in test image by maximizing the likelihood function. The experimentation is done on aerial images obtained by Geo eye satellite at the elevation of 0.6km. The percentage area covered by the labeled classes is computed for all test images. © 2014 IEEE.

Class-Aware Feature Perturbation for Long-Tailed Visual Recognition

Item Type Conference Paper

Author X. Chen

Author H. Ye

Author F. Zhou

Abstract The distribution of data in the real world is often imbalanced, with a small number of classes having a large number of instances, while most other classes have relatively few sample instances, resulting in a long-tailed distribution. Supervised contrastive learning still tends to favor classes with more samples, making it challenging to learn discriminative and robust features in imbalanced settings. In our work, we theoretically analyze the advantages of hard samples in contrastive learning and propose an end-to-end training framework based on class-aware perturbation. Specifically, we introduce different levels of perturbation based on class priors to construct hard samples, improve the disadvantaged position of tail classes, balance the feature space distribution, and dynamically adjust the classifier output with a combination of local batch priors and global priors. Experimental results show that our method achieves competitive performance across multiple long-tailed benchmark datasets. © 2024 IEEE.

Class-Aware Federated Early Exit Networks for Efficient Distributed Inference

Item Type	Conference Paper
Author	M. Ayyat
Author	T. Nadeem
Abstract	Early-exit models improve efficiency by allowing inputs to terminate inference at shallow layers, while class-aware variants further prioritize critical classes for faster processing. Yet existing solutions assume centralized training and cannot accommodate distributed settings where devices may have distinct class priorities. We introduce CAFED (Class-Aware Federated Early-Exit Network), the first framework that integrates class-aware early exits into federated learning. CAFED combines clustered aggregation with layer freezing: shared lower layers capture general features, while personalized upper layers host exits aligned with local priorities. Experiments show that CAFED accelerates inference for prioritized classes by up to 40% and improves accuracy by up to 30% over conventional federated and early-exit baselines, establishing a new path for privacy-preserving collaborative learning with class prioritization. © 2025 IEEE.

Class-Conditional Conformal Prediction for Reliable Anomaly Detection Under Extreme Class Imbalance

Item Type Journal Article**Author** B. Althani

Abstract Anomaly detection systems deployed in critical applications require not only high accuracy but also reliable uncertainty quantification and coverage guarantees. This paper is an empirical study—rather than a contribution of new conformal-prediction machinery—of class-conditional (Mondrian) conformal prediction for anomaly detection under extreme class imbalance, characterizing where standard conformal prediction fails and how class-conditional calibration restores valid coverage. Class-conditional conformal prediction constructs prediction sets that, under exchangeability, contain the true label with user-specified confidence (e.g., 90%), enabling systems to abstain on uncertain predictions. Unlike standard conformal prediction that fails catastrophically under extreme imbalance—achieving only 52.94% anomaly coverage at a 1:345 imbalance ratio—class-conditional calibration maintains 90.59% anomaly coverage by computing quantiles separately for each class. We apply the standard softmax-based nonconformity score (Formula presented.) within each class, ensuring valid coverage for both normal and anomalous instances with coverage gaps ranging from 0.50% to 5.18% depending on dataset characteristics. Extensive experiments on three real-world datasets (Microsoft Azure KPI, Yahoo, NAB) demonstrate that the method achieves empirical coverage within 0.06–0.33% of theoretical targets at confidence levels (Formula presented.) ; on the most imbalanced benchmark (Microsoft Azure KPI at a 1:345 ratio and (Formula presented.)), this corresponds to a 37.65 percentage point improvement in anomaly coverage over standard conformal prediction. We restate finite-sample coverage bounds and exchangeability conditions in the binary anomaly detection setting and validate them empirically through Monte Carlo simulation. Multi-model evaluation across XGBoost, Random Forest, and Neural Networks demonstrates the model-agnostic property of the framework, while also identifying conditions (poor base-

classifier discrimination, small minority calibration sets) under which coverage may be marginally violated. Comparison with alternative uncertainty quantification methods (isotonic probability calibration, Monte Carlo dropout) shows that only conformal prediction provides formal guarantees while maintaining 90.59% anomaly coverage versus 76.47% and 84.71% for alternatives. The abstention mechanism identifies 34–66% of predictions as uncertain at high confidence levels (99%), enabling safety-critical systems to defer difficult cases to human experts while preserving baseline discrimination (ROC-AUC unchanged). © 2026 by the author.

Class-prior probability estimation using density ratio between unlabeled instances and positively labeled noisy instances

Item Type Journal Article

Author T. Yoshida

Author E. Shin'ya

Author T. Washio

Abstract In this paper, the authors propose a new approach for determining the mixture proportions of positive and negative instances in both a small set of positively labeled instances contaminated with an unknown proportion of negative instances and an unlabeled instance set with an unknown mixture of positive and negative instances.

The unique advantage of this method lies in its ability to derive these proportions with a high level of accuracy by directly leveraging probability density ratio estimation. Experiments conducted on synthetic and UCI repository data demonstrate that the proposed technique can robustly estimate class-prior probabilities with greater speed and better accuracy compared to existing methods, particularly in the presence of instance number and imbalance challenges. © 2024 Elsevier B.V.

Class-prioritized compression of multispectral imagery data

Item Type Journal Article

Author J.A. Saghri

Author A.G. Tescher

Author M.G.H. Omran

Abstract A joint classification-compression scheme that provides the user with added capability to prioritize classes of interest in the compression process is proposed. The dual compression system includes a primary unit for conventional coding of a

multispectral image set followed by an auxiliary unit to code the resulting error induced on pixel vectors that represent classes of interest. This technique effectively allows classes of interest in the scene to be coded at a relatively higher level of precision than nonessential classes. Prioritized classes are selected from a thematic map or directly specified by their unique spectral signatures. Using the specified spectral signatures of the prioritized classes as end members, a modified linear spectral unmixing procedure is applied to the original data as well as to the decoded data. The resulting two sets of concentration maps, which represent classes prioritized before and after compression, are compared and the differences between them are coded via an auxiliary compression unit and transmitted to the receiver along with a conventionally coded image set. At the receiver, the differences found are blended back into the decoded data for enhanced restoration of the prioritized classes. The utility of this approach is that it works with any multispectral compression scheme. This method has been applied to test the imagery from various platforms including NOAA's AVHRR (1.1 km GSD), and LANDSAT 5 TM (30 m GSD), LANDSAT 5 MSS (79 m GSD). © 2002 SPIE and IS&T.

Class-Specific Reconstruction Transfer Learning for Visual Recognition across Domains

Item Type Journal Article**Author** S. Wang**Author** L. Zhang**Author** W. Zuo**Author** B. Zhang

Abstract Subspace learning and reconstruction have been widely explored in recent transfer learning work. Generally, a specially designed projection and reconstruction transfer functions bridging multiple domains for heterogeneous knowledge sharing are wanted. However, we argue that the existing subspace reconstruction based domain adaptation algorithms neglect the class prior, such that the learned transfer function is biased, especially when data scarcity of some class is encountered. Different from those previous methods, in this article, we propose a novel class-wise reconstruction-based adaptation method called Class-specific Reconstruction Transfer Learning (CRTL), which optimizes a well modeled transfer loss function by fully exploiting intra-class dependency and inter-class independency. The merits of the CRTL are three-fold. 1) Using a class-specific reconstruction matrix to align the source domain with the target domain fully exploits the class prior in modeling the domain distribution consistency, which benefits the cross-domain classification. 2) Furthermore, to keep the intrinsic relationship between data and labels after feature augmentation, a projected Hilbert-Schmidt Independence Criterion (pHSIC), that measures the dependency between data and label, is first proposed in transfer learning community by mapping the data from raw space to RKHS. 3) In addition, by imposing low-rank and sparse constraints on the class-specific reconstruction coefficient matrix, the global and local data structure that contributes to domain correlation can be effectively preserved. Extensive experiments on challenging benchmark datasets demonstrate the superiority of the proposed method over state-of-the-art representation-based domain adaptation methods. The demo code is available in <https://github.com/wangshanshanCQU/CRTL>. © 1992-2012 IEEE.

Class-Specific Reconstruction Transfer Learning via Sparse Low-Rank Constraint

Item Type Conference Paper**Author** S. Wang**Author** L. Zhang**Author** W. Zuo

Abstract Subspace learning and reconstruction have been widely explored in recent transfer learning work and generally a specially designed projection and reconstruction transfer matrix are wanted. However, existing subspace reconstruction based algorithms neglect the class prior such that the learned transfer function is biased, especially when data scarcity of some class is encountered. Different from those previous methods, in this paper, we propose a novel reconstruction-based transfer learning method called Class-specific Reconstruction Transfer Learning (CRTL), which optimizes a well-designed transfer loss function without class bias. Using a class-specific reconstruction matrix to align the source domain with the target domain which provides help for classification with class prior modeling. Furthermore, to keep the intrinsic relationship between data and labels after feature augmentation, a projected Hilbert-Schmidt Independence Criterion (pHSIC), that measures the dependency between two sets, is first proposed by mapping the data from original space to RKHS in transfer learning. In addition, combining low-rank and sparse constraints on the class-specific reconstruction coefficient matrix, the global and local data structures can be effectively preserved. Extensive experiments demonstrate that the proposed method outperforms conventional representation-based domain adaptation methods. © 2017 IEEE.

Classification and knowledge discovery in protein databases

Item Type Journal Article

Author P. Radivojac

Author N.V. Chawla

Author A.K. Dunker

Author Z. Obradovic

Abstract We consider the problem of classification in noisy, high-dimensional, and class-imbalanced protein datasets. In order to design a complete classification system, we use a three-stage machine learning framework consisting of a feature selection stage, a method addressing noise and class-imbalance, and a method for combining biologically related tasks through a prior-knowledge based clustering. In the first stage, we employ Fisher's permutation test as a feature selection filter. Comparisons with the alternative criteria show that it may be favorable for typical protein datasets. In the second stage, noise and class imbalance are addressed by using minority class over-sampling, majority class under-sampling, and ensemble learning. The performance of logistic regression models, decision trees, and neural networks is systematically evaluated. The experimental results show that in many cases ensembles of logistic regression classifiers may outperform more expressive models due to their robustness to noise and low sample density in a high-dimensional feature space. However, ensembles of neural networks may be the best solution for large datasets. In the third stage, we use prior knowledge to partition unlabeled data such that the class distributions among non-overlapping clusters significantly differ. In our experiments, training classifiers specialized to the class distributions of each cluster resulted in a further decrease in classification error. © 2004 Elsevier Inc. All rights reserved.

Classification and Measurement of Land Cover of Wildfires in Australia Using Remote Sensing

Item Type Journal Article

Author A.H. Thary Al-Ghrai

Author E.K. Hassan

Author H.M. Saeed

Abstract Remote sensing techniques used in many studies for classfying and measuring of wildfires. Satellite Landsat8(OLI) imagery is used in the presented work. The satellite is considered as a near-polar orbit, with a high multispectral resolution for covering Wollemi National Park in Australia. The work aims to study and measure wildfire natural resources prior to and throughout fire breakout which occurred in Wollemi National Park in Australia for a year (October, 2019), as well as analyzing the harm resulting from such wildfires and their effects on earth and environment through recognizing satellite images for studied region prior to and throughout wildfires. A

discussion of methods for computing the affected area is covered regarding each one of the classes and lessening or limiting the quickly-spreading wildfires damage. This paper propose a 2-phases techniques: Training and classifying. In the training phase, the number of clustering is computed by using C# Programming Language and feature extracted and clustered as a group and stored in the dataset. The classification used the moments with (K-Means) classification approach in RS (Remote Sensing) for classified image. The results of classification showed 5 distinctive classes (trees, rivers, bare earth, buildings with no trees, and buildings with trees) in which it might be indicates that the region is secured via each one of the classes prior to and throughout wildfires as well as the changed pixels with regard to all the classes. Also, the classification experimental methods results indicate an excellent performance recision with a good classifying and result analysis about the harms caused by fires in the study area. © 2022 University of Baghdad-College of Science. Classification and quantification based on image analysis for sperm samples with uncertain damaged/intact cell proportions

Item Type Conference Paper

Author L. Sánchez

Author V. González

Author E. Alegre

Author R. Alaiz

Abstract Classifying damaged-intact cells in a semen sample presents the peculiarity that the test class distribution is unknown. This paper studies under which design conditions the misclassification rate is minimum for the uncertainty region of interest (ratio of damaged cells lower than 20%) and (b) deals with quantifying the proportion of damaged/intact sperm cells in a given sample based on computer vision and supervised learning. We have applied a discrete wavelet transform to the spermatozoa head images and computed the mean and standard deviation (WSF) and four Haralick descriptors (WCF). Using a backpropagation neural network, the error rate averaged over distributions in the region of interest is 4.85% with WCF. The assessment of several quantification methods shows the conditions under which the Adjusted Count method leads to an overall mean absolute error of 3.2 and the Classify & Count method yields 2.4, both with WCF features. Deviations of this order are considered reasonable for this field. © 2008 Springer-Verlag Berlin Heidelberg.

Abstract Sesame oil is often adulterated with cheaper oils, necessitating accurate authentication and quantification methods. This study investigates the performance of AI-based models using ¹H NMR spectral data for edible oil classification and sesame oil quantification in adulterated mixtures. All classification models—PCA-LDA, SVM, and 1D-CNN—achieved 100 % accuracy, with 1D-CNN additionally capturing both lignan and fatty acid signals. For regression, PLSR and SVR models achieved RMSEP values of 1.94 and 1.40 ($R^2 = 0.998$), while the 1D-CNN regression model demonstrated superior performance (RMSEP = 1.03, $R^2 = 0.999$) with broader spectral feature integration. External test samples incorporating previously unused oil types further validated the robustness of the CNN model, which accurately predicted sesame oil content within a 2 % error margin. These findings highlight the potential of explainable deep learning integrated with NMR spectroscopy for reliable detection and quantification of adulterated sesame oil. © 2025 Elsevier Ltd

Classification based Integration of Quantifications for LC-MS Analysis

Item Type Conference Paper

Author T. Li

Author L. Chen

Author H. Wei

Abstract A classification based integration of quantification method for the Liquid Chromatography - Mass Spectrometry (LC-MS) analysis is described in this paper. Typically, one biological tissue may be sent to the LC-MS many times in practice to generate multiple LC-MS data. Due to the precise level or the profile of the search engine, these multiple individual quantitative results of the multiple LC-MS data may be partially identical. Here we proposed a method to integrate the quantitative results for the case where there are multiple individual measurements but the results are only partially identical. This proposed method applies a classifier to the peptides and treats the predicted probabilities of the classification as the weights to combine these multiple individual quantitative results into a better one. Experimental results show that in the task of quantitative LC-MS, the results generated by this integration method perform better than the ones produced by other individual measurements. © 2018 IEEE.

Classification Error Bound for Low Bayes Error Conditions in Machine Learning

Item Type Conference Paper

Author Z. Yang

Author V. Eminyan

Author R. Schlüter

Author H. Ney

Abstract In statistical classification and machine learning, classification error is an important performance measure, which is minimized by the Bayes decision rule. In practice, the unknown true distribution is usually replaced with a model distribution estimated from the training data in the Bayes decision rule. This substitution introduces a mismatch between the Bayes error and the model-based classification error. In this work, we apply classification error bounds to study the relationship between the error mismatch and the Kullback-Leibler divergence in machine learning. Motivated by recent observations of low model-based classification errors in many machine learning tasks, bounding the Bayes error to be lower, we propose a linear approximation of the classification error bound for low Bayes error conditions. Then, the bound for class priors are discussed.

Moreover, we extend the classification error bound for sequences. Using automatic speech recognition as a representative example of machine learning applications, this work analytically discusses the correlations among different performance measures with extended bounds, including cross-entropy loss, language model perplexity, and word error rate. © 2025 IEEE.

Classification from only positive and unlabeled functional data

Item Type Journal Article

Author Y. Terada

Author I. Ogasawara

Author K. Nakata

Abstract In various fields, data recorded continuously during a time interval and curve data, such as spectral data, become common. These kinds of data can be interpreted as functional data. In this paper we have studied binary classification from only positive and unlabeled functional data (PU classification for functional data). Our first contribution is to present a simple classification algorithm for this problem. The key

feature of the algorithm is that it is not required an estimation of the unknown class prior (or the constant probability that a positive object is labeled). It is worth noting that the idea of our method can be applied to kernel linear discriminant analysis for general data. Our second contribution is to prove that, under mild regularity conditions similar to those in a supervised context, the proposed algorithm can achieve perfect asymptotic classification in the context of PU classification. In fact, we show that the proposed algorithm works well not only in numerical experiments but also for real data examples. Moreover, as an important practical application, we have used the proposed algorithm to identify handball players at risk for anterior cruciate ligament (ACL) injury based on ground reaction force data. © Institute of Mathematical Statistics, 2020.

Classification from positive and unlabeled data based on likelihood invariance for measurement

Item Type Journal Article

Author T. Yoshida

Author T. Washio

Author T. Ohshiro

Author M. Taniguchi

Abstract We propose novel approaches for classification from positive and unlabeled data (PUC) based on maximum likelihood principle. These are particularly suited to measurement tasks in which the class prior of the target object in each measurement is unknown and significantly different from the class prior used for training, while the likelihood function representing the observation process is invariant over the training and measurement stages. Our PUCs effectively work without estimating the class priors of the unlabeled objects. First, we present a PUC approach called Naive Likelihood PUC (NL-PUC) using the maximum likelihood principle in a nontrivial but rather straightforward manner. The extended version called Enhanced Likelihood PUC (EL-PUC) employs an algorithm iteratively improving the likelihood estimation of the positive class. This is advantageous when the availability of the labeled positive data is limited. These characteristics are demonstrated both theoretically and experimentally. Moreover, the practicality of our PUCs is demonstrated in a real application to single molecule measurement. © 2021 - IOS Press. All rights reserved.

Classification methods and models for automatic determination of goods code by foreign economic activity goods nomenclature

Item Type Conference Paper

Author J.U. Sevinov

Author G.R. Khamroev

Editor Tanaino I.

Editor Dzholdosheva T.

Abstract Classification methods and models for automatic determination of goods code according to the commodity nomenclature of foreign economic activity (CN FEA) are considered. In the classification procedure, the object is reduced to one or more classes based on the results of the comparison to evaluate the proximity and make a conclusion. The relationship between vectors calculated by scalar multiplication was used as a measure of proximity. In order to determine the most informative symbols for classes, linguostatistical methods based on the information about the a priori probability of occurrence of terms and symbols were used. In doing so, macro-average and micro-average methods, which are considered effective in assessing the quality of classification for several classes, were used. Also, on the basis of syntactic and linguostatistical analysis, a generalized scheme of the process of automatic classification of goods in column 31_1 of the goods declaration graph is proposed. This recommended method of automatic identification of the CN FEA code allows participants of foreign economic activity to ease the processes of filling out declarations for goods. © The Authors, published by EDP Sciences. Classification of 3D structures based on an object detection for facade elements in multiple views during the reconstruction process

Item Type Conference Paper

Author R. Baumann

Author J.-F. Evers-Senne

Author M. Strand

Abstract The objective of this paper is to propose an approach which combines the multi view 3D reconstruction process of a building's facade with semantic information obtained by a deep neural network on the 2D observations of the considered scene. The object detector was used to annotate precise 2D features with semantic labels based on the object proposals. In a next step, spatially connected 2D features were evaluated to extend the initially computed labels to the whole facade element. The set of annotated 2D precise features was used to derive a classification of reconstructed 3D features. The a priori probabilities of the object detection model were used to compensate for biased predictions. The described approach was evaluated thoroughly with a view to different strategies for the annotation correction in 2D. Several failure patterns occurring in the considered application of facade reconstruction were observed and suggested solutions were given. © 2019 IEEE.

Classification of Breast Tumors Using Elastographic and B-mode Features: Comparison of Automatic Selection of Representative Slice and Physician-Selected Slice of Images

Item Type Journal Article

Author W.K. Moon

Author S.-C. Chang

Author J.M. Chang

Author N. Cho

Author C.-S. Huang

Author J.-W. Kuo

Author R.-F. Chang

Abstract Inter-observer variability and image quality are two key factors that can affect the diagnostic performance of elastography and B-mode ultrasound for breast tumor characterization. The purpose of this study is to use an image quantification method that automatically chooses a representative slice and then segments the tumor contour to evaluate the diagnostic features for tumor characterization. First, the representative slice is selected based on either the stiffness inside the tumor (the signal-to-noise ratio on the elastogram [SNRe]) or the contrast between the tumor and the surrounding normal tissue (the contrast-to-noise ratio on the elastogram [CNRe]). Next, the level set method is used to segment the tumor contour. Finally, the B-mode and elastographic features related to the segmented tumor are extracted for tumor characterization. The performance of the representative slice selected using the proposed methods is compared to that of the physician-selected slice in 151 biopsy-proven lesions (89 benign and 62 malignant). The diagnostic accuracies using elastographic features are 82.1% (124/151) for the slice with the maximum CNRe value, 82.1% (124/151) for the slice with the maximum SNRe value and 82.8% (125/151) for the physician-selected slice, whereas the diagnostic accuracies using B-mode features are 80.8% (122/151) for the slice with the maximum CNRe value, 87.4% (132/151) for the slice with the maximum SNRe value and 84.1% (127/151) for the physician-selected slice. When using both the B-mode and elastographic features to characterize the tumor, the accuracy of diagnosis is 86.1% (130/151) for the slice with the maximum CNRe value, 90.1% (136/151) for the slice with the maximum SNRe value and 89.4% (135/151) for the physician-selected slice. Our results show that the representative slice selected by SNRe and CNRe could be used to reduce the observer variability and to increase the diagnostic performance by the B-mode and elastographic features. © 2013 World Federation for Ultrasound in Medicine & Biology.

Classification of collective actions for rural community vitalization in Chugoku Mountainous region, Japan: applying multiple correspondence analysis

Item Type Journal Article

Author N. Yasunaga

Abstract This study quantitatively examines the classification of collectivities in rural communities and the factors affecting the collectivities in hilly and mountainous areas. Using the collective action data of rural communities in the Chugoku region (Tottori, Shimane, Okayama, Hiroshima, and Yamaguchi Prefectures) obtained from the Census of Agriculture and Forestry in view of social, economic, and environmental aspects. We quantitatively examined the typological characteristics and the factors of collectivities in rural communities based on the multiple

correspondence analysis (quantification method, type III). We made three main findings. First, we extracted the dimensions of weak-strong independence of community (there are relatively strong and weak communities linked with other communities in terms of collectivity), high-low collective behavior of community (there are strong and weak collectivity on social, economic, and environmental collective activities), and economic-social nature of collective behavior of community. Second, the forms of collectivities in rural communities were classified into three or four forms from the cluster analysis using the sample scores obtained from the multiple correspondence analysis. Locational factors such as closeness to DID, road station and expressway partially influence the differences among the forms. Third, as well as locational factors, the elements of human capital, bonding social capital, bridging social capital have an influence on the levels of collectivities. These findings indicate that it is critical to take measures to consider the rural vitalization conditions across the rural communities for the sustainability of rural resources. © 2020, The Japan Section of the Regional Science Association International.

Classification of dynamical diffusion states in single molecule tracking microscopy

Item Type Journal Article

Author P.J. Bosch

Author J.S. Kanger

Author V. Subramaniam

Abstract Single molecule tracking of membrane proteins by fluorescence microscopy is a promising method to investigate dynamic processes in live cells. Translating the trajectories of proteins to biological implications, such as protein interactions, requires the classification of protein motion within the trajectories. Spatial information of protein motion may reveal where the protein interacts with cellular structures, because binding of proteins to such structures often alters their diffusion speed. For dynamic diffusion systems, we provide an analytical framework to determine in which diffusion state a molecule is residing during the course of its trajectory. We compare different methods for the quantification of motion to utilize this framework for the classification of two diffusion states (two populations with different diffusion speed). We found that a gyration quantification method and a Bayesian statistics-based method are the most accurate in diffusion-state classification for realistic experimentally obtained datasets, of which the gyration method is much less computationally demanding. After classification of the diffusion, the lifetime of the states can be determined, and images of the diffusion states can be reconstructed at high resolution. Simulations validate these applications. We apply the classification and its applications to experimental data to demonstrate the potential of this approach to obtain further insights into the dynamics of cell membrane proteins. © 2014 Biophysical Society.

Classification of Left Atrial Diseased Tissue Burden Determined by Automated Voltage Analysis Predicts Outcomes after Ablation for Atrial Fibrillation

Item Type Journal Article

Abstract Background. The burden and persistence of atrial fibrillation (AF) have been associated with the presence and extent of left atrial (LA) fibrosis. Recent reports have implicated an association between the extent of LA fibrosis and the outcome of pulmonary vein isolation (PVI). We aimed to analyse the value of an automated scar quantification method in the prediction of success following PVI. Methods. One hundred and nine consecutive patients undergoing PVI for paroxysmal or persistent AF were included in our observational study with a 2-year follow-up. Prior to PVI, patients underwent high-definition LA electroanatomical mapping, and scar burden was quantified by automated software (Voltage Histogram Analysis, CARTO 3, Biosense Webster), then classified into 4 subgroups (Dublin Classes I-IV). Recurrence rates were analysed on and off antiarrhythmic drug therapy (AAD), respectively. Results. The overall success rate was 74% and 67% off AAD at 1- and 2-year follow-up, respectively. Patients with Dublin Class IV had significantly lower success rates ($p=0.008$, off AAD). Dublin Class IV ($OR=2.27$, $p=0.022$, off AAD) and the presence of arrhythmia in the blanking period ($OR=3.28$, $p=0.001$, off AAD) were the only significant predictors of recurrence. The use of AAD did not affect these results. Conclusions. We propose a classification of low voltage areas based on automated quantification by software during 3D mapping prior to PVI. Patients with high burden of low voltage areas ($>31\%$ of <0.5 mV, Dublin Class IV) have a higher risk of recurrence following PVI. Information gathered during electroanatomical mapping may have important prognostic value. © 2021 Szilvia Herczeg et al.

Classification of Micromobility Vehicles in Thermal-Infrared Images Based on Combined Image and Contour Features Using Neuromorphic Processing

Item Type Journal Article**Author** B. Stahl**Author** J. Apfelbeck**Author** R. Lange

Abstract Trends of environmental awareness, combined with a focus on personal fitness and health, motivate many people to switch from cars and public transport to micromobility solutions, namely bicycles, electric bicycles, cargo bikes, or scooters. To accommodate urban planning for these changes, cities and communities need to know how many micromobility vehicles are on the road. In a previous work, we proposed a concept for a compact, mobile, and energy-efficient system to classify and count micromobility vehicles utilizing uncooled long-wave infrared (LWIR) image sensors and a neuromorphic co-processor. In this work, we elaborate on this concept by focusing on the feature extraction process with the goal to increase the classification accuracy. We demonstrate that even with a reduced feature list compared with our early concept, we manage to increase the detection precision to more than 90%. This is achieved by reducing the images of 160×120 pixels to only 12×18 pixels and combining them with contour moments to a feature vector of only 247 bytes. © 2023 by the authors.

Classification of natural areas in Northern Finland using optical remote sensing images and data fusion

Item Type Conference Paper

Author M. Törmä

Abstract The aim of this study was to make CORINE 2000 classification better in Northern Finland by making the classes of natural areas more separable using optical remote sensing images and decision based data fusion methods. Phenological time-series derived from MODIS images and ETM-image mosaic were classified using Maximum Likelihood classifier. Classification results were merged using different data fusion methods and their result compared. The used methods were not particularly successful, because the overall accuracy of CORINE 2000-classification, 52%, was better than the overall accuracies of spectral classifications and data fusion methods. The best data fusion methods were maximum joint a posteriori probability-classification and classification where a priori probabilities have been acquired from lower resolution classification. © 2007 IEEE.

Abstract This research presents a quantification method for the estimation of normalised correlation-spectral cardiac signal parameters that applies a probabilistic model of the cardiac signal as a random and a priori nonstationary process. The high sensitivity and informative significance of the proposed parameters of nonstationarity are confirmed by statistical cardiac signal classification (significance testing) and multi-alternative discrimination by types of cardiac state. The possibility is shown for the building of the absolute metric scales of the cardiac states. © 2019 Taylor & Francis Group, London.

Classification of pollen species using autofluorescence image analysis

Item Type Journal Article

Author K. Mitsumoto

Author K. Yabusaki

Author H. Aoyagi

Abstract A new method to classify pollen species was developed by monitoring autofluorescence images of pollen grains. The pollens of nine species were selected, and their autofluorescence images were captured by a microscope equipped with a digital camera. The pollen size and the ratio of the blue to red pollen autofluorescence spectra (the B/R ratio) were calculated by image processing. The B/R ratios and pollen size varied among the species. Furthermore, the scatter-plot of pollen size versus the B/R ratio showed that pollen could be classified to the species level using both parameters. The pollen size and B/R ratio were confirmed by means of particle flow image analysis and the fluorescence spectra, respectively. These results suggest that a flow system capable of measuring both scattered light and the autofluorescence of particles could classify and count pollen grains in real time. © 2008 The Society for Biotechnology, Japan. Classification of Width 1 Lattice Tetrahedra by Their Multi-Width

Item Type	Journal Article
Author	G. Hamm
Abstract	We introduce the multi-width of a lattice polytope and use this to classify and count all lattice tetrahedra with multi-width $(1, w_2, w_3)$. The approach used in this classification can be extended into a computer algorithm to classify lattice tetrahedra of any given multi-width. We use this to classify tetrahedra with multi-width $(2, w_2, w_3)$ for small w_2 and w_3 and make conjectures about the function counting lattice tetrahedra of any multi-width. © The Author(s) 2024.

Abstract Labeled data for classification could often be obtained by sampling that restricts or favors choice of certain classes. A classifier trained using such data will be biased, resulting in wrong inference and sub-optimal classification on new data. Given an unlabeled new data set we propose a bootstrap method to estimate its class probabilities by using an estimate of the classifier's accuracy on training data and an estimate of probabilities of classifier's predictions on new data. Then, we propose two methods to improve classification accuracy on new data. The first method can be applied only if a classifier was designed to predict posterior class probabilities where predictions of an existing classifier are adjusted according to the estimated class probabilities of new data. The second method can be applied to an arbitrary classification algorithm, but it requires retraining on the properly resampled data. The proposed bootstrap algorithm was validated through experiments with 500 replicates calculated on 1,000 realizations for each of 16 choices of data set size, number of classes, prior class probabilities and conditional probabilities describing a classifier's performance. Applications of the proposed methodology to a benchmark data set with various class probabilities on unlabeled data and balanced class probabilities on the training data provided strong evidence that the proposed methodology can be successfully used to significantly improve classification on unlabeled data. © Springer-Verlag Berlin Heidelberg 2001.

Abstract An open scientific challenge is how to classify events with reliable measures of uncertainty, when we have a mechanistic model of the data-generating process but the distribution over both labels and latent nuisance parameters is different between train and target data. We refer to this type of distributional shift as generalized label shift (GLS). Direct classification using observed data X as covariates leads to biased predictions and invalid uncertainty estimates of labels Y . We overcome these biases by proposing a new method for robust uncertainty quantification that casts classification as a hypothesis testing problem under nuisance parameters. The key idea is to estimate the classifier's receiver operating

characteristic (ROC) across the entire nuisance parameter space, which allows us to devise cutoffs that are invariant under GLS. Our method effectively endows a pretrained classifier with domain adaptation capabilities and returns valid prediction sets while maintaining high power. We demonstrate its performance on two challenging scientific problems in biology and astroparticle physics with data from realistic mechanistic models. Copyright 2024 by the author(s)

Classification with the pot–pot plot

Item Type Journal Article

Author O. Pokotylo

Author K. Mosler

Abstract We propose a procedure for supervised classification that is based on potential functions. The potential of a class is defined as a kernel density estimate multiplied by the class's prior probability. The method transforms the data to a potential–potential (pot–pot) plot, where each data point is mapped to a vector of potentials.

Separation of the classes, as well as classification of new data points, is performed on this plot. For this, either the α -procedure (α -P) or k-nearest neighbors (k-NN) are employed. For data that are generated from continuous distributions, these classifiers prove to be strongly Bayes-consistent. The potentials depend on the kernel and its bandwidth used in the density estimate. We investigate several variants of bandwidth selection, including joint and separate pre-scaling and a bandwidth regression approach. The new method is applied to benchmark data from the literature, including simulated data sets as well as 50 sets of real data. It compares favorably to known classification methods such as LDA, QDA, max kernel density estimates, k-NN, and DD-plot classification using depth functions. © 2016, Springer-Verlag Berlin Heidelberg.

Classification, deconstruction and evaluation of frost heave models: How modeling methods cause simulation error

Item Type Journal Article

Author P.-Z. Duan

Author Y.-B. Wang

Abstract Frost heave models are important tools to study engineering damage in cold regions. However, multi-physical-field-coupling and different methods of coupling components bring difficulties to compare the models and to optimize their error sources. Therefore, classifying and deconstructing of different frost heave models and further evaluating them are significant for model development. We reviewed frost heave models for the past 50 years and built frost heave model families to show the classification and inheritance relationships. Then, the models were deconstructed by the thermal–hydraulic framework (THF) and frost heave quantification method (FHQM). Finally, based on simulated and experimental data in cited papers, the model errors caused by different THFs and FHQMs were analyzed. The results show: (a) Present frost heave models can be classified as porosity increase based (P) and ice lens increase based (I) models and they are tending to merge with each other; (b) THFs of P models regarding freezing soil as porous medium are the main reason for water migration error in the region of multi-ice layers, which also results high uncertainty of hydraulic parameters under different simulation conditions; (c) The most used two FHQMs of P models cause error exceeding 20 % because inaccurate relationship between pore strain and frost heave displacement; (d) The errors of THFs and FHQMs offset each other, which will hidden the error sources of the models. This paper can provide a reference for the improvement of frost heave models used in engineering. © 2022

Abstract Adversarial purification is one of the promising approaches to defend neural networks against adversarial attacks. Recently, methods utilizing diffusion probabilistic models have achieved great success for adversarial purification in image classification tasks. However, such methods fall into the dilemma of balancing the needs for noise removal and information preservation. This paper points out that existing adversarial purification methods based on diffusion models gradually lose sample information during the core denoising process, causing occasional label shift in subsequent classification tasks. As a remedy, we suggest to suppress such information loss by introducing guidance from the classifier confidence. Specifically, we propose Classifier-cOnfidence gUided Purification (COUP) algorithm, which purifies adversarial examples while keeping away from the classifier decision boundary. Experimental results show that COUP can achieve better adversarial robustness under strong attack methods.

Classifying cadmium contaminated leafy vegetables using hyperspectral imaging and machine learning

Item Type Journal Article**Author** A. Souza**Author** M.Z. Rojas**Author** Y. Yang**Author** L. Lee**Author** L. Hoagland

Abstract Cadmium (Cd) is a toxic element that can accumulate in edible plant tissues and negatively impact human health. Traditional Cd quantification methods are time-consuming, expensive, and generate a lot of toxic waste, slowing development of methods to reduce uptake. The objective of this study was to determine whether hyperspectral imaging (HSI) and machine learning (ML) can be used to predict Cd concentrations in plants using kale (*Brassica oleracea*) and basil (*Ocimum basilicum*) as model crops. The experiments were conducted in an automated phenotyping facility where all environmental conditions except soil Cd concentration were kept constant. Cd concentrations were determined at harvest using traditional methods and used to train the ML models with data collected from the imaging sensor. Visible/near infrared (VNIR) images were also collected at harvest and processed to calculate reflectance at 473 bands between 400 to 998 nm. All reflectance spectra were subject

to the feature selection algorithm ReliefF and Principal Component Analysis (PCA) to generate data and provide input to evaluate three ML classification models: artificial neural network (ANN), ensemble learning (EL), and support vector machine (SVM). Plants were categorized according to Cd concentrations higher or lower than the safety threshold of 0.2 mg kg⁻¹ Cd. Wavelengths with the highest ranks for Cd detection were between 519 and 574, and 692 and 732 nm, indicating that Cd content likely altered the plants' chlorophyll content and altered leaf internal structure. All models were able to sort the plants into groups, though the model with the best F1 score was the ANN for the validation subset that utilized reflectance from all wavelengths. This study demonstrates that HSI and ML are promising technologies for the fast and precise diagnosis of Cd in leafy green plants, though additional studies are needed to adapt this approach for more complex field environments. © 2022 The Author(s)

Abstract We consider the problem of classifying images, ordered in a sequence (series), to several classes. A distinguishing feature of this problem is the presence of a slowly varying, reoccurring concept drift which results in the existence of relatively long subsequences of similar images from the same class. It seems useful to incorporate this knowledge into a classifier. To this end, we propose a novel idea of constructing a Markov chain (MC) that predicts a class label for the next image to be recognized. Then, the feedback is used in order to modify slightly a priori probabilities of class memberships. In particular, the a priori probability of the class predicted by the MC is increased at the expense of decreasing the a priori probabilities of other classes. The idea of applying an MC predictor of classes with the feedback to a priori probabilities is rather general. Thus, it can be applied not only to images but also to vectors of features arising in other applications. Additionally, this idea can be combined with any classifier that is able to take into account a priori probabilities. We provide an analysis when this approach leads to the reduction of the classification errors in comparison to classifying each image separately. As a vehicle to elucidate the idea we selected a recently proposed classifier (see [23, 25]) that is based on assuming matrix normal distribution (MND) of classes. We use a specific structure of the MND's covariance matrix that can be estimated directly from images without feature extraction. The proposed approach was tested on simulated images as well as on an example of the sequence of images from an industrial gas burner's flames. The aim of the classification is to decide whether natural gas contains a sufficient amount of methane (the combustion process is proper, lower air pollution) or not. © 2020, Springer Nature Switzerland AG.

Abstract An attempt is made to address the problem of classifying incomplete vectors using decision trees. The essence of the approach is the proposal that in supervised learning classification of incomplete vectors can be improved in probabilistic terms. This approach, which is based on the a priori probability of each value determined from the instances at that node of the tree that has specified values, first exploits the total probability and Bayes' theorems and then the probit and logit model probabilities. The proposed approach (developed in three versions) is evaluated using 21 machine learning datasets from its effect or tolerance of incomplete test data. Experimental results are reported, showing the effectiveness of the proposed approach in comparison with multiple imputation and fractioning of instances strategy. Classifying interpersonal interaction in virtual reality: sensor-based analysis of human interaction with pre-recorded avatars

Item Type Journal Article

Author Y. Arima

Author Y. Harada

Author M. Okada

Abstract This study investigates human engagement with a non-responsive, pre-recorded avatar in VR environments. Rather than bidirectional collaboration, we focus on unidirectional synchrony from human participants to the avatar and evaluate its detectability using sensor-based machine learning. Using a random forest model, we classified interactions into cooperation, conformity, and competition, achieving an F1 score of 0.89. Feature importance analysis identified hand rotation and head position as key predictors of interaction states. We compared human-human and human interaction with a non-responsive avatar (pre-recorded motion replay) during a joint Simon task by covertly switching collaborators between humans and non-responsive avatars. Using the classification model, a synchrony index was derived from VR motion data to quantify behavioral coordination patterns during joint actions. The classification indexes were associated with higher cooperation in human-human interactions (Formula presented.) and greater conformity in human interaction with a non-responsive avatar (Formula presented.). The synchrony index was significantly lower in the non-responsive avatar condition (Formula presented.), indicating reduced interpersonal synchrony with non-responsive avatars. These findings demonstrate the feasibility of using VR sensor data and machine learning to quantify social interaction dynamics. This study aimed to explore the feasibility of a sensor-based machine learning model for classifying interpersonal interactions in VR, based on preliminary data from small-sample experiments. Classifying microwave radar images using decision based data fusion

Item Type Conference Paper

Author M. Törmä

Author M. Engdahl

Editor Kerle N.

Editor Skidmore A.

Abstract Four different data fusion methods for classifying SAR images with different spatial resolutions were tested and compared. Test area was Helsinki region in Southern Finland and test data 14 ERS-1/2 Tandem pairs. The best method was a method where a posteriori probabilities of lower spatial resolution classification are used as a priori probabilities of higher resolution classification. The increase of overall accuracy was 7-14 %-units depending on date and 10.4% on average when compared to original Tandem pairs. Median filtering increased classification accuracy, but not that much when data fusion methods were used. This means that the need of spatial filtering can be at least partially compensated using data fusion of different spatial resolution images. © 2006 International Society for Photogrammetry and Remote Sensing. Abstract The source area of the Yangtze River (SAYR), part of the Tibetan Plateau, is an ecologically fragile alpine region sensitive to climate change. Current research has predominantly examined hydrological and ecological responses as isolated systems, failing to address the coupled mechanisms through which permafrost degradation mediates water-carbon interactions. In this study, we used a fully coupled eco-hydrological model that integrates permafrost processes, along with multi-source remote sensing data, experimental monitoring, and machine learning, to quantify the water retention and carbon sequestration capacity over the past 20 years. The region was categorized into three risk zones based on changes in soil moisture, net ecosystem productivity (NEP), and dissolved organic carbon (DOC) fluxes in streams. We evaluated eight factors, including precipitation, temperature, vegetation phenology and cover, and their contributions to changes of water retention and carbon sequestration using an interpretable machine learning approach. Results show that the central and eastern regions of the study area face the highest risk of declining water retention and carbon sequestration capacity. The changes of temperatures and precipitation have led to depletion of soil water and carbon reserves. This depletion raises concerns about the potential shift from a carbon sink to a carbon source considering land-to-river carbon loss. Our study provides critical insights into the water and carbon flux dynamics and offers valuable guidance for water resource and ecological management in alpine river systems. © 2025 Elsevier Ltd

Climate warming increases extreme daily wildfire growth risk in California

Item Type Journal Article

Author P.T. Brown

Author A.K. Kochanski

Author C.B. Clements

Abstract California has experienced enhanced extreme wildfire behaviour in recent years 1–3, leading to substantial loss of life and property 4,5. Some portion of the change in wildfire behaviour is attributable to anthropogenic climate warming, but formally quantifying this contribution is difficult because of numerous confounding factors 6,7 and because wildfires are below the grid scale of global climate models. Here we use machine learning to quantify empirical relationships between temperature (as well as the influence of temperature on aridity) and the risk of extreme daily wildfire growth (>10,000 acres) in California and find that the influence of temperature on the risk is primarily mediated through its influence on fuel moisture. We use the uncovered relationships to estimate the changes in extreme daily wildfire growth risk under anthropogenic warming by subjecting historical fires from 2003 to 2020 to differing background climatological temperatures and aridity conditions. We find that the influence of anthropogenic warming on the risk of extreme daily wildfire growth varies appreciably on a fire-by-fire and day-by-day basis, depending on whether or not climate warming pushes conditions over certain thresholds of aridity, such as 1.5 kPa of vapour-pressure deficit and 10% dead fuel moisture. So far, anthropogenic warming has enhanced the aggregate expected frequency of extreme daily wildfire growth by 25% (5–95 range of 14–36%), on average, relative to preindustrial conditions. But for some fires, there was approximately no change, and for other fires, the enhancement has been as much as 461%. When historical fires are subjected to a range of projected end-of-century conditions, the aggregate expected frequency of extreme daily wildfire growth events increases by 59% (5–95 range of 47–71%) under a low SSP1–2.6 emissions scenario compared with an increase of 172% (5–95 range of 156–188%) under a very high SSP5–8.5 emissions scenario, relative to preindustrial conditions. © 2023, The Author(s), under exclusive licence to Springer Nature Limited.

Abstract Health-damaging surface ozone tends to be lower in populated urban areas than in the surroundings, yet this urban–rural difference is narrowing. While evidence from observations have attributed this narrowing to the reduced inhibition effect of urban nitrogen oxides, we lack clarity on how intensified humid-heat modulates precursor sensitivity in ways that reconfigure the urban–rural gradient under climate warming. Here, we integrated high-resolution air pollutant reanalysis with interpretable machine learning to quantify the global spatial patterns and temporal evolution of paired urban–rural ozone gradients. We show that meteorology–chemistry synergy in urban areas, encompassing weakened inhibition effects of NO2 and dewpoint temperature and an intensified positive effect of radiation, contributes significantly to the reversal of urban–rural ozone disparities in tropical regions and to the long-term global convergence (0.1 μg m^{−3} year^{−1}, 2005–2023). Although heatwaves have become more frequent, ozone anomalies have diminished driven by moist atmospheric conditions and stringent emission cuts. Yet urban anomalies exceed rural

ones, with the differences during moist heatwaves nearly 2-fold those observed in dry events. Our study urges targeted and proactive policies to prevent climate warming synergies from disproportionately worsening urban ozone burdens. © 2026 American Chemical Society

Abstract Background: Community-acquired pneumonia (CAP) is a frequent complication of chronic obstructive pulmonary disease (COPD), but previous studies are often contradictory. Objectives: We aimed to ascertain the characteristics and outcomes of CAP in patients with COPD as well as to determine the risk factors for mortality and *Pseudomonas aeruginosa* pneumonia in COPD patients with CAP. We also describe the etiology and outcomes of CAP in COPD patients receiving chronic oxygen therapy at home and those receiving inhaled steroids. Methods: An observational analysis of a prospective cohort of hospitalized adults with CAP (1995-2011) was performed. Results: We documented 4121 CAP episodes, of which 983 (23.9%) occurred in patients with COPD; the median FEV1 value was 50%, and 57.8% were classified as stage III or IV in the GOLD classification. Fifty-eight per cent of patients were receiving inhaled steroids, and 14.6% chronic oxygen therapy at home. Patients with COPD presented specific clinical features. *S. pneumoniae* was the leading causative organism overall, but *P. aeruginosa* was more frequent in COPD (3.4 vs. 0.5%; $p < 0.001$). Independent risk factors for case-fatality rate in patients with COPD were multilobar pneumonia, *P. aeruginosa* pneumonia, and high-risk PSI classes. Prior pneumococcal vaccination was found to be protective. FEV1 was an independent risk factor for *P. aeruginosa* pneumonia. Conclusions: CAP in patients with COPD presents specific characteristics and risk factors for mortality. Prior pneumococcal vaccine has a beneficial effect on outcomes. *P. aeruginosa* pneumonia is associated with low FEV1 values and poor prognosis. © 2014 Gómez-Junyent et al.

Author Á. González

Abstract Background and aims: Patients' response to treatment in differentiated thyroid cancer (DTC) is classified according to serum thyroglobulin concentrations (Tg), usually using the American Thyroid Association guidelines and considering potential interfering anti-thyroglobulin antibodies (Ab-Tg). We aim to evaluate the clinical implications of changing Tg and Ab-Tg quantification method. Material and methods: Tg and Ab-Tg were quantified in 82 serum samples (60 from DTC patients) by Elecsys and Access immunoassays. Results: Elecsys immunoassay rendered higher values of Tg than Access: mean bias 5.03 ng/mL (95%CI:-14.14–24.21). In DTC patients, there was an almost perfect agreement for response classification (kappa index = 0.833). Discrepancies appeared in patients with undetermined response, with a more tendency to subclassification with Access. Ab-Tg showed a poor correlation ($r = 0.5394$). When Elecsys cut-off was reduced to 43 IU/mL, agreement for positive/negative classification improved from a kappa index of 0.607 to 0.650. Prospective study with personalized follow-up showed that only 6.3% of Tg results required an analytical confirmation, being confirmed 93% of them. Conclusions: Despite the biases observed, clinical impact of an analytical change is minimal in patients' management. However, cautious and personalized follow-up

period after the change is still mandatory, especially in patients with Tg levels between 0.2 and 1 ng/mL. © 2023

Abstract Urinary tract infection (UTI) flare-ups pose a significant health risk for older adults with chronic conditions. These infections often go unnoticed until they become severe, making early detection through innovative smart home technologies crucial. Traditional machine learning (ML) approaches relying on simple binary classification for UTI detection offer limited utility to nurses and practitioners as they lack insight into prediction uncertainty, hindering informed clinical decision-making. This paper presents a clinician-in-the-loop (CIL) smart home system that leverages ambient sensor data to extract meaningful behavioral markers, train robust predictive ML models, and calibrate them to enable uncertainty-aware decision support. The system incorporates a statistically valid uncertainty quantification method called Conformal-Calibrated Interval (CCI), which quantifies uncertainty and abstains from making predictions (“I don’t know”) when the ML model’s confidence is low. Evaluated on real-world data from eight smart homes, our method outperforms baseline methods in recall and other classification metrics while maintaining the lowest abstention proportion and interval width. A survey of 42 nurses confirms that our system’s outputs are valuable for guiding clinical decision-making, underscoring their practical utility in improving informed decisions and effectively managing UTIs and other condition flare-ups in older adults. © 2026, Association for the Advancement of Artificial Intelligence (www.aaai.org). ClipMix for Domain Generalization

Item Type Journal Article

Author A.-A. Liu

Author H.-C. Li

Author W.-H. Li

Author D. Song

Author H.-S. Tian

Author L.-J. Wang

Abstract Domain Generalization (DG) is a growing field in machine learning that aims to train the model across multiple source domains, thereby enabling effective generalization to new, unseen target domains. Recent studies suggest that data augmentation, which enhances the diversity of the source domain, might be a promising solution to address this task. Current data augmentation methods use random fusion coefficients or local regional fusion, which cannot adaptively design the weights based on data, or preserve the integrity of original semantics. Inspired by the pre-trained model CLIP, which contains extensive multimodal knowledge, we propose ClipMix to address these limitations. Firstly, we use the CLIP model as the external knowledge to adaptively evaluate the alignment between images and their labels, using this alignment to assess the complexity of learning each image and guide adaptive augmentation. Secondly, we implement a label shift mechanism to dynamically assign soft labels to fused images, helping the model focus on hard-to-learn patterns and also gather domain-agnostic representation. Furthermore, we enhance the diversity of fused images at both the pixel and feature levels. Experimental results across sixteen domains from four databases verify the effectiveness of our method. © 1991-2012 IEEE.

Cluster cooperation and risk level in small and medium-sized enterprises

Item Type Journal Article

Author K. Havierníková

Author M. Okręglicka

Author A. Lemańska-Majdzik

Abstract One of the most important stages in the process of risk management is the risk identification and classification, which are required in each entity located and operating in the environment that is: dynamic, influenced by various external and internal factors and exposed to some types of risks. The main research aim is to identify the most important categories of risk and to develop knowledge about risk management in cluster cooperation. The proposal of the methodology is based on the results of the survey conducted in small and medium sized enterprises in Slovakia in 2016 and the literature review. Risk categories will be analyzed and evaluated with the use of quantification method – non-parametric multi-selective Kruskal-Wallis test. The contribution of the paper consists in pointing out the types of risk the entities have to consider in the framework of cluster cooperation. The results of the paper show that the most important categories of risk are mainly market, political and technical risks. © 2016 Czestochowa University of Technology. All rights reserved.

Abstract Background Cluster headache is a highly disabling trigeminal autonomic cephalalgia associated with substantial diagnostic delay, severe pain-related disability, and limited access to evidence-based treatments. In Brazil, epidemiological data are scarce, and CH is not formally recognized within rare-disease policy frameworks. Clarifying the available prevalence evidence may help guide surveillance, research priorities, and health-policy planning. Objective To analyze the prevalence of cluster headache (CH) in Brazil and assess whether the currently available Brazilian population-based evidence is compatible with national rare-disease criteria, while discussing clinical and public-health implications. Methods We conducted a systematic review of population-based epidemiological studies on CH in Brazilian adults, reported according to PRISMA 2020. Searches were performed in PubMed/MEDLINE, LILACS, and SciELO on March 1, 2026, covering publications from January 1, 2010, to March 1, 2026, with no language restrictions. Eligible studies were original Brazilian population-based studies in adults reporting CH prevalence or providing a denominator allowing prevalence estimation. Diagnosis was required to be based on

ICHD-3, ICHD-3 beta, ICHD-2, or clearly described clinical criteria compatible with CH diagnosis. Brazilian Ministry of Health and CONITEC documents were reviewed to identify regulatory definitions and policy criteria for rare-disease classification. Methodological quality and risk of bias were assessed using the JBI Critical Appraisal Checklist for Studies Reporting Prevalence Data. Results The search identified 19 records. After removal of 12 duplicates, 7 records were screened, 4 full-text articles were assessed for eligibility, and 1 population-based Brazilian study met inclusion criteria. The eligible study, conducted in Barbacena, Minas Gerais, identified 15 CH cases among 36,145 adults, corresponding to a prevalence of 41.4 per 100,000 adults. This estimate is below the Brazilian rare-disease threshold of 65 per 100,000 inhabitants. The best available Brazilian population-based estimate is therefore compatible with CH meeting the Brazilian rare-disease prevalence threshold, although national confirmation requires additional population-based studies. Conclusion Current Brazilian population-based evidence is compatible with cluster headache meeting the national rare-disease prevalence threshold. However, this conclusion is based on a single population-based study, and further multicenter epidemiological research is required. Formal recognition may be scientifically justified and could support public-health planning, epidemiological surveillance, professional training, and development of national care pathways for diagnosis and treatment. © 2026, Brazilian Headache Society. Abstract Federated learning empowers multiple parties to train machine learning models collaboratively while preserving data within local confines. However, due to the intrinsic non-independent and identically distributed (Non-IID) nature of client-side data, aggregating these diverse local models into a global model remains a significant challenge. Clustered Federated Learning (CFL) offers a compelling solution to mitigate the impact of data heterogeneity by organizing clients into clusters. Existing CFL methods often involve unstable, time-consuming cluster identity estimation during training. In this work, we propose an innovative federated learning approach that efficiently identifies similarities among client data distributions by analyzing client's prototypes. Our method accurately identifies client cluster identities during the initialization phase. Clients employ the same randomly initialized model to compute the client's prototypes for their local data and provide it to the server. The server performs one-shot client clustering by comparing the similarity of the client's prototypes. We further design a unique inter-cluster aggregation strategy that adapts inter-cluster aggregation weights based on the similarity of the client's prototypes, thereby enhancing model convergence. We evaluate two mixed datasets with three Non-IID settings, and our approach outperforms several popular baseline methods. Compared to IFCA and FlexCFL, our approach yields more reasonable clustering results. It achieves an average test accuracy improvement of over 11.51% in the feature and label shift Non-IID setting of the Digits-5 dataset. © 2024 IEEE.

Abstract Answer Selection is an important subtask of Question Answering tasks. For this learning-to-rank problem, deep learning methods have outperformed traditional methods. To train a high-quality deep answer selection model, it often requires large amounts of labeled data, which is a costly and noise-prone process. Active learning and semi-supervised learning are usually applied in the modelling training procedure to achieve optimal accuracy with fewer labeled training samples. However, traditional active learning methods rely on good uncertainty estimates that are hard to obtain with standard neural networks. And the performance of semi-supervised learning methods are always affected adversely by the quality of the pseudo-labeled data. In this work, we propose a new framework integrating active learning and self-paced learning in training deep answer selection models. This framework proposes an uncertainty quantification method based on Bayesian neural network, which can guide active learning and self-paced learning in the same iterative process of model training. Experiments were conducted on two kinds of deep answer selection models with real-world datasets including YahooCQA and SemiEvalCQA. The results reveal that the proposed method can significantly reduce the labeled samples for model training.

Combined effects of class imbalance and class overlap on instance-based classification

Item Type Conference Paper

Author V. García

Author R. Alejo

Author J.S. Sánchez

Author J.M. Sotoca

Author R.A. Mollineda

Abstract In real-world applications, it has been often observed that class imbalance (significant differences in class prior probabilities) may produce an important deterioration of the classifier performance, in particular with patterns belonging

to the less represented classes. This effect becomes especially significant on instance-based learning due to the use of some dissimilarity measure. We analyze the effects of class imbalance on the classifier performance and how the overlap has influence on such an effect, as well as on several techniques proposed in the literature to tackle the class imbalance. Besides, we study how these methods affect to the performance on both classes, not only on the minority class as usual. © Springer-Verlag Berlin Heidelberg 2006.

Combining accuracy and prior sensitivity for classifier design under prior uncertainty

Item Type Conference Paper

Author T. Landgrebe

Author R.P.W. Duin

Abstract Considering the classification problem in which class priors or misallocation costs are not known precisely, receiver operator characteristic (ROC) analysis has become a standard tool in pattern recognition for obtaining integrated performance measures to cope with the uncertainty. Similarly, in situations in

which priors may vary in application, the ROC can be used to inspect performance over the expected range of variation. In this paper we argue that even though measures such as the area under the ROC (AUC) are useful in obtaining an integrated performance measure independent of the priors, it may also be important to incorporate the sensitivity across the expected prior-range. We show that a classifier may result in a good AUC score, but a poor (large) prior sensitivity, which may be undesirable. A methodology is proposed that combines both accuracy and sensitivity, providing a new model selection criterion that is relevant to certain problems. Experiments show that incorporating sensitivity is very important in some realistic scenarios, leading to better model selection in some cases. © Springer-Verlag Berlin Heidelberg 2006.

Combining adaptive local aggregation average and test-time energy adaptation for federated learning

Item Type Journal Article

Author J. Liao

Author C. Yi

Author K. Chen

Author Q. Peng

Abstract Federated test-time adaptation (FTTA) aims to adapt knowledge from diverse source models to different but related unlabeled target data in an online and privacy-aware manner. However, existing FTTA methods struggle with decreased adaptation performance caused by data distribution shifts among clients. In this paper, we propose an FTTA method (ALAA-TTEA) called adaptive local aggregation average and test-time energy adaptation. The method consists of two continuous stages. First, in the federated aggregation stage, clients adaptively aggregate the global model and local model through adaptive local aggregation (ALA) to initialize the client model. Then, they obtain the global model through personalized training and model averaging. Second, in the test-time adaptation stage, test-time energy adaptation (TTEA) uses an energy function to transform the global model into an energy-based model. It aligns the model distribution with the test data distribution, thereby enhancing the model's ability to adapt to the test distribution and improving overall performance. Extensive experiments demonstrate that ALAA-TTEA effectively handles data distribution shifts, including feature shift, label shift, hybrid shift, and domain shift. Moreover, it consistently outperforms existing FTTA methods under most conditions. © The Author(s), under exclusive licence to Springer-Verlag GmbH Germany, part of Springer Nature 2025.

Combining instance selection and self-training to improve data stream quantification

Item Type Journal Article

Author A.G. Maletzke

Author D.M. dos Reis

Author G.E.A.P.A. Batista

Abstract In the last years, learning from data streams has attracted the attention of researchers and practitioners due to its large number of applications. These applications have motivated the research community to propose a significant amount of methods to solve problems in diverse tasks, more prominently in classification, clustering, and anomaly detection. However, a relevant task known as quantification has remained mostly unexplored. The quantification goal is to provide an estimate of the class prevalence in an unlabeled set. Recently, we proposed the SQSI algorithm to quantify data streams with concept drifts. SQSI uses a statistical test to identify concept drifts and retrain the classifiers. However, the retraining involves requiring the labels for all newly arrived instances. In this paper, we extend SQSI algorithm by exploring instance selection techniques allied to semi-supervised learning. The idea is to request the classes of a smaller subset of recent examples. Our experiments demonstrate that SQSI's extension significantly reduces the dependency on actual labels while maintaining or improving the quantification accuracy. © 2018, The Author(s).

Combining similarity and transformer methods for case law entailment

Item Type Conference Paper**Author** J. Rabelo**Author** M.-Y. Kim**Author** R. Goebel

Abstract We tackle the complex problem of determining entailment relationships between case law documents, one of the tasks in the Competition on Legal Information Extraction and Entailment (COLIEE). With input of an entailed fragment from a case coupled with a candidate entailing paragraph from a noticed case, our approach relies on four main components: (1) extraction of similarity measures between the two pieces of text; (2) application of a transformer-based technique on the input text; (3) applying a threshold-based classifier; and (4) post-processing the results considering the a priori probability determined by the data distribution on the training samples and combining the results of (1) and (2). Our experiments achieved an F-score of 0.70 on the official COLIEE test dataset, ranking first among all competitors for that task in the 2019 competition. © 2019 Association for Computing Machinery.

CoMBO: Conflict Mitigation via Branched Optimization for Class Incremental Segmentation

Item Type Conference Paper
Author K. Fang
Author A. Zhang
Author G. Gao
Author J. Jiao
Author C.H. Liu
Author Y. Wei
Abstract Effective Class Incremental Segmentation (CIS) requires simultaneously mitigating catastrophic forgetting and ensuring sufficient plasticity to integrate new classes. The inherent conflict above often leads to a back-and-forth, which turns the objective into finding the balance between the performance of previous (old) and incremental (new) classes. To address this conflict, we introduce a novel approach, Conflict Mitigation via Branched Optimization (CoMBO). Within this approach, we present the Query Conflict Reduction module, designed to explicitly refine queries for new classes through lightweight, class-specific adapters. This module provides an additional branch for the acquisition of new classes while preserving the original queries for distillation. Moreover, we develop two strategies to further mitigate the conflict following the branched structure, i.e., the Half-Learning Half-Distillation (HDHL) over classification probabilities, and the Importance-Based Knowledge Distillation (IKD) over query

features. HDHL selectively engages in learning for classification probabilities of queries that match the ground truth of new classes, while aligning unmatched ones to the corresponding old probabilities, thus ensuring retention of old knowledge while absorbing new classes via learning negative samples. Meanwhile, IKD assesses the importance of queries based on their matching degree to old classes, prioritizing the distillation of important features and allowing less critical features to evolve. Extensive experiments in Class Incremental Panoptic and Semantic Segmentation settings have demonstrated the superior performance of CoMBO. Comment on: “A comprehensive landscape of AI applications in broad-spectrum drug interaction prediction: a systematic review” (Marzouk et al., 2025)

Item Type Journal Article

Author A. Kargar

Author M.A. Zamani

Author G. Mohammadnezhad

Abstract Marzouk et al. reviewed 147 studies on artificial intelligence (AI) applications for predicting drug–drug, drug–disease, and drug–nutrient interactions, providing a broad overview of current machine learning and deep-learning approaches. However, several methodological and conceptual limitations reduce the reproducibility and interpretability of the review. The search strategy appears largely restricted to PubMed with title- and abstract-level filtering, while manual record removal is reported without explicit criteria defining “irrelevant” studies, limiting transparency and reproducibility. Protocol registration, duplicate independent screening, standardized extraction procedures, and formal bias assessment using established frameworks such as ROBIS, PROBAST+AI, and TRIPOD+AI were not clearly reported. The review reports performance metrics such as area under the receiver operating characteristic curve (AUROC), but does not provide a structured framework for interpreting or comparing metrics across heterogeneous datasets, prediction tasks, and evaluation protocols. Because the interpretation of AUROC and precision–recall metrics depends on class prevalence, outcome definition, and the intended prediction task, future reviews should report complementary discrimination metrics, calibration, uncertainty estimates, and external validation rather than assuming that any single metric is universally preferable. Claims of superior model performance should be supported by confidence intervals and statistical comparisons appropriate to the evaluation design, such as paired DeLong testing when applicable. Claims of superior model performance should also be supported by appropriate statistical testing, including methods such as the nonparametric DeLong test. Several conceptual clarifications are also warranted. AI models may prioritize hypotheses but do not replace experimental or clinical validation under current regulatory standards. Furthermore, AUROC should not be conflated with pharmacokinetic area under the curve, and SciBERT should not be characterized as a three-dimensional molecular graph framework. Future reviews should adopt transparent multi-database searches, structured bias assessment, and reproducible reporting practices. © The Author(s) 2026.

Comparative analysis of the predictive capabilities of some machine learning models: A case study using wind speed data

Item Type Journal Article

Author K. Makubyane

Author C. Sigauke

Abstract The widespread use of fossil fuels for global energy production significantly contributes to global warming. This study presents a comparative analysis of various machine learning models, which are the long short-term memory (LSTM) network, support vector regression (SVR), and gradient boosting method (GBM). Gaussian process regression (GPR) is a benchmark model across different forecasting horizons. The study uses South African wind speed data from 1 January 2018 to 31 December 2021, sourced from the Western Cape province. The dataset underwent preprocessing, and diverse feature selection techniques were implemented to enhance model accuracy. Performance evaluation of the models was done using mean absolute error (MAE), root mean squared error (RMSE), and mean absolute scaled error (MASE). Results indicate that SVR exhibits superior accuracy to other models for two distinct forecast horizons ($h = 670$ and $h = 1339$), respectively. Additionally, GPR surpasses other models for the forecasting horizon $h = 224$. This study provides insights into the comparative strengths and weaknesses of different machine learning models for wind speed prediction, which could be useful in selecting an appropriate model for future applications in renewable energy and weather forecasting. Potential areas for future research include improving prediction accuracy via ensemble deep learning algorithms and incorporating additional meteorological variables. Moreover, investigating temporal dynamics, broadening geographical coverage and integrating uncertainty quantification methods can improve wind speed prediction, thereby facilitating more effective renewable energy planning and decision-making processes

Comparative analysis of wastewater sample processing methods for antimicrobial resistance surveillance

Item Type Journal Article
Author H.F. Leal
Author A. Ouradou
Author N. Koukene
Author A. Barka
Author C. Quach
Author É. Bédard

Abstract Antimicrobial resistance monitoring in wastewater represents a key challenge, especially in light of the multiple methods available. Our study assessed the impact of selected sample processing techniques on microbial diversity and antimicrobial resistance gene recovery from wastewater. We analyzed 38 subsamples derived from 12 wastewater samples collected across three wastewater treatment plants over 4 months. We compared the effects of different centrifugation volumes (50, 250 mL), speeds (3,400 x g vs 15,000 x g), and pellet versus filter concentration methods, as well as the performance of two DNA extraction kits—DNeasy PowerSoil Pro Kit and DNeasy PowerLyzer Kit (Qiagen, DE)—on wastewater samples. Additionally, we compared the performance of two DNA quantification instruments, NanoDrop One and Invitrogen Qubit 4 (Thermo Scientific, US). The analysis involved 16S rRNA gene sequencing on an Illumina MiSeq platform (PE250, 10M reads) and quantitative PCR (qPCR) of 11 selected antimicrobial resistance genes (ARGs). Higher centrifugation speeds and larger sample volumes lead to improved DNA yield. Pellets generally exhibited higher (1.32 times) ARG recoveries compared to filters. DNA quantification methods showed strong positive correlation (Pearson R = 0.78, Spearman ρ = 0.81, P < 0.01) with each other and with qPCR data. The approach

implemented in this study (centrifuging 200 mL samples at 15,000 x g, followed by extraction with the DNeasy PowerSoil Pro Kit) shows promise for antimicrobial resistance (AMR) monitoring. IMPORTANCE To monitor the prevalence of antimicrobial resistance genes (ARGs) is crucial for anticipating and mitigating the spread of antimicrobial resistance (AMR). Urban wastewater provides community-level data to inform timely interventions. By establishing a method that balances efficiency and feasibility, this protocol represents a step toward a standardized wastewater surveillance (WS) framework for AMR, enhancing our ability to safeguard community health. Comparative Analysis Yolov5 and Yolov8 for Vehicle Classification

Item Type Conference Paper

Author M. Jain

Author R. Sharma

Editor Dwivedi R.K.

Editor Saxena A.Kr.

Editor Sharma R.

Editor Bhardwaj S.

Editor Gupta R.

Abstract The research describes a system it use adaptive background reduction and object tracking to count vehicles on the highways and roads. Background subtraction that adapts, picture vehicle counting, segmentation, and vehicle tracking are its four primary phases of operation. Video streams from stationary cameras placed on roads and highways are used. This system's precise vehicle tracking and counting is meant to improve traffic surveillance. Its capacity to efficiently count automobiles and produce extremely accurate findings are among its key qualities. The study analyses traffic recordings for vehicle detection, classification, and counting using sort algorithms based on artificial intelligence. Vehicles in three classes-cars, trucks, buses-were identified and categorised with an average accuracy of using YOLOv5 and YOLOv8, a deep learning technique. After detection, the number of passing vehicles was counted using the SORT algorithm, which yielded an average accuracy rate of 95%. Based on the experimental results, it is possible to successfully recognise, classify, and count vehicles in flowing traffic films by utilising the YOLOv5 and YOLOv8 to SORT algorithms. © 2024 IEEE.

Comparative assessment of statistical brain MR image segmentation algorithms and their impact on partial volume correction in PET

Item Type Journal Article

Author H. Zaidi

Author T. Ruest

Author F. Schoenahl

Author M.-L. Montandon

Abstract Magnetic resonance imaging (MRI)-guided partial volume effect correction (PVC) in brain positron emission tomography (PET) is now a well-established approach to compensate the large bias in the estimate of regional radioactivity concentration, especially for small structures. The accuracy of the algorithms developed so far is, however, largely dependent on the performance of segmentation methods partitioning MRI brain data into its main classes, namely gray matter (GM), white matter (WM), and cerebrospinal fluid (CSF). A comparative evaluation of three brain MRI segmentation algorithms using simulated and clinical brain MR data was performed, and subsequently their impact on PVC in 18F-FDG and 18F-DOPA brain PET imaging was assessed. Two algorithms, the first is bundled in the Statistical Parametric Mapping (SPM2) package while the other is the Expectation Maximization Segmentation (EMS) algorithm, incorporate a priori probability images derived from MR images of a large number of subjects. The third, here referred to as the HBSA algorithm, is a histogram-based segmentation algorithm incorporating an Expectation Maximization approach to model a four-Gaussian mixture for both global and local histograms. Simulated under different combinations of noise and intensity non-uniformity, MR brain phantoms with known true volumes for the different brain classes were generated. The algorithms' performance was checked by calculating the kappa index assessing similarities with the "ground truth" as well as multiclass type I and type II errors including misclassification rates. The impact of image segmentation algorithms on PVC was then quantified using clinical data. The segmented tissues of patients' brain MRI were given as input to the region of interest (RoI)-based geometric transfer matrix (GTM) PVC algorithm, and quantitative comparisons were made. The results of digital MRI phantom studies suggest that the use of HBSA produces the best performance for WM classification. For GM classification, it is suggested to use the EMS. Segmentation performed on clinical MRI data show quite substantial differences, especially when lesions are present. For the particular case of PVC, SPM2 and EMS algorithms show very similar results and may be used interchangeably. The use of HBSA is not recommended for PVC. The partial volume corrected activities in some regions of the brain show quite large relative differences when performing paired analysis on 2 algorithms, implying a careful choice of the segmentation algorithm for GTM-based PVC. © 2006 Elsevier Inc. Comparative Evaluation of 24 LDL-C Estimation Equations Against Direct Assays in Two Independent Cohorts

Item Type Journal Article
Author I. Györfi
Author O.R. Oprea
Author I.B. Mănescu
Author A. Curici
Author M. Dobreanu

Abstract Background: Low-density lipoprotein cholesterol (LDL-C) is essential in diagnosing and managing dyslipidemias. While direct assays are faster than the reference beta-quantification method, many labs continue using the Friedewald (FW) equation, despite its limitations. Methods: Two large datasets were analyzed: 10,174 hospital samples (Cobas/Roche) and 21,091 private lab samples (Alinity/Abbott). Various literature-based LDL-C equations were compared, focusing on FW, Sampson (SN), and Martin–Hopkins (MH). Direct LDL-C served as the reference. Evaluation metrics included bias and classification accuracy. Results: In samples with triglycerides < 400 mg/dL, several lesser-known equations showed acceptable bias ($\pm 5\%$), outperforming FW, SN, and MH, which had biases from -7.4% to -4.9% . Classification accuracy was higher with equations like Vujovic (up to 82.5%), compared to FW (65.8%), SN (73.1%), and MH (72.4%). The Vujovic equation showed minimal bias across triglyceride levels and the highest net gain in correct classification (3.4% and 1.57%). Conclusions: Multiple lesser-known LDL-C formulas outperformed widely used ones. The Vujovic equation yielded the best results, but the limited net clinical improvement suggests that replacing Friedewald may not be urgently necessary. © 2025 by the authors.

Comparative performance of Chenomx and MagMet in NMR-based metabolite profiling with validation by liquid chromatography coupled with tandem mass spectrometry

Item Type Journal Article

Author W.A. Ali

Author A.A. Thomas

Author L. Belkacem

Author H.E. Mustafa

Author H. Alsafar

Author S.E. Richards

Abstract In this work, two computational approaches for metabolite quantification in serum samples using ¹H NMR spectroscopy were evaluated: the spectral matching method (MSM) implemented in MagMet and the non-linear least squares method (MNLLS) implemented in Chenomx. The comparison focused on their underlying methodologies, including deconvolution algorithms and user workflows, to assess their relative performance and suitability for metabolomics data analysis. As various analyses (e.g. pattern recognition, classification, biomarker discovery, and pathway analysis) rely on the precision and consistency of input features (e.g., metabolite concentrations), selecting a robust quantification method is essential. Variability in quantification can introduce noise and impact the stability and comparability of analytical outputs. To validate performance, MSM (MagMet) and MNLLS (Chenomx) were benchmarked against quantitative NMR (qNMR) and liquid chromatography–tandem mass spectrometry (LC-MS/MS), the latter serving as the primary reference due to its high sensitivity and broad metabolite coverage (Gika et al., 2014) [1]. Although LC–MS/MS may be affected by matrix effects and ion suppression; these factors are well characterized and routinely mitigated through isotope-labeled internal standards and validated analytical workflows. Moreover, LC–MS offers substantially higher sensitivity than NMR, typically by two to three orders of magnitude, enabling the detection and quantification of hundreds to thousands of metabolites within a single analysis (Nagana Gowda and Raftery, 2022) [2]. qNMR was included as a complementary technique to provide orthogonal validation rather than serving as the sole benchmark. Ten independent serum control samples from a healthy reference group were analyzed to account for natural biological variability, enhancing the generalizability of the findings. The comparison was structured around four criteria: (i) quantitative performance, (ii) computational stability, (iii) usability and processing time, and (iv) method-based similarity via partial least squares–discriminant analysis (PLS-DA). This work differs from prior studies by integrating statistical validation, repeatability testing, and practical usability assessment, and by benchmarking computational quantification pipelines against experimentally grounded methods such as qNMR and LC-MS/MS [3–5]. The selected approach is expected to demonstrate improved consistency in quantification relative to the alternative, contributing to more reliable biological interpretations and more reproducible analytical outcomes across datasets. © 2026 Elsevier B.V.

Abstract To date, seven novel parvoviruses have been identified in pigs and designated as porcine parvovirus 2–7 (PPV2–7). The presence of these emerging viruses has been reported in several countries around the world, although their pathogenic role and clinical and economical relevance are largely unknown. Here, we report the estimated prevalence and genetic diversity of novel PPV2–7 in Hungarian pig herds and the detection of these viruses in two Slovakian pig farms. For the comparative prevalence estimation, 2505 serum samples from different age groups, 218 oral fluid samples, and 111 processing fluid samples were collected from 26 large-scale Hungarian farms according to a systematic, cross-sectional sampling protocol. All samples were tested by real-time quantitative polymerase chain reaction (qPCR), and the presence of at least one PPV was detected in 24 of the 26 (92%) Hungarian and both Slovakian farms, suggesting high levels of subclinical circulation in most herds. The estimated PPV2–7 prevalence in Hungary varied from 50% to 89%, with PPV4 being the least and PPV2 being the most prevalent virus. The highest detection rates were observed in oral fluid samples, indicating that this sample type is most suitable for screening PPVs, but all viruses were also detected in serum samples and processing fluids. All novel PPVs were most frequently detected in the serum samples of weaned pigs and fatteners, with slightly higher viral burden in the younger age groups. These results may suggest an age-related susceptibility, which could play a significant role in the epidemiology of these viruses, impacting herd health and productivity. Comparing Machine Learning and Binary Thresholding Methods for Quantification of Callose Deposits in the Citrus Phloem

Item Type Journal Article**Author** S. Welker**Author** A. Levy

Abstract Callose is a polysaccharide that can be fluorescently stained to study many developmental and immune functions in plants. High-throughput methods to accurately gather quantitative measurements of callose from confocal images are useful for many applications in plant biology. Previous callose quantification methods relied upon binary local thresholding, which had the disadvantage of not being able to differentiate callose in conditions with low contrast from background material. Here, a measurement approach that utilizes the Ilastik supervised machine learning imagery data collection software is described. The Ilastik software method provided superior efficiency for acquiring counts of callose deposits. We also determined the accuracy of these methods as compared to manual counts. We demonstrate that the automated software methods are both good predictors of manual counts, but that the Ilastik counts are significantly closer. Researchers can use this information to guide their choice of method to quantify callose in their work. © 2022 by the authors. Licensee MDPI, Basel, Switzerland.

Comparing the quality of neural network uncertainty estimates for classification problems

Item Type Conference Paper**Author** D. Ries**Author** J. Michalenko**Author** T. Ganter**Author** R.I.-F. Baiyasi**Author** J. Adams**Editor** Wani M.A.**Editor** Kantardzic M.**Editor** Palade V.**Editor** Neagu D.**Editor** Yang L.**Editor** Chan K.-Y.

Abstract Traditional deep learning (DL) models are powerful classifiers, but many approaches do not provide uncertainties for their estimates. Uncertainty quantification (UQ) methods for DL models have received increased attention in the literature due to their usefulness in decision making, particularly for high-consequence decisions. However, there has been little research done on how to evaluate the quality of such methods. We use statistical methods of frequentist interval coverage and interval width to evaluate the quality of credible intervals, and expected calibration error to evaluate classification predicted confidence. These metrics are evaluated on Bayesian neural networks (BNN) fit using Markov Chain Monte Carlo (MCMC) and variational inference (VI), bootstrapped neural networks (NN), Deep Ensembles (DE), and Monte Carlo (MC) dropout. We apply these different UQ for DL methods to a hyperspectral image target detection problem and show the inconsistency of the different methods' results and the necessity of a UQ quality metric. To reconcile these differences and choose a UQ method that appropriately quantifies the uncertainty, we create a simulated data set with fully parameterized probability distribution for a two-class classification problem. The gold standard MCMC performs the best overall, and the bootstrapped NN is a close second, requiring the same computational expense as DE. Through this comparison, we demonstrate that, for a given data set, different models can produce uncertainty estimates of markedly different quality. This in turn points to a great need for principled assessment methods of UQ quality in DL applications. © 2022 IEEE.

Abstract Objective. To compare the International Obesity Task Force (IOTF) 2005, Centers for Disease Control and Prevention (CDC) 2000, and World Health Organization (WHO) 2007 body mass index (BMI) classification systems in terms of prevalence estimation and association with demographic factors. Methods. The 18 265 children and adolescents ages 5 to 18 years (mean = 11.2 years, standard deviation = 3.9 years) in the nationally representative Colombian National Nutrition Survey of 2005 were classified as overweight or obese according to IOTF, CDC, and WHO criteria. Prevalence estimates were compared according to each system and associations with age, sex, socioeconomic status, and population density were tested. Results. Prevalence estimates of combined overweight and obesity differed by system (males: IOTF = 8.5%, CDC = 10.8%, WHO = 14.1%; females: IOTF = 14.6%, CDC = 13.8%, WHO = 17.1%; $P < 0.001$). The association between combined overweight and obesity and age and sex varied by system. The odds of having overweight and obesity in children (5 to 10 years) compared with adolescents (11 to 18 years) were: IOTF, odds ratio (OR) = 0.87 and 95% confidence interval (CI) = 0.77-0.98; CDC, OR = 1.27 and CI = 1.14-1.42; WHO, OR = 1.21 and CI = 1.08-1.35. The values for females compared with males were: IOTF, OR = 1.84 and CI = 1.6-2.10; CDC, OR = 1.33 and CI = 1.17-1.51; WHO, OR = 1.25 and CI = 1.12-1.41. Conclusions. There is a lack of consistency among the three main international systems in assessing overweight and obesity in children and adolescents. Appreciably different estimates of prevalence and associations with age and sex are obtained depending on which system is used. Future studies should assess how well each system reflects valid measures of body composition.

Abstract In Brazilian laboratories, the determination of micronutrient contents for soil fertility analyses is based on extraction with Mehlich-1 solution (M-1), at a 1:5 w/v soil:extractant ratio, with subsequent quantification by atomic absorption spectrometry (AAS). However, many laboratories also use a 1:10 w/v soil:extractant M-1 ratio for the determination of macronutrients, and/or quantification by optical emission spectrometry with inductively coupled plasma (ICP OES), instead of AAS. As comparative studies between the micronutrient concentrations obtained by these alternative methods are scarce, the aim of this work was to investigate significant differences in results from these different extraction and quantification methods. In this work, statistical analysis showed that the Fe and Mn concentrations using both soil:extractant M-1 ratios (1:5 and 1:10) and Zn concentrations at 1:10 w/v soil:extractant M-1 ratio were similar regardless the quantification equipment. However, the Cu concentrations using both soil:extractant M-1 ratios and the Zn concentrations at 1:5 w/v soil:extractant M-1 ratio differed according to the equipment used to quantify these nutrients. Also, all Cu, Fe, Mn and Zn concentrations determined at 1:5 w/v differed from those at 1:10 w/v soil:extractant M-1 ratio, regardless of the quantification technique. Most of these concentrations were higher at a ratio of 1:5 w/v and affected the classification of the contents. It is therefore not recommended to use a soil:extractant ratio of 1:5 for the extraction of the micronutrients Cu, Fe, Mn and Zn from soil samples.

Comparison of current state of control valve stiction detection and quantification techniques

Item Type Journal Article**Author** V. Akavalappil**Author** T.K. Radhakrishnan

Abstract The process control and automation system is one of the significant features in any process plant. The control valve is considered a fundamental part of the process control system. It regulates the fluid flow by changing the size of the flow passage as directed by the controller. If properly maintained, the control valves can help to reduce process variability and improve product quality, which in turn increases the overall efficiency of the plant. But control valve stiction is an enduring concern within process industries which eventually affects the efficiency of plant operation. Hence, it is extremely essential to detect and quantify stiction at the earliest opportunity, to determine the correct maintenance measures. Numerous methods related to stiction detection and estimation have been carried out so far by researchers. A literature study of the latest publications in stiction detection and quantification discloses that research in the conventional methods of stiction detection and quantification such as limit cycle pattern-based, waveform shape-based, nonlinearity-based, and model-based methods is gradually declining. At the same time, most stiction detection/quantification methods reported in the recent literature are based on artificial neural network and convolutional neural network. This implies that future stiction detection and quantification research will be focused towards machine learning (ML) algorithms. Taking this into consideration, this paper aims to provide a literature review of stiction detection and quantification methods by focusing on the latest research ideas and innovative approaches. This review also aims to compare recent techniques based on ML algorithms with conventional methods by pointing out the relationship among different methods, differences, and possible points of weakness. © The Author(s) 2021.

Comparison of different approaches for estimation of prevalence of type 2 diabetes mellitus in the Czech Republic

Item Type Journal Article

Author P.H.M. S

Author M. Škodová

Author P. Kučová

Author J. Votápková

Abstract Prevalence of type 2 diabetes in the Czech Republic can be estimated from data reported by health care providers either to the statistical office or to health insurers. The latter include both diagnosis and prescribed drugs. Patient classification to a certain chronic condition based on consumption of drugs (Pharmacy-based Cost Groups classification) has been used in the Czech Republic for the purpose of redistribution of collected funds among health insurers since the beginning of 2018. This article compares prevalence of diabetes estimated from statistical data and from data reported to health insurers, and discusses current and future advantages and disadvantages of all methodologies. Diagnoses reporting in outpatient care are considered to be inaccurate, on the other hand peroral antidiabetics do not seem to be prescribed to all indicated patients. The appropriate approach to prevalence

estimation from data reported to health insurers is becoming even more important after the creation of National Diabetes Register based on insurance data and the related abatement of direct reporting to the statistical office.

Comparison of different criteria for rheumatic heart disease screening: an empirical study in Sierra Leone

Item Type Journal Article

Author B. Fernández-de-Toro

Author L. Cobarro

Author J. Pérez-Martín

Author F.J. Díez

Abstract Background: Rheumatic heart disease (RHD) affects approximately 40 million people, primarily in low- and middle-income countries. Transthoracic echocardiography is the gold standard for early detection of RHD. Yet, no single echocardiographic finding or combination of findings unequivocally confirms RHD, especially in subclinical stages. As a result, multiple diagnostic guidelines have been proposed. Objectives: To characterise the echocardiographic RHD findings and criteria included in five of those guidelines; to assess how these diagnostic criteria differ when applied to a concrete population, namely a cohort of high-school students

in Sierra Leone; and, as a secondary objective, to provide an initial estimate of the burden of RHD in this country. **Methods:** Our study has two parts. First, we performed a qualitative comparison of five major echocardiographic guidelines, mapping every diagnostic criterion into four roles (required, sufficient, combined, or not considered) for each guideline. Second, we conducted a school-based screening in Sierra Leone. A cohort of 604 asymptomatic female students (aged 10–22 years) underwent a two-phase echocardiographic protocol. We quantified regurgitant jet characteristics and morphological signs according to the criteria of the compared guidelines. **Results:** Guideline discrepancies were substantial, particularly in jet length thresholds and the diagnostic role of morphological features. These differences shifted individual classifications across categories. In our cohort, 13 students (2.2%) had findings beyond normal under at least one guideline, and positive cases ranged from 0.99% to 2.15% depending on the guideline. Using the World Heart Federation (WHF) 2023 criteria, 1.16% (95% CI: 0.47–2.37) were classified as positive. **Conclusions:** Variability in echocardiographic criteria influences RHD classification and prevalence estimation. Our empirical study shows that the use of rigid echocardiographic cut-offs may lead to discarding some cases suspicious of RHD, especially in the WHF 2023 screening guideline, because one unfulfilled criterion automatically leads to a negative diagnosis, regardless of the number and relevance of positive findings. We argue that a probabilistic causal model that ponders the numerical measurements and considers correlations among findings would be more appropriate for screening and diagnosis. © The Author(s) 2026.

Comparison of inverse uncertainty quantification methods for critical flow test

Item Type Journal Article

Author P. Domitr

Author M. Włostowski

Author R. Laskowski

Author R. Jurkowski

Abstract A problem of epistemic uncertainties introduced by code input parameters that cannot be estimated other than by user expertise has existed in nuclear reactor systems analyses since first uncertainty analyses were conducted. Inverse Uncertainty Quantification (IUQ) methods aim at providing an estimation of the distributions of such parameters. This paper compares and assesses two approaches to quantify the uncertainty of critical flow model parameters available in the TRACE code. First novel approach is based on a machine-learning algorithm, using a Random Forest classifier to assign the results of calculations to one of the defined classes of prediction accuracy with respect to experimental data. The second approach is based on Markov Chain Monte Carlo sampling and Bayesian inference. Both methods allows to assign probability distribution functions to TRACE internal variables, which is a goal for IUQ methods. Both approaches were used to estimate uncertainties for four critical flow parameters available in the TRACE code based on the Marviken critical flow experiment. In case of two parameters both methods produced similar results of the probability density functions. Based on the results of machine learning two additional parameters were deemed noninfluential, while for the second method such definitive assessment could not be made. © 2022 Elsevier Ltd

Comparison of machine learning and semi-quantification algorithms for (I123)FP-CIT classification: the beginning of the end for semi-quantification?

Item Type Journal Article

Author J.C. Taylor

Author J.W. Fenner

Abstract Background: Semi-quantification methods are well established in the clinic for assisted reporting of (I123) Ioflupane images. Arguably, these are limited diagnostic tools. Recent research has demonstrated the potential for improved classification performance offered by machine learning algorithms. A direct comparison between methods is required to establish whether a move towards widespread clinical adoption of machine learning algorithms is justified. This study compared three machine learning algorithms with that of a range of semi-quantification methods, using the Parkinson's Progression Markers Initiative (PPMI) research database and a locally derived clinical database for validation. Machine learning algorithms were based on support vector machine classifiers with three different sets of features: Voxel intensities Principal components of image voxel intensities Striatal binding ratios from the putamen and caudate. Semi-quantification methods were based on striatal binding ratios (SBRs) from both putamina, with and without consideration of the caudates. Normal limits for the SBRs were defined through four different methods: Minimum of age-matched controls Mean minus 1/1.5/2 standard deviations from age-matched controls Linear regression of normal patient data against age (minus 1/1.5/2 standard errors) Selection of the optimum operating point on the receiver operator characteristic curve from normal and abnormal training data Each machine learning and semi-quantification technique was evaluated with stratified, nested 10-fold cross-validation, repeated 10 times. Results: The mean accuracy of the semi-quantitative methods for classification of local data into Parkinsonian and non-Parkinsonian groups varied from 0.78 to 0.87, contrasting with 0.89 to 0.95 for classifying PPMI data into healthy controls and Parkinson's disease groups. The machine learning algorithms gave mean accuracies between 0.88 to 0.92 and 0.95 to 0.97 for local and PPMI data respectively. Conclusions: Classification performance was lower for the local database than the research database for both semi-quantitative and machine

learning algorithms. However, for both databases, the machine learning methods generated equal or higher mean accuracies (with lower variance) than any of the semi-quantification approaches. The gain in performance from using machine learning algorithms as compared to semi-quantification was relatively small and may be insufficient, when considered in isolation, to offer significant advantages in the clinical context. © 2017, The Author(s).

Comparison of Pakistani CKD-EPI, new Asian-modified CKD-EPI and revised Lund–Malmö study equations in a South Asian CKD population: a study from a Pakistani CKD cohort

Item Type Journal Article

Author A. Safdar

Author W. Akram

Author M.A. Khan

Author M.N. Alvi

Abstract Background: Newly proposed estimating glomerular filtration rate equations need to be studied, evaluated and compared for chronic kidney disease staging, diagnosis and medication dosing in South Asians. The objectives of the study were (1) to assess the performance of the CKD-EPIPK, CKD-EPIAsian-Modified, and LMRevised equations in the Pakistani chronic kidney disease population, and (2) to investigate prospective implications on chronic kidney disease classification and end-stage kidney disease prevalence. Methods: We conducted a cross-sectional analysis on a chronic kidney disease cohort of 385 participants 18 years of age or above. Results: CKD-EPIPK showed the lowest bias (-1.33 ml/min/ 1.73 m 2), highest precision [IQR, 2.33 (-2.36 , -0.03)] and enhanced P30 accuracy (89.35%) compared to the CKD-EPIAsian-Modified and LMRevised equations. The mean difference (ml/min/ 1.73 m 2), 95% limit of agreement (ml/min/ 1.73 m 2) of the equations were; CKD-EPIAsian-Modified: -5.98 , -13.03 , LMRevised: -4.06 , -8.13 and CKD-EPIPK: -1.18 , -6.14 ($P < 0.001$). CKD-EPIAsian-Modified and LMRevised showed upward re-classification of the GFR categories compared to the CKD-EPIPK equation except in the G5 category where the highest count (217, 56.36%) was noted for the CKD-EPIPK equation. End-stage kidney disease prevailed in all age groups according to all equations, and the prevalence was high in females in all equations. Conclusion: CKD-EPIPK showed the best performance, whereas both CKD-EPIAsian-Modified and LMRevised showed poor performance and did not offer a sufficient advantage in chronic kidney disease classification and end-stage kidney disease prevalence estimation over CKD-EPIPK. Hence, CKD-EPIPK seems ideal for South Asians, thus appropriate measures should be taken for its implementation, at least in Pakistani laboratories. Comparison of rapid eye movement without atonia quantification methods to diagnose rapid eye movement sleep behavior disorder: a systematic review

Item Type Journal Article

Author J.-I. Byun

Author T.-W. Yang

Author J.-S. Sunwoo

Author W.C. Shin

Author O.-Y. Kwon

Author K.-Y. Jung

Abstract Study Objectives: Rapid eye movement (REM) sleep without atonia (RWA) is essential for diagnosing REM sleep behavior disorder (RBD). Manual and automatic quantifications of RWA that use different criteria have been validated. This study compared the RWA quantification methods for diagnosing RBD. Methods: The PubMed, EMBASE, Web of Science, and Cochrane Library databases were systemically searched for studies published from inception to December 2021. The inclusion criteria were cohort, cross-sectional, and case-control studies assessing the sensitivity and specificity of RWA quantification methods. Pooled estimates of the sensitivity, specificity, diagnostic odds ratio (DOR), and area under the curve (AUC) were determined. Risk of bias and certainty of evidence was assessed using the Quality Assessment of Diagnostic Accuracy Studies tool and the Grading of Recommendations, Assessment, Development, and Evaluations framework, respectively. Results: Fourteen articles including 402 patients with RBD met the inclusion criteria. Manual methods evaluating any chin and phasic flexor digitorum superficialis (FDS) activity had the highest DOR (138.8, 95% CI = 21.8% to 881.7%) and AUC (0.9686). The automatic REM atonia index (RAI) showed similar or higher sensitivity (89.1%, 95% CI = 84.6% to 92.7%) but a lower specificity (73.5%), DOR (43.1), and AUC (0.9369) than the manual techniques. Conclusions: In this meta-

analysis, manual RWA quantification that employed chin or phasic FDS activity had the best RBD diagnostic performance. The automatic RAI method may be useful for screening patients with RBD. The results should be interpreted carefully because of the high risk of bias in patient selection and significant heterogeneity among the studies. Comparison of the performance of partial least squares and support vector regressions for predicting fatty acids and fatty acid classes in marine oil dietary supplements by using vibrational spectroscopic data

Item Type Journal Article

Author S.R. Karunathilaka

Author B.J. Yakes

Author S.H. Choi

Author L. Brückner

Author M.M. Mossoba

Abstract Simple, fast, and accurate analytical techniques for verifying the accuracy of label declarations for marine oil dietary supplements containing eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are required because of the increased consumption of these products. We recently developed broad-based partial least squares regression (PLS-R) models to quantify six fatty acids (FAs) and FA classes by using the spectroscopic data from a portable Fourier transform infrared (FTIR) device and a benchtop Fourier transform near infrared (FT-NIR) spectrometer. We developed an improved quantification method for these FAs and FA classes by incorporating a nonlinear calibration approach based on the machine learning technique support vector machines. For the two spectroscopic methods, high accuracy in prediction was indicated by low root mean square error of prediction and by correlation coefficients (R^2) close to 1, indicating excellent model performance. The percent accuracy of the support vector regression (SV-R) model predicted values for EPA and DHA in the reference material was 90 to 110%. In comparison to PLS-R, SV-R accuracy for prediction of FA and FA class concentrations was up to 2.4 times higher for both ATRFTIR and FT-NIR spectroscopic data. The SV-R models also provided closer agreement with the certified and reference values for the prediction of EPA and DHA in the reference standard. Based on our findings, the SV-R methods had superior accuracy and predictive quality for predicting the FA concentrations in marine oil dietary supplements. The combination of SV-R with ATR-FTIR and/or FT-NIR spectroscopic data can potentially be applied for the rapid screening of marine oil products to verify the accuracy of label declarations. © 2020 International Association for Food Protection. Comparison of Total Kidney Volume Quantification Methods in Autosomal Dominant Polycystic Disease for a Comprehensive Disease Assessment

Item Type Journal Article

Author D. Turco

Author M. Busutti

Author R. Mignani

Author R. Magistroni

Author C. Corsi

Abstract Background: In recent times, the scientific community has been showing increasing interest in the treatments aimed at slowing the progression of the autosomal dominant polycystic kidney disease (ADPKD). Therefore, in this paper, we test and evaluate the performance of several available methods for total kidney volume (TKV) computation in ADPKD patients - from echography to MRI - in order to optimize patient classification. Methods: Two methods based on geometric assumptions (mid-slice [MS], ellipsoid [EL]) and a third one on true contour detection were tested on 40 ADPKD patients at different disease stage using MRI. The EL method was also tested using ultrasound images in a subset of 14 patients. Their performance was compared against TKVs derived from reference manual segmentation of MR images. Patient clinical classification was also performed based on computed volumes. Results: Kidney volumes derived from echography significantly underestimated reference volumes. Geometric-based methods applied to MR images had similar acceptable results. The highly automated method showed better performance. Volume assessment was accurate and reproducible. Importantly, classification resulted in 79, 13, 10, and 2.5% of misclassification using kidney volumes obtained from echo and MRI applying the EL, the MS and the highly automated method respectively. Conclusion: Considering the fact that the image-based technique is the only approach providing a 3D patient-specific kidney model and allowing further analysis including

cyst volume computation and monitoring disease progression, we suggest that geometric assumption (e.g., EL method) should be avoided. The contour-detection approach should be used for a reproducible and precise morphologic classification of the renal volume of ADPKD patients. © 2017 S. Karger AG, Basel. Comparison of two-class and three-class Bayesian artificial neural networks in estimation of observations drawn from simulated bivariate normal distributions

Item Type Conference Paper

Author N. Bhooshan

Author D. Edwards

Author M. Giger

Abstract The development and application of multi-class BANN classifiers in computer-aided diagnosis methods motivated this study in which we compared estimates produced by two-class and three-class BANN classifiers to true observations drawn from simulated distributions. Observations were drawn from three Gaussian bivariate distributions with distinct means and variances to generate G1, G2, and G3 simulated datasets. A two-class BANN was trained on each training dataset for a total of ten different trained BANNs. The same testing dataset was run on each trained BANN. The average and standard deviation of the resulting ten sets of BANN outputs were then calculated. This process was repeated with three-class BANNs. Different sample numbers and values of a priori probabilities were investigated. The relationship between the average BANN output and true distribution was measured using Pearson and Spearman coefficients, R-squared and mean square error for two-class and three-class BANNs. There was significantly high correlation between the average BANN output and true distribution for two-class and three-class BANNs; however, subtle non-linearities and spread were found in comparing the true and estimated distributions. The standard deviations of two-class and three-class BANNs were comparable, demonstrating that three-class BANNs can perform as reliably as two-class BANN classifiers in estimating true distributions and that the observed non-linearities and spread were not simply due to statistical uncertainty but were valid characteristics of the BANN classifiers. In summary, three-class BANN decision variables were similar in performance to those of two-class BANNs in estimating true observations drawn from simulated bivariate normal distributions. © 2011 SPIE.

Comparison of WHO, CDC and IOTF growth references in relation to overweight and obesity in school going adolescents of Delhi, India

Item Type Journal Article**Author** B. Deepika**Author** S. Kalyani**Author** S. Manisha

Abstract Background and Objective: Obesity has become a serious public health problem. Accurate measurement of this health issue is crucial in defining its burden. Thus the objective of the study was to compare the body mass index (BMI) classification systems for World Health Organization (WHO), Centers for Disease Control and Prevention (CDC) and International Obesity Task Force (IOTF) prevalence estimation of overweight and obesity and in terms of level of agreement between the classification systems. Method: In a cross sectional survey, 877 school going adolescents of age 12 to 15 years (mean = 13.04 years) were included in the study. Height and weight of subjects were measured to calculate the BMI. Subjects were classified as overweight and obese according to IOTF, CDC, and WHO criteria and Kappa statistics was used to calculate the level of agreement between the three classification systems. Results: Prevalence estimates of combined overweight and obesity differed by system (males WHO = 33.16%, CDC=29.78%, IOTF=28.55%; females WHO = 33.54%, CDC=29.71%, IOTF = 29.39%). A substantial agreement was observed between CDC vs IOTF and WHO vs CDC (Kappa=0.82) and a moderate agreement between WHO vs IOTF (kappa=0.70). Conclusion: IOTF is a frequently used system for BMI classification of children and adolescents in India but it reports the lowest combined prevalence in comparison to CDC and WHO. Although the agreement between CDC vs IOTF and WHO vs CDC is substantial but the system which is most suitable to a country like India is WHO, 2007 since the sample includes children from India among other countries. © 2016, Indian Journal of Public Health Research and Development. Complete group-type quantification of petroleum middle distillates based on comprehensive two-dimensional gas chromatography time-of-flight mass spectrometry (GCxGC-TOFMS) and visual basic scripting

Item Type Journal Article

Author M.K. Jennerwein

Author M. Eschner

Author T. Gröger

Author T. Wilharm

Author R. Zimmermann

Abstract The subject of the presented work was the development of a two-dimensional GCxGC - time-of-flight mass spectrometric method (GCxGC-TOFMS) for the complete group-type quantification of petroleum middle distillates. The development of this method was possible due to the inherent features of GCxGC-TOFMS, namely the structured arrangement of compound groups and the mass fragmentation pattern, which provide the possibility of using Visual Basic Scripts as an analytical tool and thereby the classification of several thousand different compounds. The analysis method was focused on common petroleum based fuels from light to heavier middle distillation fractions. For the implementation of an absolute quantification method, a set of standard substances representing the main substance classes and carbon numbers within middle distillates and well-separated and recognizable internal standards were thoroughly chosen in order to obtain individual response factors and group specific response curves. The results of the qualitative and quantitative analysis were compared to well-established standard methods used in the petrochemical industry. The quantification of aromatic hydrocarbons was compared to EN 12916, a high performance liquid chromatography (HPLC) method that provides a rough separation between mono-, di-, and higher aromatics. Further, the quantification of

the fatty acid methyl ester (FAME) content in diesel fuel was compared to EN 14078 and the distribution of single FAMES was compared to EN 14103. It could be stated that an absolute quantification as the here presented method has not been reported before and the results were in good agreement with the reference methods. Furthermore, the here presented GCxGC-TOFMS quantification method is able to itemize according substance classes and carbon number. The detection limit of the method allows accurate and sensitive quantification for different limiting values of middle distillates with a single method. © 2014 American Chemical Society.

Complexity Evaluation of Test Scenarios for Autonomous Vehicle Safety Validation Using Information Theory

Item Type Journal Article

Author M. Issler

Author Q. Goss

Author M.İ. Akbaş

Abstract The validation of autonomous vehicles remains a vexing challenge for the automotive industry's goal of fully autonomous driving. The systematic hierarchization of the test scenarios would provide valuable insights for the development, testing, and verification of autonomous vehicles, enabling nuanced performance evaluations based on scenario complexity. In this paper, an information entropy-based quantification method is proposed to evaluate the complexity of autonomous vehicle validation scenarios. The proposed method addresses the dynamic uncertainties within driving scenarios in a comprehensive way which includes the unpredictability of dynamic agents such as autonomous vehicles, human-driven vehicles, and pedestrians. The numerical complexity calculation of the approach and the ranking of the scenarios are presented through sample scenarios. To automate processes and assist with the calculations, a novel software tool with a user-friendly interface is developed. The performance of the approach is also evaluated through six example driving scenarios, then through extensive simulation using an open-source microscopic traffic simulator. The performance evaluation results confirm the numerical classification and demonstrate the method's adaptability to diverse scenarios with a comparison of complexity calculation ranking to the ratio of collision, near collision, and normal operation tests observed during simulation testing. The proposed quantification method contributes to the improvement of autonomous vehicle validation procedures by addressing the multifaceted nature of scenario complexities. Beyond advancing the field of validation, the approach also aligns with the broad and active drive of the industry for the widespread deployment of fully autonomous driving. © 2024 by the authors.

Abstract The coast of the Red Sea in Jeddah City is home to a unique microbial community that has adapted to extreme environmental conditions. Therefore, it is essential to characterize the microbial community in this unique microbiome to predict how environmental changes will affect it. The aim of this study was to conduct metagenomic sequencing of 16S rRNA and ITS rRNA genes for the taxonomic classification of the microbial community in soil samples associated with the halophytic plants *Tamarix aphylla* and *Halopeplis perfoliata*. Fifteen soil samples were collected in triplicate to enhance robustness and minimize sampling bias. Firstly, to identify novel microbial candidates, the gDNAs were isolated from the saline soil samples surrounding each plant, and then bacterial 16S (V3–V4) and fungal ITS1 regions were sequenced utilizing a high-throughput approach (next-generation sequencing; NGS) on an Illumina MiSeq platform. Quality assessment of the constructed amplicon libraries was conducted using Agilent Bioanalyzer and fluorometric quantification methods. The raw data were processed and analyzed using the Pipeline (Nova Lifetech, Singapore) for bioinformatics analysis. Based on the total number of readings, it was determined that the phylum Actinobacteriota was the most prevalent in the soil samples examined, followed by the phylum Proteobacteria. Based on ITS rRNA gene analysis, the alpha and beta fungal diversity in the studied soil samples revealed that the fungal population is structured into various groups according to the crust (c) and/or rhizosphere (r) plant parts. Fungal communities in the soil samples indicated that Ascomycota and Basidiomycota were the two most abundant phyla based on the total amount of sequence reads. Secondly, heat-map analysis of the diversity indices showed that the bacterial alpha diversity, as measured by Shannon, Simpson, and InvSimpson, was associated with soil crust (Hc and Tc

enclosing *H. perfoliata* and *T. aphylla*, respectively) and that the soil rhizosphere (Hr and Tr) was strongly correlated with bacterial beta diversity. Finally, fungal-associated Tc and Hc samples clustered together, according to observations made using the Fisher and Chao1 methods, and Hr and Tr samples clustered together according to Shannon, Simpson, and InvSimpson analyses. As a result of the soil investigation, potential agents that have been identified could lead to innovative agricultural, medical, and industrial applications. © 2023 by the authors.

Comprehensive marine substrate classification applied to Canada's Pacific shelf

Item Type Journal Article

Author E.J. Gegr

Author D.R. Haggarty

Author S.C. Davies

Author C. Fields

Author J. Lessard

Abstract Maps of bottom type are essential to the management of marine resources and biodiversity because of their foundational role in characterizing species' habitats. They are also urgently needed as countries work to define marine protected areas.

Current approaches are time consuming, focus largely on grain size, and tend to overlook shallow waters. Our random forest classification of almost 200,000 observations of bottom type is a timely alternative, providing maps of coastal substrate at a combination of resolution and extents not previously achieved. We correlated the observations with depth, depth-derivatives, and estimates of energy to predict marine substrate at 100 m resolution for Canada's Pacific shelf, a study area of over 135,000 km². We built five regional models with the same data at 20 m resolution. In addition to standard tests of model fit, we used three independent data sets to test model predictions. We also tested for regional, depth, and resolution effects. We guided our analysis by asking: 1) does weighting for prevalence improve model predictions? 2) does model resolution influence model performance? And 3) is model performance influenced by depth? All our models fit the build data well with true skill statistic (TSS) scores ranging from 0.56 to 0.64. Weighting models with class prevalence improved fit and the correspondence with known spatial features. Class-based metrics showed differences across both resolutions and spatial regions, indicating non-stationarity across these spatial categories. Predictive power was lower (TSS from 0.10 to 0.36) based on independent data evaluation. Model performance was also a function of depth and resolution, illustrating the challenge of accurately representing heterogeneity. Our work shows the value of regional analyses to assessing model stationarity and how independent data evaluation and the use of error metrics can improve understanding of model performance and sampling bias. Computationally efficient class-prior estimation under class balance change using energy distance

Item Type Journal Article

Author H. Kawakubo

Author M.C. Du Plessis

Author M. Sugiyama

Abstract In many real-world classification problems, the class balance often changes between training and test datasets, due to sample selection bias or the non-stationarity of the environment. Naive classifier training under such changes of class balance systematically yields a biased solution. It is known that such a systematic bias can be corrected by weighted training according to the test class balance. However, the test class balance is often unknown in practice. In this paper, we consider a semi-supervised learning setup where labeled training samples and unlabeled test samples are available and propose a class balance estimator based on the energy distance. Through experiments, we demonstrate that the proposed method is computationally much more efficient than existing approaches, with comparable accuracy. Computer aided characterization of the solitary pulmonary nodule using volumetric and contrast enhancement features

Item Type Journal Article**Author** S.K. Shah**Author** M.F. McNitt-Gray**Author** S.R. Rogers**Author** J.G. Goldin**Author** R.D. Suh**Author** J.W. Sayre**Author** I. Petkovska**Author** H.J. Kim**Author** D.R. Aberle

Abstract Rationale and Objectives. To investigate the utility of a computer-aided diagnosis (CAD) in the task of differentiating malignant nodules from benign nodules based on quantitative features extracted from volumetric thin section CT image data acquired before and after the injection of contrast media. Materials and Methods. 35 volumetric CT datasets of solitary pulmonary nodules (SPN) with proven diagnoses (19 malignant/16 benign) were contoured by a thoracic radiologist. All studies had at least a baseline series obtained without contrast media and at least one series following an intravenous contrast injection at 45, 90, 180, and 360 seconds. Two separate contours were created for each nodule: one including only the solid portion and another including the ground-glass component, if any, of the nodule. For each contour 31 features were calculated that measured the attenuation, shape, and enhancement of the nodule due to the injection of contrast. These features were input into a feature selection step and three different classifiers to determine if the diagnosis could be predicted from the resulting feature vector. In addition, observer input was introduced to two of the classifiers as an a priori probability of malignancy and the resulting performance was compared. Training and testing was conducted in a resubstitution and leave-one-out fashion and performance was evaluated using ROC analysis. Results. In a leave-one-out testing methodology, the classifiers achieved areas under the ROC curves (AZ) that ranged from 0.69 to 0.92. A classifier based on logistic regression performed the best with an AZ of 0.92 while a classifier based on quadratic discriminant analysis performed the poorest (AZ, 0.69). The AZ increased when using a priori observer input in most cases reaching a maximum of 0.95. Conclusion. Based on this initial work with a limited number of nodules in our dataset, it appears that CAD using volumetric and contrast-enhanced data has the potential to assist radiologists in the task of differentiating solitary pulmonary nodules and in the management of these patients. Further studies with an increased number of patients are required to validate these results. © AUR, 2005.

Computer Aided Diagnosis Based Hand Thermal Image Analysis: A Potential Tool for the Evaluation of Rheumatoid Arthritis

Item Type Journal Article

Author S. Umapathy

Author S. Vasu

Author N. Gupta

Abstract The aim of the study was to evaluate the potential of the thermogram in diagnosing rheumatoid arthritis and to compare the implementation of k-means algorithm and fuzzy c means algorithm using a computer aided diagnostic tool for classification of rheumatoid arthritis (RA) and normal based on the feature extracted from the

segmented thermal image. The skin surface temperature measurement, thermal image segmentation based on k-means and fuzzy c-means algorithm and the feature extraction were used in this study. The average skin surface temperature measured at the second meta carpo-phalangeal (MCP) and MCP3 in RA patients ($35.40 \pm 0.6^\circ\text{C}$ and $35.52 \pm 0.7^\circ\text{C}$, respectively) were significantly higher ($p < 0.01$) than those measured in normal subjects ($33.66 \pm 0.2^\circ\text{C}$ and $33.74 \pm 0.2^\circ\text{C}$, respectively). The mean difference in temperature between RA patients and healthy controls in the MCP2 and MCP3 region was found to be 1.74 and 1.78°C respectively. The receiver operating characteristics (ROC) curve depicted a sensitivity of 86.6% and specificity of 79% achieved in the MCP region of the hand thermal image. Thermal image segmentation using the k-means algorithm provided better segmentation results compared to the fuzzy c-means algorithm in diagnosing the disease. Therefore, the computer aided diagnostic based thermography method could be used as a validated quantification method for interpreting and evaluating arthritis. © 2017, Taiwanese Society of Biomedical Engineering.

Computer aided quantification for retinal lesions in patients with moderate and severe non-proliferative diabetic retinopathy: A retrospective cohort study

Item Type Journal Article

Author H. Wu

Author X. Zhang

Author X. Geng

Author J. Dong

Author G. Zhou

Abstract Background: Detection of retinal lesions like micro-aneurysms and exudates are important for the clinical diagnosis of diabetes retinopathy. The traditional subjective judgments by clinicians are dependent on their experience and can be subject to lack of consistency and therefore a quantification method is worthwhile. Methods: In this study, 10 moderate non-proliferative diabetes retinopathy (NPDR) patients and 10 severe NPDR ones were retrospectively selected as a cohort. Mathematical morphological methods were used for automatic segmentation of lesions. For exudates detection, images were pre-processed with adaptive histogram equalization to enhance contrast, then binary images for area calculation were obtained by threshold classification. For micro-aneurysms detection, the images were pre-processed by top-hat and bottom-hat transformation, then Otsu method and Hough transform were used to classify micro-aneurysms. Post-processing morphological methods were used to preclude the false positive noise. Results: After segmentation, the area of exudates divided by optic disk area (exudates/disk ratio) and counts of microaneurysms were quantified and compared between the moderate and severe non-proliferative diabetic retinopathy groups, which had significant difference ($P < 0.05$). Conclusions: In conclusion, morphological features of lesion might be an image marker for NPDR grading and computer aided quantification of retinal lesion could be a practical way for clinicians to better investigate diabetic retinopathy. © 2014 Wu et al.

Computer Aided System for Human Blood Cell Identification, Classification and Counting

Item Type Conference Paper

Author N. Christy Evangeline

Author M. Annalatha

Abstract Evaluation of Blood Smear is one of the most basic laboratory procedures in Hematology as deviations of blood cell count from their reference values can be indicators of various disease conditions. Digital Image Processing can help the technologists in the analysis and classification of blood cells and diagnosis of certain health conditions based on the CBC values and their morphology. This project aims at generating software that can identify, classify and count various blood cells from the peripheral blood smear samples. Locating, identifying and counting of Blood cells manually can be tedious, time consuming and inaccurate. On the other hand, Automatic Hematology Analyzers that work on Flow cytometry principle for classification are expensive and can perform only quantitative analysis. Thus taking into consideration, the wide scope of Image processing in the field of medicine, this proposed work aims to generate a preliminary framework of Automatic Analysis of Human Blood smear for identification, classification and counting of blood cells by using various Image processing. © 2018 IEEE.

Computer image analysis and classification of giant ragweed seeds

Item Type Journal Article

Author Y. Sako

Author M.B. McDonald

Abstract Giant ragweed exhibits a high degree of polymorphism among individual plants in seed size, shape, spininess, and color. These features may play an important role in giant ragweed seed survival and predation avoidance; however, they are difficult to evaluate because of lack of quantification methods. A computer imaging technique was developed for describing and classifying giant ragweed seeds using digital images of the seed top and side views. Seed samples collected from 20 different giant ragweed plants (classes) were mounted and digitally scanned. Quantitative features were extracted from the seed images, including color, width, height, area, and seed perimeter. A polygon (convex hull) of the seed image based on the seed outline was constructed, from which spininess indices were developed. Fisher's linear discriminant with normalized nearest neighbor classification was used to classify randomly selected images of individual seeds according to class (maternal origin), using the extracted features as a database. The best classification rate achieved was 99%, with 138 out of 140 seeds correctly matched using data from both the top and side views. Seed features were easily extracted and varied from 1.2- to 4.5-fold

among classes. Area and perimeter measurements varied least within classes but varied most among classes, suggesting that these features discriminate effectively among seeds from different plants in giant ragweed. Convex hull area : seed area ratio, using the seed top view images, was the best index of seed spininess, aligning well with visual assessment and providing greatest discrimination among classes. This experiment shows that in the case of giant ragweed, seeds from different plants are distinguishable in an objective and quantitative manner. This imaging technique can be applied to identification of seeds from different species and to studies on variable seed morphology within a species.

Computer-aided assessment of regional abdominal fat with food residue removal in CT

Item Type Journal Article

Author S. Makrogiannis

Author G. Caturegli

Author C. Davatzikos

Author L. Ferrucci

Abstract Rationale and Objectives: Separate quantification of abdominal subcutaneous and visceral fat regions is essential to understand the role of regional adiposity as risk factor in epidemiological studies. Fat quantification is often based on computed tomography (CT) because fat density is distinct from other tissue densities in the

abdomen. However, the presence of intestinal food residues with densities similar to fat may reduce fat quantification accuracy. We introduce an abdominal fat quantification method in CT with interest in food residue removal. **Materials and Methods:** Total fat was identified in the feature space of Hounsfield units and divided into subcutaneous and visceral components using model-based segmentation. Regions of food residues were identified and removed from visceral fat using a machine learning method integrating intensity, texture, and spatial information. Cost-weighting and bagging techniques were investigated to address class imbalance. **Results:** We validated our automated food residue removal technique against semimanual quantifications. Our feature selection experiments indicated that joint intensity and texture features produce the highest classification accuracy at 95%. We explored generalization capability using k-fold cross-validation and receiver operating characteristic (ROC) analysis with variable k. Losses in accuracy and area under ROC curve between maximum and minimum k were limited to 0.1% and 0.3%. We validated tissue segmentation against reference semimanual delineations. The Dice similarity scores were as high as 93.1 for subcutaneous fat and 85.6 for visceral fat. **Conclusions:** Computer-aided regional abdominal fat quantification is a reliable computational tool for large-scale epidemiological studies. Our proposed intestinal food residue reduction scheme is an original contribution of this work. Validation experiments indicate very good accuracy and generalization capability. © 2013.

Computer-assisted lip diagnosis on traditional Chinese medicine using multi-class support vector machines

Item Type Journal Article

Author F. Li

Author C. Zhao

Author Z. Xia

Author Y. Wang

Author X. Zhou

Author G.-Z. Li

Abstract Background: In Traditional Chinese Medicine (TCM), the lip diagnosis is an important diagnostic method which has a long history and is applied widely. The lip color of a person is considered as a symptom to reflect the physical conditions of organs in the body. However, the traditional diagnostic approach is mainly based on observation by doctor's nude eyes, which is non-quantitative and subjective. The non-quantitative approach largely depends on the doctor's experience and influences accurate the diagnosis and treatment in TCM. Developing new quantification methods to identify the exact syndrome based on the lip diagnosis of TCM becomes urgent and important. In this paper, we design a computer-assisted classification model to provide an automatic and quantitative approach for the diagnosis of TCM based on the lip images. Methods: A computer-assisted classification method is designed and applied for syndrome diagnosis based on the lip images. Our purpose is to classify the lip images into four groups: deep-red, red, purple and pale. The proposed scheme consists of four steps including the lip image preprocessing, image feature extraction, feature selection and classification. The extracted 84 features contain the lip color space component, texture and moment features. Feature subset selection is performed by using SVM-RFE (Support Vector Machine with recursive feature elimination), mRMR (minimum Redundancy Maximum Relevance) and IG (information gain). Classification model is constructed based on the collected lip image features using multi-class SVM and Weighted multi-class SVM (WSVM). In addition, we compare SVM with k-nearest neighbor (kNN) algorithm, Multiple Asymmetric Partial Least Squares Classifier (MAPLSC) and Naïve Bayes for the diagnosis performance comparison. All displayed faces image have obtained consent from the participants. Results: A total of 257 lip images are collected for the modeling of lip diagnosis in TCM. The feature selection method SVM-RFE selects 9 important features which are composed of 5 color component features, 3 texture features and 1 moment feature. SVM, MAPLSC, Naïve Bayes, kNN showed better classification results based on the 9 selected features than the results obtained from all the 84 features. The total classification accuracy of the five methods is 84%, 81%, 79% and 81%, 77%, respectively. So SVM achieves the best classification accuracy. The classification accuracy of SVM is 81%, 71%, 89% and 86% on Deep-red, Pale

Purple, Red and lip image models, respectively. While with the feature selection algorithm mRMR and IG, the total classification accuracy of WSVM achieves the best classification accuracy. Therefore, the results show that the system can achieve best classification accuracy combined with SVM classifiers and SVM-REF feature selection algorithm. Conclusions: A diagnostic system is proposed, which firstly segments the lip from the original facial image based on the Chan-Vese level set model and Otsu method, then extracts three kinds of features (color space features, Haralick co-occurrence features and Zernike moment features) on the lip image. Meanwhile, SVM-REF is adopted to select the optimal features. Finally, SVM is applied to classify the four classes. Besides, we also compare different feature selection algorithms and classifiers to verify our system. So the developed automatic and quantitative diagnosis system of TCM is effective to distinguish four lip image classes: Deep-red, Purple, Red and Pale. This study puts forward a new method and idea for the quantitative examination on lip diagnosis of TCM, as well as provides a template for objective diagnosis in TCM. © 2012 Li et al.; licensee BioMed Central Ltd.

Conditional adaptation deep networks for unsupervised cross domain image classification

Item Type Conference Paper

Author Y. Chen

Author C. Yang

Author Y. Zhang

Author Y. Li

Abstract Unsupervised domain adaptation aims at improving the performance on an unknown target domain by utilizing the knowledge learned from a related source domain. In this paper, we proposed a conditional adaptation deep network (CADN) to deal with the unsupervised domain adaptation problem. CADN is implemented based on a deep neural network and attempts to learn domain invariant features. We present a conditional adaptation strategy to reduce the domain distribution discrepancy and to solve the category mismatch and class prior bias, which are usually ignored in marginal adaptation approaches. We perform a set of comparative experiments on the standard domain adaptation benchmarks. The results demonstrate that the proposed CADN outperforms previous adaptation methods. © 2019 IEEE.

Conditional Calibrated Explanations: Finding a Path Between Bias and Uncertainty

Item Type Conference Paper

Author H. Löfström

Author T. Löfström

Editor Longo L.

Editor Lapuschkin S.

Editor Seifert C.

Abstract While Artificial Intelligence and Machine Learning models are becoming increasingly prevalent, it is essential to remember that they are not infallible or inherently objective. These models depend on the data they are trained on and the inherent bias of the chosen machine learning algorithm. Therefore, selecting and sampling data for training is crucial for a fair outcome of the model. A model predicting, e.g., whether an applicant should be taken further in the job application process, could create heavily biased predictions against women if the data used to train the model mostly contained information about men. The well-known concept of conditional categories used in Conformal Prediction can be utilised to address this type of bias in the data. The Conformal Prediction framework includes uncertainty quantification methods for classification and regression. To help meet the challenges of data sets with potential bias, conditional categories were incorporated into an existing explanation method called Calibrated Explanations, relying on conformal methods. This approach allows users to try out different settings while simultaneously having the possibility to study how the uncertainty in the predictions is affected on an individual level. Furthermore, this paper evaluated how the uncertainty changed when using conditional categories based on attributes containing potential bias. It showed that the uncertainty significantly increased, revealing that fairness came with a cost of increased uncertainty. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2024.

Confidence bounds of petrophysical predictions from conventional neural networks

Item Type Journal Article**Author** P.M. Wong**Author** A.G. Bruce**Author** T.D. Gedeon

Abstract Neural networks are powerful tools for solving the complex regression problems which abound in geosciences. Estimation of prediction confidence from neural networks is an important area. Many procedures are available to date, but it is often tedious for practitioners to implement such procedures without significant modification of the existing learning algorithms. In many cases, the procedures are also computationally intensive. This paper presents a practical solution using conventional backpropagation networks with simple data pre-processing and post-processing algorithms. The methodology involves conversions of the target outputs into linguistic variables (classes) prior to learning. When the classification network converges, minimum and maximum predictions are derived from the output activations using a simple averaging algorithm. Two examples from petroleum reservoirs are used to demonstrate the proposed methodology. The results show that the confidence bounds of the petrophysical predictions are realistic in both cases. The proposed methodology is generally useful, and can be implemented in simple spreadsheets without altering any existing neural network code.

Confidence Intervals for Class Prevalences under Prior Probability Shift

Item Type Journal Article

Author D. Tasche

Abstract Point estimation of class prevalences in the presence of dataset shift has been a popular research topic for more than two decades. Less attention has been paid to the construction of confidence and prediction intervals for estimates of class prevalences. One little considered question is whether or not it is necessary for practical purposes to distinguish confidence and prediction intervals. Another question so far not yet conclusively answered is whether or not the discriminatory power of the classifier or score at the basis of an estimation method matters for the accuracy of the estimates of the class prevalences. This paper presents a simulation study aimed at shedding some light on these and other related questions. © 2019 by the author.

Conformal prediction based on principal component analysis for high-dimensional outlier detection

Item Type Conference Paper

Author X. Qian

Author J. Wu

Author Y. Lin

Editor Kong X.

Editor Dai W.

Abstract Current outlier detection methods exhibit many limitations in high-dimensional settings. Traditional statistical approaches rely on strong assumptions and lack practicality and generality. Meanwhile, despite the better performance, machine learning methods suffer from low interpretability and reliability due to their complex mechanisms and the absence of confidence estimation. Although outlier detection methods based on principal component analysis (PCA) have shown some advantages by extracting important features from high-dimensional data, they have not entirely solved these problems. Conformal prediction, a finite-sample distribution-free uncertainty quantification method recently applied to outlier detection, produces a set-valued prediction with a Type-I error guarantee and false discovery rate control. This paper proposes a new distribution-free method for high-dimensional outlier detection, PCA-CP, combining principal component analysis and conformal prediction. PCA-CP overcomes the shortcomings of previous methods, demonstrating high generality and reliability while achieving high performance. Experiments on simulation and real data show that PCA-CP outperforms previous methods, achieving higher power and lower False Discovery Rate, thus proving its significant advantages. © 2024 SPIE.

Abstract Federated Learning (FL) is a machine learning framework where many clients collaboratively train models while keeping the training data decentralized. Despite recent advances in FL, the uncertainty quantification topic (UQ) remains partially addressed. Among UQ methods, conformal prediction (CP) approaches provides distribution-free guarantees under minimal assumptions. We develop a new federated conformal prediction method based on quantile regression and take into account privacy constraints. This method takes advantage of importance weighting to effectively address the label shift between agents and provides theoretical guarantees for both valid coverage of the prediction sets and differential privacy. Extensive experimental studies demonstrate that this method outperforms current competitors. © 2023 Proceedings of Machine Learning Research. All rights reserved.

Conformal prediction for stochastic decision-making of PV power in electricity markets

Item Type Journal Article**Author** Y. Renkema**Author** N. Brinkel**Author** T. Alskauf

Abstract This paper studies the use of conformal prediction (CP), an emerging probabilistic forecasting method, for day-ahead photovoltaic power predictions to enhance participation in electricity markets. First, machine learning models are used to construct point predictions. Thereafter, several variants of CP are implemented to quantify the uncertainty of those predictions by creating CP intervals and cumulative distribution functions. Optimal quantity bids for the electricity market are estimated using several bidding strategies under uncertainty, namely: trust-the-forecast, worst-case, Newsvendor and expected utility maximization (EUM). Results show that CP in combination with k-nearest neighbors and/or Mondrian binning outperforms its corresponding linear quantile regressors. Using CP in combination with certain bidding strategies can yield high profit with minimal energy imbalance. In concrete, using conformal predictive systems with k-nearest neighbors and Mondrian binning after random forest regression yields the best profit and imbalance regardless of the decision-making strategy. Combining this uncertainty quantification method with the EUM strategy with conditional value at risk (CVaR) can yield up to 93% of the potential profit with minimal energy imbalance. © 2024 The Author(s)

Abstract The Random Forests classifier, a widely utilized off-the-shelf classification tool, assumes training and test samples come from the same distribution as other standard classifiers. However, in safety-critical scenarios like medical diagnosis and network attack detection, discrepancies between the training and test sets, including the potential presence of novel outlier samples not appearing during training, can pose significant challenges. To address this problem, we introduce the Conformalized Semi-Supervised Random Forest (CSForest), which couples the conformalization technique Jackknife+aB with semi-supervised tree ensembles to construct a set-valued prediction $C(x)$. Instead of optimizing over the training distribution, CSForest employs unlabeled test samples to enhance accuracy and flag unseen outliers by generating an empty set. Theoretically, we establish CSForest to cover true labels for previously observed inlier classes under arbitrarily label-shift in the test data. We compare CSForest with state-of-the-art methods using synthetic examples and various real-world datasets, under different types of distribution changes in the test domain. Our results highlight CSForest's effective prediction of inliers and its ability to detect outlier samples unique to the test data. In addition, CSForest shows persistently good performance as the sizes of the training and test sets vary. Codes of CSForest are available at <https://github.com/yujinhan98/CSForest>. Abstract This paper explores uncertainty quantification (UQ) methods in the context of Kolmogorov–Arnold Networks (KANs). We apply an ensemble approach to KANs to obtain a heuristic measure of UQ, enhancing interpretability and robustness in modeling complex functions. However, particularly in data-limited and complex scientific settings, ensemble-based uncertainty estimates, as is the case for many UQ methods, are sensitive to implicit distributional assumptions and do not provide formal coverage guarantees. Building on this, we develop conformalized-KANs, a conformal UQ framework for KANs that combines ensemble-based uncertainty estimates with split conformal prediction to generate calibrated prediction intervals with formal coverage guarantees. Numerical experiments are conducted to evaluate the effectiveness of these methods, focusing particularly on the robustness and accuracy of the prediction intervals under various hyperparameter settings. We further show that this framework extends naturally to recent KAN variants, including finite basis KANs and multi-fidelity KANs. The results demonstrate the potential of our approaches to improve the reliability and applicability of KANs in scientific machine learning. © 2026 The Author(s). Published by IOP Publishing Ltd. Considerations for point-of-care diagnostics: Evaluation of acridine orange staining and postprocessing methods for a three-part leukocyte differential test

Item Type Journal Article

Author A.J. Powless

Author R.J. Conley

Author K.A. Freeman

Author T.J. Muldoon

Abstract There exists a broad range of techniques that can be used to classify and count white blood cells in a point-of-care (POC) three-part leukocyte differential test. Improvements in lenses, light sources, and cameras for image-based POC systems have renewed interest in acridine orange (AO) as a contrast agent, whereby subpopulations of leukocytes can be differentiated by colorimetric analysis of AO fluorescence emission. We evaluated the effect on test accuracy using different AO staining and postprocessing methods in the context of an image-based POC

colorimetric cell classification scheme. Thirty blood specimens were measured for percent cell counts using our POC system and a conventional hematology analyzer for comparison. Controlling the AO concentration used during whole-blood staining, the incubation time with AO, and the colorimetric ratios among the three population of leukocytes yielded a percent deviation of 0.706%, -1.534%, and -0.645% for the lymphocytes, monocytes, and granulocytes, respectively. Overall, we demonstrated that a redshift in AO fluorescence was observed at elevated AO concentrations, which lead to reproducible inaccuracy of cell counts. This study demonstrates there is a need for a strict control of the AO staining and postprocessing methods to improve test accuracy in these POC systems. © 2017 The Authors. CONSISTENT MULTI-CLASS CLASSIFICATION FROM MULTIPLE UNLABELED DATASETS

Item Type Conference Paper

Author Z. Wei

Author S. Shu

Author Y. Cao

Author H. Wei

Author B. An

Author L. Feng

Abstract Weakly supervised learning aims to construct effective predictive models from imperfectly labeled data. The recent trend of weakly supervised learning has focused on how to learn an accurate classifier from completely unlabeled data, given little supervised information such as class priors. In this paper, we consider a newly proposed weakly supervised learning problem called multi-class classification from multiple unlabeled datasets, where only multiple sets of unlabeled data and their class priors (i.e., the proportion of each class) are provided for training the classifier. To solve this problem, we first propose a classifier-consistent method (CCM) based on a probability transition function. However, CCM cannot guarantee risk consistency and lacks of purified supervision information during training. Therefore, we further propose a risk-consistent method (RCM) that progressively purifies supervision information during training by importance weighting. We provide comprehensive theoretical analyses for our methods to demonstrate the statistical consistency. Experimental results on multiple benchmark datasets across various settings demonstrate the superiority of our proposed methods. © 2024 12th International Conference on Learning Representations, ICLR 2024. Consistent prompt learning for vision-language models

Item Type Journal Article

Author Y. Zhang

Author X. Tian

Abstract Pre-trained vision-language models, such as CLIP, have shown remarkable capabilities across various downstream tasks by learning prompts that consist of context concatenated with a class name; for example, ‘a photo of a [dog]’ with [dog] as a class prior. Advanced prompt-learning methods typically initialize and optimize the context; for example, ‘a photo of a’ for downstream task adaptation. However, context optimization typically leads to poor generalization performance over novel classes or datasets sampled from different distributions. This may be attributed to prompt inconsistency; namely, prompts optimized using one image distribution may differ from those optimized using a different image distribution. To improve the generalization performance of optimized prompts, we propose the novel consistent prompt learning (CPL) approach that identifies and addresses the image distribution that causes prompt inconsistency by performing distributional exploration. CPL identifies and mitigates prompt inconsistency in an adversarial training scheme, in which prompt inconsistency is measured as the similarity discrepancy between images and two different prompts. Specifically, CPL calculates two similarities between a query image and two prompts, and determines the prompt inconsistency through the discrepancy between these two similarities. Subsequently, CPL performs distributional exploration to enlarge the discrepancy and uses an adversarial-training approach to mitigate the discrepancy. Consequently, the model predictions are insensitive to prompt changes. The optimized prompt performs well under various image distributions. Comprehensive experiments show that the proposed CPL method performs favorably on four types of representative tasks across 11 datasets, which improves on existing prompt-learning methods, achieving state-of-the-art performance. © 2025 Elsevier B.V.

Constraint-based, transductive learning for distributed ensemble classification

Item Type Conference Paper

Author D.J. Miller

Author S. Pal

Author Y. Wang

Abstract We consider ensemble classification when there is no common labeled data for designing the function which aggregates classifier decisions. In recent work, we dubbed this problem distributed ensemble classification, addressing e.g. when local classifiers are trained on different (e.g. proprietary, legacy) databases or operate on different sensing modalities. Typically, fixed (untrained) rules of classifier combination such as voting methods are used in this case. However, these may perform poorly, especially when the local class priors, used in training, differ from the true (test batch) priors. Alternatively, we proposed a transductive strategy, optimizing the combining rule for an objective function measured on the test batch. We proposed both maximum likelihood (ML) and information-theoretic (IT) objectives and found that IT achieved superior performance. Here, we identify that the fundamental advantage of the IT method is its ability to properly account for statistical redundancy in the ensemble. We also develop an extension of IT that improves its performance. Experiments are conducted on the UC Irvine machine learning repository. © 2006 IEEE.

CONTINUAL MOMENTUM FILTERING ON PARAMETER SPACE FOR ONLINE TEST-TIME ADAPTATION

Item Type Conference Paper

Author J.-H. Lee

Author J.-H. Chang

Abstract Deep neural networks (DNNs) have revolutionized tasks such as image classification and speech recognition but often falter when training and test data diverge in distribution. External factors, from weather effects on images to varied speech environments, can cause this discrepancy, compromising DNN performance. Online test-time adaptation (OTTA) methods present a promising solution, recalibrating models in real-time during the test stage without requiring historical data. However, the OTTA paradigm is imperfect, often falling prey to issues such as catastrophic forgetting due to its reliance on noisy, self-trained predictions. Although some contemporary strategies mitigate this by tying adaptations to the static source model, this restricts model flexibility. This paper introduces a continual momentum filtering (CMF) framework, leveraging the Kalman filter (KF) to strike a balance between model adaptability and information retention. The CMF intertwines optimization via stochastic gradient

descent with a KF-based inference process. This methodology not only aids in averting catastrophic forgetting but also provides high adaptability to shifting data distributions. We validate our framework on various OTTA scenarios and real-world situations regarding covariate and label shifts, and the CMF consistently shows superior performance compared to state-of-the-art methods. © 2024 12th International Conference on Learning Representations, ICLR 2024. Continuous Sweep for Binary Quantification Learning

Item Type Journal Article

Author K. Kloos

Author J.D. Karch

Author Q.A. Meertens

Author S. Scholtus

Author M. de Rooij

Abstract A quantifier is a supervised machine learning algorithm that focuses on estimating the class prevalence in a data set rather than labeling its individual observations. We introduce continuous sweep, a new parametric binary quantifier inspired by the well-performing median sweep, which is an ensemble method based on adjusted count estimators. We modified two aspects of median sweep: (1) using parametric class distributions instead of empirical distributions for the true and false positive rates; (2) using the mean instead of the median of a set of adjusted count estimates. These two modifications allow for a theoretical analysis of the bias and variance of the continuous sweep. Furthermore, the expressions of bias and variance can be used to define optimal decision boundaries of the set of adjusted count estimates to be used in the ensemble. In three simulation studies, we show that continuous sweep outperforms the quantifiers in the group classify, count, and correct, including median sweep, and is competitive with the two best quantifiers in the group distribution matchers. Also, an empirical data set is analyzed with these quantifiers, showing similar performances. © The Author(s) 2026.

Continuous target shift adaptation in supervised learning

Item Type Conference Paper

Author T.D. Nguyen

Author M.C. Du Plessis

Author M. Sugiyama

Abstract Supervised learning in machine learning concerns inferring an underlying relation between covariate x and target y based on training covariate-target data. It is traditionally assumed that training data and test data, on which the generalization performance of a learning algorithm is measured, follow the same probability distribution. However, this standard assumption is often violated in many real-world applications such as computer vision, natural language processing, robot control, or survey design, due to intrinsic non-stationarity of the environment or inevitable sample selection bias. This situation is called dataset shift and has attracted a great deal of attention recently. In the paper, we consider supervised learning problems under the target shift scenario, where the target marginal distribution $p(y)$ changes between the training and testing phases, while the target-conditioned covariate distribution $p(x|y)$ remains unchanged. Although various methods for mitigating target shift in classification (a.k.a. class prior change) have been developed so far, few methods can be applied to continuous targets. In this paper, we propose methods for continuous target shift adaptation in regression and conditional density estimation. More specifically, our contribution is a novel importance weight estimator for continuous targets. Through experiments, the usefulness of the proposed method is demonstrated. © 2015 T.D. Editor Bhattacharya S.

Editor Pal U.

Abstract Many existing unsupervised domain adaptation (UDA) methods primarily focus on covariate shift, limiting their effectiveness in imbalanced domain adaptation (IDA) where both covariate shift and label shift coexist. Recent IDA methods have achieved promising results based on self-training using target pseudo labels. However, under the IDA scenarios, the classifier learned in the source domain will exhibit different decision bias from the target domain. It will potentially make target pseudo labels unreliable, and will further lead to error accumulation with incorrect class alignment. Thus, we propose contrastive conditional alignment based on label shift calibration (CCA-LSC) for IDA, to address both covariate shift and label shift. Initially, our contrastive conditional alignment resolve covariate shift to learn representations with domain invariance and class discriminability, which include domain adversarial learning, sample-weighted moving average centroid alignment and discriminative feature alignment. Subsequently, we estimate the probability distribution of the target domain, and calibrate target sample classification predictions based on label shift metrics to encourage labeling pseudo-labels more consistently with the distribution of real target data. Extensive experiments are conducted and demonstrate that our method outperforms existing UDA and IDA methods on benchmarks with both label shift and covariate shift. Our code is available at <https://github.com/ysxcj-hub/CCA-LSC>. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2025.

Abstract Generative models have been frequently used as a sample augmentation tool to tackle Generalized Zero-Shot Learning (GZSL). Generative ZSL methods aim to produce diverse and high-fidelity visual features. They do this from limited category semantics. However, on one hand, mainstream generative model families, such as GANs, VAEs, and diffusion models, cannot balance sampling speed, quality, and diversity effectively, which reduces their utility in GZSL. On the other hand, the extreme information shift between visual and semantic spaces severely restricts the discriminative and generalization abilities of the generated features. To address these challenges, we propose a novel hybrid generative model named Contrastive Diffusion Generative Adversarial Network (CD-GAN) for GZSL. As a hybrid model of the diffusion model and Generative Adversarial

Network (GAN), CD-GAN incorporates the merits of the diffusion model in terms of the diversity and quality of generated features, as well as the merits of GAN in terms of feature generation efficiency. CD-GAN potentially aligns visuals and semantics by unifying real and generated features into a common embedding space and then conducting contrastive learning guided by between-class prior knowledge in this space. Moreover, we strengthen visual-semantic alignment by introducing a classification regularization. This technique further guarantees that the embedding encodes corresponding semantics. Compared to baseline models, CD-GAN achieves promising performance, as demonstrated by extensive experiments on four popular datasets. © The Author(s), under exclusive license to Springer Nature Singapore Pte Ltd. 2025.

Abstract BACKGROUND: – Hypertension induces structural and functional damage in multiple organs. Evidence of subclinical damage increases risk of vascular events and death but can be difficult to identify in the clinic. We developed a novel machine learning approach that quantifies current hypertension-associated multiorgan damage, mapping progression from health to advanced disease, in a pseudotemporal manner and predicts organ-specific disease progression trajectories. METHODS: – We analyzed 566 multimodal imaging and nonimaging variables from 27 099 participants in the UK Biobank imaging substudy to develop a semisupervised contrastive trajectory inference (cTI) framework that models multiorgan alterations associated with hypertension exposure, including heart, brain, kidneys, vasculature, lungs, liver, and metabolic information. Model stability was validated through multiple internal validation steps, and external validity was tested on 5507 participants from the Atherosclerosis Risk in Communities study (ARIC). Clinical relevance was evaluated against existing risk scores and through ability to predict survival and incident multiorgan disease for up to 7 years, across both UK Biobank and ARIC. RESULTS: – In the UK Biobank (mean age 63.27 ± 7.48 years; 53.4% women) our global organ damage score (HyperScore) achieved an area under the curve of 0.964 (0.941–0.987) for identification of individuals with severe end-organ disease and robust stability in cross-validation with a mean root mean square error of 0.104 ± 0.084 . Survival odds differed significantly across HyperScore stages ($P < 0.001$), whereas stratification by blood pressure was nonsignificant. We further revealed 6 hypertensive disease phenotypes (HyperTrajectory), characterized by predominant cardiac, lipoprotein, atherothrombosis, brain, cardiorenal, and liver features, respectively. External testing

in ARIC confirmed stability of the model, with Jensen-Shannon distances as low as 0.10 for HyperScore distributions, without significant deviation in organ damage progression patterns ($P>0.05$) and consistent end-organ and outcome characteristics between ARIC and UK Biobank across HyperTrajectories. **CONCLUSIONS:** – Machine learning–derived global organ damage scores are feasible in hypertension and enable identification of distinct hypertension-associated organ-disease phenotypes. New frameworks for hypertension assessment and monitoring using imaging to derive personalized risk assessment and phenotype-specific intervention may be achievable. © 2026 The Authors.

Contributions of strength and body composition to the gender difference in anaerobic power

Item Type Journal Article

Author J.L. Mayhew

Author K. Hancock

Author L. Rollison

Author T.E. Ball

Author J.C. Bowen

Abstract Background: The purpose of this study was to determine the significant factors contributing to the difference between men and women in anaerobic power (AP) generation. Methods: Participants: college men (n=113) and women (n=175) were randomly selected for evaluation from a fitness class prior to training. Measures: AP was determined from the Margaria-Kalamen stair run. Dynamic strength was evaluated from the 1-RM single-leg extension. Body composition was estimated from gender-specific skinfold prediction equations. Results: Discriminant analysis identified %fat, fat-free mass (FFM), and leg extension strength as significant components differentiating between men and women and allowed proper gender classification in 99% of the cases. When both strength and body composition variables were held constant by covariance, there was no significant difference between men and women in AP ($F=1.25$). A multiple regression equation using %fat, FFM, and leg extension strength predicted AP ($R=0.91$) with an error of 150 W. When the multiple regression equations was applied to a cross-validation sample, AP could be accurately predicted ($r=0.91$, $t=0.17$) with an average error of $3\% \pm 21\%$. Conclusions: Body size and dynamic strength are the major factors explaining the explosive leg power difference between men and women without a specific or unique gender quality.

Controlled False Negative Reduction of Minority Classes in Semantic Segmentation

Item Type Conference Paper**Author** R. Chan**Author** M. Rottmann**Author** F. Huger**Author** P. Schlicht**Author** H. Gottschalk

Abstract In semantic segmentation datasets, classes of high importance are oftentimes underrepresented, e.g., humans in street scenes. Neural networks are usually trained to reduce the overall number of errors, attaching identical loss to errors of all kinds. However, this is not necessarily aligned with human intuition. For instance, an overlooked pedestrian seems more severe than an incorrectly detected one. One possible remedy is to deploy different decision rules by introducing class priors that assign more weight to underrepresented classes. While reducing the false negatives of the underrepresented class, at the same time this leads to a considerable increase of false positive indications. In this work, we combine decision rules with methods for false positive detection. Therefore, we fuse false negative detection with uncertainty based false positive meta classification. We present the efficiency of our method for the semantic segmentation of street scenes on the Cityscapes dataset based on predicted instances of the 'human' class. In the latter we employ an advanced false positive detection method using uncertainty measures aggregated over instances. We, thereby, achieve improved trade-offs between false negative and false positive samples of the underrepresented classes. © 2020 IEEE.

CONTROLLING DIRECTIONS ORTHOGONAL TO A CLASSIFIER

Item Type Conference Paper

Author Y. Xu

Author H. He

Author T. Shen

Author T. Jaakkola

Abstract We propose to identify directions invariant to a given classifier so that these directions can be controlled in tasks such as style transfer. While orthogonal decomposition is directly identifiable when the given classifier is linear, we formally define a notion of orthogonality in the non-linear case. We also provide a surprisingly simple method for constructing the orthogonal classifier (a classifier utilizing directions other than those of the given classifier). Empirically, we present three use cases where controlling orthogonal variation is important: style transfer, domain adaptation, and fairness. The orthogonal classifier enables desired style transfer when domains vary in multiple aspects, improves domain adaptation with label shifts and mitigates the unfairness as a predictor. The code is available at https://github.com/Newbeeer/orthogonal_classifier. © 2022 ICLR 2022 - 10th International Conference on Learning Representations. All rights reserved.

Controlling factors for the distribution of sapric peat soils extracted by GIS analysis

Item Type Journal Article

Author M. Morishita

Author M. Kawahigashi

Abstract This study aimed to clarify the distribution trend of sapric peat soils in Japanese agricultural fields from the view point of drainage and landform conditions using the Geographic Information System (GIS). To this end, the environmental conditions in the distribution area of organic soils were divided by combining existing GIS databases of environmental factors that consist of groundwater level, drainage condition, landform classification, and grain size of sediment. In order to evaluate the contribution of these environmental factors to the distribution trend of sapric peat soils, we applied quantification method type II to construct the discrimination model that enables the differentiation of the distribution area of sapric and non-sapric peat soils. In the case of organic soils without mineral surface cover, our discrimination model clearly suggests that sapric peat soils tend to be distributed under good drainage condition on floodplains, and with coarse sediments. This indicates that the effect of drainage conditions on peat decomposition is determined by landform condition. On the other hand, in the case of the land covered with mineral soils on the surface, sapric peat soil distribution was not well estimated. Determining the relationships between the distribution trend of sapric peat soils and the environmental factors by analyzing the existing GIS database is a new application. This was achieved by the combination of GIS and quantification method type II, which contributes to the description of the peat decomposition process from the viewpoint of geographical conditions. © 2018, © 2018 Japanese Society of Soil Science and Plant Nutrition.

Abstract Federated learning (FL) is an increasingly popular paradigm for protecting data privacy in machine learning systems. However, the data heterogeneity and high computation cost/latency are challenging barriers for employing FL in real-world applications with heterogeneous devices. In this paper, we propose a novel personalized FL framework named CompFL allowing cooperative training of models with varied structures to mitigate those issues. First, CompFL initializes a set of expert models in varied sizes and allows each client to choose one or multiple expert models for training according to their capacities. Second, CompFL combines the model decoupling strategy and local-global feature alignment to mitigate the adverse impact of label heterogeneity, where clients only share the feature extractor part for each model architecture. Third, to encourage mutual enhancement of various models, knowledge distillation in local training is further applied to improve the overall performance. To make our framework workable in real systems, we implement it in both centralized settings

with server-coordinated parallel training, and decentralized settings with newly developed device-to-device training-forwarding schemes. Extensive experiments on benchmark datasets are conducted to verify the potential of our framework for personalized FL over heterogeneous devices. © 2024 IEEE.

COPING WITH LABEL SHIFT VIA DISTRIBUTIONALLY ROBUST OPTIMISATION

Item Type Conference Paper

Author J. Zhang

Author A.K. Menon

Author A. Veit

Author S. Bhojanapalli

Author S. Kumar

Author S. Sra

Abstract The label shift problem refers to the supervised learning setting where the train and test label distributions do not match. Existing work addressing label shift usually assumes access to an unlabelled test sample. This sample may be used to estimate the test label distribution, and to then train a suitably re-weighted classifier. While approaches using this idea have proven effective, their scope is limited as it is not always feasible to access the target domain; further, they require repeated retraining if the model is to be deployed in multiple test environments. Can one instead learn a single classifier that is robust to arbitrary label shifts from a broad family? In this paper, we answer this question by proposing a model that minimises an objective based on distributionally robust optimisation (DRO). We then design and analyse a gradient descent-proximal mirror ascent algorithm tailored for large-scale problems to optimise the proposed objective. Finally, through experiments on CIFAR-100 and ImageNet, we show that our technique can significantly improve performance over a number of baselines in settings where label shift is present. © 2021 ICLR 2021 - 9th International Conference on Learning Representations. Correcting a class of complete selection bias with external data based on importance weight estimation

Item Type Conference Paper

Author V.-T. Tran

Author A. Aussem

Editor Arik S.

Editor Huang T.

Editor Lai W.K.

Editor Liu Q.

Abstract We present a practical bias correction method for classifier and regression models learning under a general class of selection bias. The method hinges on two assumptions: (1) a feature vector, X_s , exists such that S , the variable that controls the inclusion of the samples in the training set, is conditionally independent of (X, Y) given X_s ; (2) one has access to some external samples drawn from the population as a whole in order to approximate the unbiased distribution of X_s . This general framework includes covariate shift and prior probability shift as special cases. We first show how importance weighting can remove this bias. We also discuss the case where our key assumption about X_s is not valid and where X_s is only partially observed in the test set. Experimental results on synthetic and real-world data demonstrate that our method works well in practice. © Springer International Publishing Switzerland 2015.

Correlation of HER2 levels expression through HER2 mRNA PCR vs immunohistochemistry (IHC) in hormone receptor positive (HR+)/HER2 negative (HER2-) early breast cancer

Item Type Journal Article**Author** A.L. de Sá**Author** J. Tejerina**Author** M. Amann**Author** P. Ballestín**Author** B. González**Author** A. Pascual**Author** C.D. Del Arco**Author** V. García-Barberán**Author** M. Paz-Cabezas**Author** A. De Luna**Author** J.Á. García-Sáenz**Author** F. Moreno

Abstract Purpose: To evaluate the correlation between HER2 expression levels measured by HER2 mRNA using Oncotype DX and by immunohistochemistry (IHC) in hormone receptor-positive (HR+) and HER2-negative (HER2-) early breast cancer. In addition, we assessed whether low HER2 expression is associated with distinct clinicopathological characteristics and prognosis in our series. Methods: We conducted a retrospective study that included 500 patients diagnosed with stage I–III HR+/HER2- breast cancer who underwent surgery and had Oncotype DX recurrence score determined between 2009 and 2023 at Hospital Clínico San Carlos, Madrid, Spain. HER2 mRNA levels obtained through Oncotype DX were compared across IHC groups (HER2 0+, HER2 1+, HER2 2+/ISH-negative). Event-free survival (EFS) was analyzed according to HER2 expression. Results: Although HER2 mRNA levels increased with higher IHC HER2 categories, variability and overlap were observed between subgroups. Median Oncotype DX recurrence scores also rose slightly across HER2 IHC groups but did not reach statistical significance. EFS did not differ between HER2 expression levels. Conclusions: We found that HER2 mRNA measurement by Oncotype DX provides a quantitative approach to assess HER2 expression. However, its results overlap within traditional IHC categories. While HER2-low classification may have therapeutic implications for new antibody–drug conjugates, its prognostic relevance appears limited. Further studies are needed to improve HER2 quantification methods for improved clinical decision-making. © The Author(s) 2025.

Corrosion degree detection of ferromagnetic materials using a hybrid machine learning approach and self-magnetic flux leakage technology

Item Type Journal Article

Author H. Zhang

Author H. Li

Author R. Xia

Author T. Hu

Author J. Zhou

Abstract Corrosion of ferromagnetic materials can lead to performance degradation or even failure in engineering structures. Therefore, detecting the degree of corrosion in these materials is crucial. Traditional detection methods are primarily manual and lack precision, highlighting the need for developing automated, high-precision detection techniques. In this paper, we developed a novel self-magnetic flux leakage (SMFL) scanner. We enhanced the Marine Predator Algorithm (MPA) by integrating Chaos Opposition (CO) and Group Learning (GL), resulting in the COGL-MPA-XGB model. This model optimizes Extreme Gradient Boosting parameters for accurate corrosion prediction, achieving a 96% coefficient of determination (R^2) and a mean error of 1.87. We tested the method on 170 rod-shaped steel samples with varying degrees of corrosion, evaluating its effectiveness through ablation experiments and comparisons with three other machine learning models. The results show that the combined SMFL and hybrid model strategy reduces the maximum detection error by

73.7% and offers a new perspective for quantitative corrosion detection. © 2024 Elsevier Ltd

Cost Volume Aggregation in Stereo Matching Revisited: A Disparity Classification Perspective

Item Type Journal Article

Author Y. Wang

Author L. Wang

Author K. Li

Author Y. Zhang

Author D.O. Wu

Author Y. Guo

Abstract Cost aggregation plays a critical role in existing stereo matching methods. In this paper, we revisit cost aggregation in stereo matching from disparity classification and propose a generic yet efficient Disparity Context Aggregation (DCA) module to improve the performance of CNN-based methods. Our approach is based on an insight that a coarse disparity class prior is beneficial to disparity regression. To obtain such a prior, we first classify pixels in an image into several disparity classes and treat pixels within the same class as homogeneous regions. We then generate homogeneous region representations and incorporate these representations into the cost volume to suppress irrelevant information while enhancing the matching ability for cost aggregation. With the help of homogeneous region representations, efficient and informative cost aggregation can be achieved with only a shallow 3D CNN. Our DCA module is fully-differentiable and well-compatible with different network architectures, which can be seamlessly plugged into existing networks to improve performance with small additional overheads. It is demonstrated that our DCA module can effectively exploit disparity class priors to improve the performance of cost aggregation. Based on our DCA, we design a highly accurate network named DCANet, which achieves state-of-the-art performance on several benchmarks. © 1992-2012 IEEE.

Cost-sensitive support vector machines

Item Type Journal Article

Author A. Iranmehr

Author H. Masnadi-Shirazi

Author N. Vasconcelos

Abstract Many machine learning applications involve imbalance class prior probabilities, multi-class classification with many classes (often addressed by one-versus-rest strategy), or “cost-sensitive” classification. In such domains, each class (or in some cases, each sample) requires special treatment. In this paper, we use a constructive procedure to extend SVM's standard loss function to optimize the classifier with respect to class imbalance or class costs. By drawing connections between risk minimization and probability elicitation, we show that the resulting classifier guarantees Bayes consistency. We further analyze the primal and the dual objective functions and derive the objective function in a regularized risk minimization framework. Finally, we extend the classifier to the with cost-sensitive learning with example dependent costs. We perform experimental analysis on class imbalance, cost-sensitive learning with given class and example costs and show that proposed algorithm provides superior generalization performance, compared to conventional methods. © 2019

Counting dense object of multiple types based on feature enhancement

Item Type Journal Article

Author Q. Fu

Author W. Min

Author W. Sheng

Author C. Peng

Abstract Introduction: Accurately counting the number of dense objects in an image, such as pedestrians or vehicles, is a challenging and practical task. The existing density map regression methods based on CNN are mainly used to count a class of dense objects in a single scene. However, in complex traffic scenes, objects such as vehicles and pedestrians usually exist at the same time, and multiple classes of dense objects need to be counted simultaneously. Methods: To solve the above issues, we propose a new multiple types of dense object counting method based on feature enhancement, which can enhance the features of dense counting objects in complex traffic scenes to realize the classification and regression counting of dense vehicles and people. The counting model consists of the regression subnet and the classification subnet. The regression subnet is primarily used to generate two-channel predicted density maps, mainly including the initial feature layer and the feature enhancement layer, in which the feature enhancement layer can enhance the classification features and regression counting features of dense objects in complex traffic scenes. The classification subnet mainly supervises classifying dense vehicles and people into two feature channels to assist the regression counting task of the regression subnets. Results: Our method is compared on VisDrone+ datasets, ApolloScape+ datasets, and UAVDT+ datasets. The experimental results show that the method counts two kinds of dense objects simultaneously and outputs a high-quality two-channel predicted density map. The counting performance is better than the state-of-the-art counting network in dense people and vehicle counting. Discussion: In future work, we will further improve the feature extraction ability of the model in complex traffic scenes to classify and count a variety of dense objects such as cars, pedestrians, and non-motor vehicles. Abstract Heavy metal contamination in karst ecosystems poses great environmental risks due to the interplay between high geochemical backgrounds and anthropogenic activities. This study performed an integrated source-to-risk assessment of soil metals based on 674 topsoil samples from Guangxi karst region in China, combining three machine learning models including positive matrix factorization (PMF), random forest (RF), and multiscale geographically weighted regression (MGWR). Geochemical characterization identified SiO₂ (63%), Al₂O₃ (18%), and Fe₂O₃ (6.4%) as dominant oxides in tested soils, with higher organic matter (3.3% content) than regional background value. A majority of 36 examined metals displayed concentrations exceeding local background values, of which Cd and Hg exhibited the highest enrichment levels (3.83 and 6.75 folds of background values, respectively). PMF revealed distinct source patterns across land-use types, with natural weathering dominating in forest land, and agricultural inputs prevailing in grasslands. Riparian land was primarily influenced by traffic-related anthropogenic activities, while construction land was dominated by industrial and mining/smelting sources. PMF-RF-MGWR modeling demonstrated pronounced spatial heterogeneity with contamination hotspots being mainly concentrated in industrial- and mining-intensive areas of central-western Guangxi. Notably, karst weathering increased soil metal mobility, while secondary carbonate mineral formation contributed to immobilization of Cd and Pb. Health risk assessment identified As, Cr and Ni as priority contaminants, and their presence in industrial zones posed unacceptable carcinogenic risks. Our findings underscore the role of the interplay between geological processes and anthropogenic activities in shaping metal distribution, providing valuable references for targeted soil management and contaminated land remediation in karst regions. © 2026 The Authors.

Courtyard design for energy efficiency and thermal comfort: machine learning insights across hot and warm climates

Item Type Journal Article**Author** M.A. Aloshan**Author** K.M. Aldali

Abstract Courtyards, long used as a passive climate-control element in vernacular housing, are increasingly reinterpreted in modern residential design, yet their quantified impact on energy use and comfort remains poorly documented. This study investigates how courtyard design affects energy efficiency and thermal comfort in villas across five hot and warm climates: Cairo, Riyadh, Gizan, Miami, and Sevilla. Using nearly 29,000 parametric simulations, design variables (geometry, window-to-wall ratio (WWR), glazing, insulation, and orientation) were systematically tested. Random Forest models achieved $R^2 > 0.99$ for both annual cooling demand and discomfort hours, with Shapley Additive explanations (SHAP) analysis revealing variable importance. Results show that compact courtyards with low WWR, external insulation, and high-performance glazing reduce cooling demand under 75 kWh/m² year. In contrast, elongated courtyards with higher WWR reduce discomfort to under 70 h annually in hot-dry climates, though often at the cost of increased cooling demand in hot-humid regions. Courtyard dimensions accounted for less than 3% of outcome variance, compared with > 40% for WWR and insulation. This study combines large-scale simulation with interpretable machine learning to quantify courtyard performance across climates. The findings provide climate-specific, evidence-based design guidance and demonstrate a pathway toward performance-based building codes that integrate courtyard design for hot regions. © The Author(s) 2025.

Covid-19 Pneumonia Chest X-Ray Pattern Synthesis by Stable Diffusion

Item Type Conference Paper**Author** Z. Liang**Author** Z. Xue**Author** S. Rajaraman**Author** S. Antani

Abstract In this study, we fine-tuned a stable diffusion model to synthesize high resolution chest X-ray images (512x512) with bilateral lung edema caused by COVID-19 pneumonia using the class-specific prior preservation strategy. 300 positive images were selected from the MIDRC dataset as subject instances with an additional 400 negative images for class prior preservation. We synthesized images respectively using the new technique and the conventional technique for comparison. The synthetic images by the stable diffusion fine-tuned by the prior preservation technique have the Frechet inception distance (FID) of 9.2158 and kernel inception distance (KID) 0.0818 computed with the real positive images, which is superior to the synthetic images using the conventional methods such as WGAN and DDIM. The classification accuracy is 0.9975 with precision of 1.0 and recall of 0.9950 when the synthetic positive images with the real negative images were classified by a trained vision transformer (ViT). We conclude that the stable diffusion model can synthesize high-quality and high-resolution chest x-ray images using the prior preservation strategy with a small number of real images as subject instances and text prompt as guidance for the designated patterns. © 2024 IEEE.

cPU: Consistent Risk Estimator for Positive-Unlabeled Learning

Item Type Journal Article**Author** Y. Zhang**Author** K. Wang**Author** J. Tang**Author** Y. Zhang**Author** D. Liang

Abstract As one of the classical strategies for positive-unlabeled (PU) learning, the cost-sensitive methods achieve binary classification by minimizing the overall risk. To achieve this goal, the class prior is usually exploited to guide model learning in many state-of-the-art cost-sensitive approaches. However, how to effectively mine the underlying supervision information using the class prior remains a major challenging problem. It is known that the distribution of positive and negative samples is fixed in unlabeled samples when the class prior is available. Based on this knowledge, we derive a novel supervision formulation from a risk perspective: if the class prior is known, the ratio between the positive risk distribution of negative samples and the

negative risk distribution of positive samples converges to a fixed value in unlabeled samples. By fully exploiting this brand-new constraint, we construct a consistent risk estimator to impose consistency between the negative expected risk of the positive samples and the positive expected risk of the negative samples. Moreover, we introduce Mixup regularization to mitigate the confirmation bias of the learned model, and meanwhile employ the entropy minimization technique to improve the separability of samples, which can further enhance classification performance. Experimental results on four benchmark datasets demonstrate the advantage of our model over several baseline methods. © 2012 IEEE.

Cross-domain transfer fault diagnosis by class-imbalanced deep subdomain adaptive network

Item Type Journal Article

Author J. Zhou

Author X. Zhang

Author H. Jiang

Author J. Li

Author Z. Shao

Abstract In variable working conditions and class imbalances, fault diagnosis in gearbox systems becomes difficult due to the difficulty in learning the classification boundaries of the minority class. Moreover, the diversity in fault mode distributions under various working conditions poses significant challenges for domain adaptation. To this end, this work proposed a Class-imbalanced Deep Subdomain Adaptive Network (CIDSAN) for complex cross-domain fault diagnosis scenarios involving feature and label shifts. We design a convolutional neural network embedded with SimAM (SimAM-CNN) to extract global feature information from time-domain vibration signals. Subsequently, a novel cost-sensitive classifier is presented for class re-weighting, along with a Joint Supervised Classifier that refines intra-class and inter-class distances by re-weighting class weights in the latent space using cost-sensitive classifiers while leveraging LDAM regularization to adjust classification boundaries. Diagnostic case studies on two datasets under various working conditions validate the effectiveness and superiority of the proposed approach. Cross-Lingual Sentiment Quantification

Item Type Journal Article

Author A. Esuli
Author A. Moreo
Author F. Sebastiani
Author E. Cambria

Abstract Sentiment Quantification is the task of estimating the relative frequency of sentiment-related classes-such as $\{\text{Positive}\}$ Positive and $\{\text{Negative}\}$ Negative-in a set of unlabeled documents. It is an important topic in sentiment analysis, as the study of sentiment-related quantities and trends across a population is often of higher interest than the analysis of individual instances. In this article, we propose a method for cross-lingual sentiment quantification, the task of performing sentiment quantification when training documents are available for a source language $\mathcal{S}$, but not for the target language $\mathcal{T}$, for which sentiment quantification needs to be performed. Cross-lingual sentiment quantification (and cross-lingual text quantification in general) has never been discussed before in the literature; we establish baseline results for the binary case by combining state-of-the-art quantification methods with methods capable of generating cross-lingual vectorial representations of the source and target documents involved. Experiments on publicly available datasets for cross-lingual sentiment classification show that the presented method performs cross-lingual sentiment quantification with high accuracy. © 2001-2011 IEEE.

CROSS-LINGUAL TRANSFER WITH CLASS-WEIGHTED LANGUAGE-INVARIANT REPRESENTATIONS

Item Type Conference Paper

Author R. Xian

Author H. Ji

Author H. Zhao

Abstract Recent advances in neural modeling have produced deep multilingual language models capable of extracting cross-lingual knowledge from non-parallel texts and enabling zero-shot downstream transfer. While their success is often attributed to shared representations, quantitative analyses are limited. Towards a better understanding, through empirical analyses, we show that the invariance of feature representations across languages-an effect of shared representations-strongly correlates with transfer performance. We also observe that distributional shifts in class priors between source and target language task data negatively affect performance, a largely overlooked issue that could cause negative transfer with existing unsupervised approaches. Based on these findings, we propose and evaluate a method for unsupervised transfer, called importance-weighted domain alignment (IWDA), that performs representation alignment with prior shift estimation and correction using unlabeled target language task data. Experiments demonstrate its superiority under large prior shifts, and show further performance gains when combined with existing semi-supervised learning techniques. © 2022 ICLR 2022 - 10th International Conference on Learning Representations. Cross-Modal Learning for CTC-Based ASR: Leveraging CTC-Bertscore and Sequence-Level Training

Item Type Conference Paper

Author M.-H. Lee

Author S.-E. Lee

Author J.-E. Choi

Author J.-H. Chang

Abstract Due to the nature of neural networks that easily overfit the training set, neural network-based speech recognition models are vulnerable to prior shifts in data distribution or unseen words. Therefore, studies have been conducted to overcome this problem by using language models trained with a relatively easy-to-obtain unpaired corpus. In this paper, we present a new training method that uses BERT to improve the performance of a connectionist temporal classification (CTC)-based ASR model. The proposed method follows a cross-modal learning scenario and induces the CTC model to better embed contextual information by utilizing an auxiliary objective function operating at the sequence level. We applied the proposed method to fine-tune the pre-trained wav2vec 2.0 model with CTC loss and confirmed that the proposed method improves the generalization performance of the ASR model. © 2023 IEEE.

CSNF-TimeGAN: Class-prior spatiotemporal nonlinear feature-based time series generative adversarial network for blast furnace fault diagnosis

Item Type Journal Article**Author** Y. Yang**Author** C. Yang**Author** S. Lou**Author** D. Gao**Author** X. Zhang**Author** W. Wang

Abstract Fault diagnosis for the blast furnace ironmaking process (BFIP) is vital to ensuring production stability and efficiency. However, it is challenged by the complex interplay of nonlinearity, dynamic behavior, spatial correlations, and a significant scarcity of labeled fault data. To overcome these limitations, a novel fault diagnosis method based on class-prior spatiotemporal nonlinear feature-based time series generative adversarial network (CSNF-TimeGAN) is proposed. First, we develop the class-prior spatial improved mixed kernel canonical variate analysis (CSI-MKCVA) to extract class-prior spatiotemporal nonlinear features (CSNF). Unlike existing kernel CVA variants, CSI-MKCVA introduces a novel mixed kernel architecture integrating radial basis, polynomial, and cosine kernels to capture local, global, and temporally correlated nonlinearities in a unified manner. The architecture is further enhanced by incorporating class-prior information and Laplacian regularization into covariance estimation, preserving the spatiotemporal dynamics while maximizing fault separability. An efficient alternating Lagrangian optimization algorithm ensures robust convergence. Second, CSNF-TimeGAN is proposed as a diagnosis-oriented generative framework that bridges advanced feature representation and synthetic data generation. Operating a Wasserstein GAN with gradient penalty in the CSNF space, the model achieves stable distribution matching. It innovates theoretically through a temporal consistency loss and an adaptive loss informed by classifier feedback, as formalized in new equations that mitigate mode collapse and enhance discriminability beyond standard GANs. Subsequently, an integrated fault diagnosis mechanism is designed, synergizing feature representation, data generation, and classification into a cohesive workflow. In deployment, real-time diagnosis leverages the unified CSNF feature extractor and optimized classifier, ensuring computational efficiency. Finally, CSNF-TimeGAN demonstrates leading-edge performance through validation on real BFIP operational data. © 2025 Elsevier Ltd.

Author A.E.F. Abbas

Abstract The novel anti-glaucoma ophthalmic preparation containing latanoprost, netarsudil, and benzalkonium chloride has posed a significant challenge due to its complexity and the lack of environmentally sustainable quantification methods, with only a single published method available for its quantification that lacks environmental

consideration. This study aims to address this crucial gap by presenting a novel and sustainable approach using machine learning-enhanced UV-spectrophotometric chemometric models for the concurrent quantification of latanoprost, netarsudil, benzalkonium chloride, and two related compounds in ophthalmic preparations and aqueous humour. A strategic multi-level, multi-factor experimental design creates a 25-mixture calibration set for four models (PLS, GA-PLS, PCR, and MCR-ALS). The key novelty was using the D-optimal design generated by MATLAB's candexch algorithm to construct a robust validation set, overcoming random data splitting limitations in machine learning chemometric methods and ensuring unbiased evaluation across concentrations. The optimized MCR-ALS model outperforms in predictive ability, with recovery percentages of 98–102%, low root mean square errors of calibration and prediction, favorable bias-corrected mean square error of prediction, relative root mean square error within acceptable limits, and adequate limits of detection for pharmaceutical analysis. The Greenness Index Spider Charts and the Green Solvents Selection Tool were applied to replace hazardous solvents. A total of seven advanced evaluation tools were employed to assess the method's greenness, blueness, violetness, and whiteness, highlighting its eco-friendly profile, practical relevance, and innovation potential. Additionally, the method's environmental and societal benefits were further validated using the Need, Quality, Sustainability (NQS) index. Overall, this machine learning-based framework contributes meaningfully to ten United Nations Sustainable Development Goals (UN-SDGs), underscoring its value for future-oriented pharmaceutical research. © The Author(s) 2025.

DACL-IDA: a dynamic alignment and compactness learning framework for imbalanced domain adaptation in bearing fault diagnosis

Item Type Journal Article

Author X. Peng

Author Y. Tao

Author L. Hua

Author K. Zhu

Abstract Existing unsupervised domain adaptation methods for bearing fault diagnosis under varying operating conditions generally assume identical class priors across domains, overlooking the label shift that arises in practice, where healthy-state samples far outnumber fault samples and fault-type frequencies vary with speed, load, and operating history. When feature shift and label shift coexist, prematurely introduced high-intensity alignment can severely degrade minority-class discriminability. We propose DACL-IDA (Dynamic alignment and compactness learning for imbalanced domain adaptation), built on an alignment-scheduling principle rather than a new alignment loss: global adversarial alignment is delayed until classification warmup and black-box shift estimation (BBSE) have stabilized, and is kept restrained thereafter. The BBSE estimate both re-weights the source loss and drives the scheduler, supported by intra-class compactness regularization and long-tailed optimization. A diagnostic experiment separating global adversarial from local class-conditional alignment shows that sustained class-conditional matching (local maximum mean discrepancy) progressively degrades the classifier under severe (reversed-prior) label shift; the final configuration therefore retains only the scheduled global adversarial alignment. On the Paderborn University dataset, under a strictly leakage-free protocol (fixed last-epoch reporting, no target-label model selection; 4 protocols $\times$ 12 transfer tasks $\times$ 5 seeds), DACL-IDA attains an overall mean balanced accuracy of 89.63% versus 81.30% for the strongest published competitor, DIDA (a deep imbalanced-domain-adaptation framework), winning three of the four protocols by more than 13 percentage points each (paired-t $p \leq 5.23 \times 10^{-4}$); on the remaining protocol (I2B), where scheduled alignment is counter-productive, it underperforms both DIDA and the source-only baseline—a failure reported and analyzed rather than omitted. DACL-IDA is also the most convergence-stable method in the stability comparison: outside I2B, its gap between best transient and final-epoch accuracy stays within 2.4 pp, versus 8.2–11.2 pp for DIDA. Cross-dataset experiments on the Case Western Reserve University dataset, a second backbone, imbalance ratios up to $\rho = 50$, and injected measurement noise support the reported behavior. © 2026 IOP Publishing Ltd. Damage State Recognition and Quantification Method for Shield Machine Hob Based on Deep Forest

Item Type Journal Article**Author** H. Wang**Author** Q. Gao**Author** S. Liu**Author** P. Liu**Author** X. Wang**Author** Y. Tian

Abstract The damage status of shield machine disc cutters directly impacts the safety and efficiency of tunnelling projects. Current manual inspection methods involve high risks and low efficiency, while existing detection methods suffer from low accuracy and poor real-time performance in complex environments, often lacking quantitative analysis capabilities. To address these issues, this paper proposes an intelligent identification and quantitative assessment method for disc cutter damage based on the Deep Forest (DF) model. First, an eddy current sensor calibration platform was established, and a mapping relationship between output voltage and actual wear was developed through piecewise fitting to achieve precise wear quantification. In the data preprocessing stage, signal quality was improved via filtering, and typical damage features such as edge chipping, cracks, and eccentric wear were extracted using pulse edge detection. These feature segments were then resampled to construct the model training dataset. The DF model utilizes a hierarchical ensemble structure to mine data correlations, enabling accurate identification of four states: normal, edge

chipping, eccentric wear, and cracks. Simultaneously, a DF regression model was employed to provide continuous quantitative predictions of damage size. Experimental results show that the classification model achieved accuracies of 98%, 96%, and 96% on the training, validation, and test sets, respectively, with weighted average F1-scores exceeding 0.96. The regression model achieved a coefficient of determination (R^2) of 0.9940 and a root mean square error (RMSE) of 0.4051 on the test set. Both models demonstrate excellent performance and generalization, achieving full coverage from “qualitative state identification” to “quantitative wear assessment,” thereby providing reliable decision support for cutter maintenance and replacement. © 2026 by the authors.

Abstract Data assimilation is a method of combining physical observations with prior knowledge (for instance, a computational simulation) in order to produce an improved estimate of the state of a system; that is, improved over what the physical observations or the computational simulation, alone, could offer. Recently, machine learning techniques have been deployed in order to address the significant computational burden that is associated with the procedures involved in data assimilation. In this paper we propose an approach that uses a non-intrusive reduced-order model (NIROM) as a surrogate for a high-resolution model thereby saving computational effort. The mismatch between observations and the surrogate model is propagated forwards and backwards in time in a manner similar to 4D-variational data assimilation methods. The observations and prior are reconciled in a new way which takes full advantage of the neural network used in the NIROM and also means that there is no need to form the sensitivities explicitly when propagating the mismatch. Instead, the observations are part of the input and output of the network. The key advantages of this data assimilation approach are its simplicity (as we can avoid differentiating the forward model and bypass the use of an optimisation method), and its ability to integrate with control and uncertainty quantification methodologies. Modelling the air quality in a school classroom is the test case for our demonstration. After comparing the proposed data assimilation approach with 4D Variational Data Assimilation, we investigate two scenarios. The first of these is a dual-twin type experiment, for which the proposed approach is shown to perform very well, and the second is a test case which assimilates predictions from the NIROM with observations collected from a classroom in Houndsfield Primary School. © 2024 The Author(s)

Data Augmentation and Clustering for Vehicle Make/Model Classification

Item Type Conference Paper

Author M. Nafzi

Author M. Brauckmann

Author T. Glasmachers

Editor Arai K.

Editor Kapoor S.

Editor Bhatia R.

Abstract Vehicle shape information is very important in Intelligent Traffic Systems (ITS). In this paper, we present a way to exploit a training data set of vehicles released in different years and captured under different perspectives. Also the efficacy of clustering to enhance the make/model classification is presented. Both steps led to improved classification results and a greater robustness. Deeper convolutional neural network based on ResNet architecture has been designed for the training of the vehicle make/model classification. The unequal class distribution of training data produces an a priori probability. Its elimination, obtained by removing of the bias and through hard normalization of the centroids in the classification layer, improves the classification results. A developed application has been used to test the vehicle re-identification on video data manually based on make/model and color classification. This work was partially funded under the grant. © 2020, Springer Nature Switzerland AG.

Data driven and neural network based approaches for optimization of film cooling parameters in gas turbines—A Comprehensive Review, Challenges and Future Trends

Item Type Journal Article

Author V.G. Krishna Anand

Author V. Baiju

Abstract Artificial intelligence and machine learning approaches are widely adopted for the optimization of multiple input parameters of complex thermal systems. The film cooling (FC) performance of gas turbines depends on various flow, geometric, and evaluation parameters. The optimization of these parameters is vital for the efficient design of FC systems. In this study, various data-driven and neural network-based optimization approaches applied for the optimization of geometric and flow parameters in gas turbines were summarized in detail. This study comprehensively reviews 216 articles spanning from 2005 to early 2025. The optimization approaches

were grouped into six categories: surrogate-based, machine learning-based, deep learning-based, Taguchi-based, multi-criteria decision-making-based, topology-based optimization, and other novel methods. Each optimization approach was elucidated extensively for its application to different gas turbine components, the predictive model used, input parameters, response parameter, generation of training samples, search algorithm, and factor level. The various parameters of the gas turbine FC used in the optimization are explained in detail. The uncertainty quantification method, uncertainty parameters, and distribution type applied to the gas turbine wall surface were compared and discussed in this study. In addition, the challenges involved in the implementation of optimization approaches and future research trends on gas turbine FC optimization are highlighted. © 2026 Elsevier Ltd.

Data on consistency among different methods to assess atherosclerotic plaque echogenicity on standard ultrasound and intraplaque neovascularization on contrast-enhanced ultrasound imaging in human carotid artery

Item Type Journal Article**Author** M. Cattaneo**Author** D. Staub**Author** A.P. Porretta**Author** J.M. Gallino**Author** P. Santini**Author** C. Limoni**Author** R. Wyttenbach**Author** A. Gallino

Abstract Here we provide the correlation among different carotid ultrasound (US) variables to assess echogenicity n standard carotid US and to assess intraplaque neovascularization on contrast enhanced US. We recruited 45 consecutive subjects with an asymptomatic $\geq 50\%$ carotid artery stenosis. Carotid plaque echogenicity at standard US was visually graded according to Gray–Weale classification (GW) and measured by the greyscale median (GSM), a semi-automated computerized measurement performed by Adobe Photoshop®. On CEUS imaging IPNV was graded according to the visual appearance of contrast within the plaque according to three different methods: CEUS_A (1=absent; 2=present); CEUS_B a three-point scale (increasing IPNV from 1 to 3); CEUS_C a four-point scale (increasing IPNV from 0 to 3). We have also implemented a new simple quantification method derived from region of interest (ROI) signal intensity ratio as assessed by QLAB software. Further information is available in “Contrast-enhanced ultrasound imaging of intraplaque neovascularization and its correlation to plaque echogenicity in human carotid arteries atherosclerosis (M. Cattaneo, D. Staub, A.P. Porretta, J.M. Gallino, P. Santini, C. Limoni et al., 2016) [1]. © 2016 The Authors

DATA PRUNING BY INFORMATION MAXIMIZATION

Item Type Conference Paper

Author H. Tan

Author S. Wu

Author W. Huang

Author S. Zhao

Author X. Qi

Abstract In this paper, we present InfoMax, a novel data pruning method, also known as coreset selection, designed to maximize the information content of selected samples while minimizing redundancy. By doing so, InfoMax enhances the overall informativeness of the coreset. The information of individual samples is measured by importance scores, which capture their influence or difficulty in model learning. To quantify redundancy, we use pairwise sample similarities, based on the premise that similar samples contribute similarly to the learning process. We formalize the coreset selection problem as a discrete quadratic programming (DQP) task, with the objective of maximizing the total information content, represented as the sum of individual sample contributions minus the redundancies introduced by similar samples within the coreset. To ensure practical scalability, we introduce an efficient gradient-based solver, complemented by sparsification techniques applied to the similarity matrix and dataset partitioning strategies. This enables InfoMax to seamlessly scale to datasets with millions of samples. Extensive experiments demonstrate the superior performance of InfoMax in various data pruning tasks, including image classification, vision-language pre-training, and instruction tuning for large language models. © 2025 13th International Conference on Learning Representations, ICLR 2025. Data-driven analysis of EV public charging station demand across heterogeneous built environment

Item Type Journal Article

Author J. Tian

Author S. Li

Author Z. Zheng

Author Q. Zhang

Abstract Public charging stations (PCS) have become critical infrastructure in urban transportation systems. PCS charging demand patterns are driven by complex mechanisms that conventional methods struggle to quantify, while the influence of the built environment (BE) remains underexplored. An integrated empirical framework is proposed that combines machine learning and causal inference models to analyze PCS demand patterns and generate evidence-based policy implications. Specifically, XGBoost with partial dependence plots is employed to predict demand, identify key determinants, and reveal nonlinear relationships, followed by double machine learning to quantify the causal effects of critical policy-relevant factors. We construct a real-world charging dataset incorporating BE, temporal, and price attributes for empirical analysis. Results show that charging demand is shaped by public transport accessibility and the spatial configuration of PCS. Electricity price has a stronger negative impact in areas farther away from subway stations. These findings support optimized charging infrastructure planning and targeted policy interventions. © 2026 Elsevier Ltd. Data-Driven Approach to Analyzing Factors Influencing Construction Accident Severity Using SHAP Analysis

Item Type Journal Article

Author J. Son

Author J. Jeong

Author J. Jeong

Author L. Kumi

Author H. Mun

Abstract Despite advances in construction safety research, existing studies face critical limitations, including severe data imbalance in accident severity classification and lack of interpretable machine-learning models for factor contribution analysis. This study addresses these gaps by combining extreme gradient boosting (XGBoost) with Shapley additive explanation (SHAP) analysis to quantitatively evaluate key factors influencing construction accident severity based on workday loss. Advanced oversampling techniques resolved class imbalance among severity levels (fatal, very serious, serious, and minor), while hyperparameter tuning optimized model performance. The analysis identified the top five factors influencing accident severity: original cause material (55.76), accident month (46.38), project scale

(40.17), PET range (29.04), and age (21.53). The XGBoost-SHAP framework successfully demonstrated superior performance in accident prediction while providing interpretable factor contributions, validating workday loss as an effective severity quantification method. The findings enable risk assessment in large-scale projects and extreme environmental conditions, offering a scientific basis for developing targeted accident prevention strategies and optimizing safety resource allocations. © 2025 American Society of Civil Engineers.

Data-driven machine-learning quantifies differences in the voiding initiation network in neurogenic voiding dysfunction in women with multiple sclerosis

Item Type Journal Article

Author C. Karmonik

Author T. Boone

Author R. Khavari

Abstract Purpose: To quantify the relative importance of brain regions responsible for reduced functional connectivity (FC) in their Voiding Initiation Network in female multiple sclerosis (MS) patients with neurogenic lower urinary tract dysfunction (NLUTD) and voiding dysfunction (VD). A data-driven machine-learning approach is utilized for quantification. Methods: Twenty-seven ambulatory female patients with MS and NLUTD (group 1: voiders, n = 15 and group 2: VD, n = 12) participated in a functional magnetic resonance imaging (fMRI) voiding study. Brain activity was recorded by fMRI with simultaneous urodynamic testing. The Voiding Initiation Network was identified from averaged fMRI activation maps. Four machine-learning algorithms were employed to optimize the area under curve (AUC) of the receiver-operating characteristic curve. The optimal model was used to identify the relative importance of relevant brain regions. Results: The Voiding Initiation Network exhibited stronger FC for voiders in frontal regions and stronger disassociation in cerebellar regions. Highest AUC values were obtained with 'random forests' (0.86) and 'partial least squares' algorithms (0.89). While brain regions with highest relative importance (> 75%) included superior, middle, inferior frontal and cingulate regions, relative importance was larger than 60% for 186 of the 227 brain regions of the Voiding Initiation Network, indicating a global effect. Conclusions: Voiders and VD patients showed distinctly different FC in their Voiding Initiation Network. Machine-learning is able to identify brain centers contributing to these observed differences. Knowledge of these centers and their connectivity may allow phenotyping patients to centrally focused treatments such as cortical modulation. © 2019 Korean Continence Society

Abstract Purpose: Cells are building blocks for human physiology; consequently, understanding the way cells communicate, co-locate, and interrelate is essential to furthering our understanding of how the body functions in both health and disease. Hematoxylin and eosin (H&E) is the standard stain used in histological analysis of tissues in both clinical and research settings. Although H&E is ubiquitous and reveals tissue microanatomy, the classification and mapping of cell subtypes often require the use of specialized stains. The recent CoNIC Challenge focused on artificial intelligence classification of six types of cells on colon H&E but was unable to classify epithelial subtypes (progenitor, enteroendocrine, goblet), lymphocyte subtypes (B, helper T, cytotoxic T), and connective subtypes (fibroblasts). We propose to use inter-modality learning to label previously un-labelable cell types on H&E. Approach: We took advantage of the cell classification information inherent in multiplexed immunofluorescence (MxIF) histology to create cell-level annotations for 14 subclasses. Then, we performed style transfer on the MxIF to synthesize realistic virtual H&E. We assessed the efficacy of a supervised learning scheme using the virtual H&E and 14 subclass labels. We evaluated our model on virtual H&E and real H&E. Results: On virtual H&E, we were able to classify helper T cells and

epithelial progenitors with positive predictive values of 0.34 ± 0.15 (prevalence 0.03 ± 0.01) and 0.47 ± 0.1 (prevalence 0.07 ± 0.02), respectively, when using ground truth centroid information. On real H&E, we needed to compute bounded metrics instead of direct metrics because our fine-grained virtual H&E predicted classes had to be matched to the closest available parent classes in the coarser labels from the real H&E dataset. For the real H&E, we could classify bounded metrics for the helper T cells and epithelial progenitors with upper bound positive predictive values of 0.43 ± 0.03 (parent class prevalence 0.21) and 0.94 ± 0.02 (parent class prevalence 0.49) when using ground truth centroid information. Conclusions: This is the first work to provide cell type classification for helper T and epithelial progenitor nuclei on H&E. © 2024 SPIE. All rights reserved.

Data-Driven Tooth Selection Enhances Partial-Mouth Periodontal Screening

Item Type Journal Article

Author N. Lin

Author C. Wang

Author Y. Shan

Author Z. Wu

Abstract The high prevalence of periodontitis has imposed a significant global disease burden. Epidemiologic surveys rely on full-mouth periodontal examination (FMPE) or partial-mouth periodontal examination (PMPE). While FMPE is resource-intensive, the efficiency of PMPE remains questionable. Moreover, the value of subpopulation-tailored PMPE protocols is still unassessed. To address these gaps, we developed an interpretable, data-driven framework that ranks the importance of teeth using SHapley Additive exPlanations (SHAP) values from machine learning models. Using data from the National Health and Nutrition Examination Survey 2009–2014, XGBoost (XGB) and LightGBM (LGB) were trained on maximum interproximal probing depth and clinical attachment loss across 28 teeth from adults aged 35 y and older. Absolute SHAP values were aggregated separately for each model to calculate global tooth importance. The top 10 teeth were then evaluated and benchmarked against the Community Periodontal Index (CPI) and modified Ramfjord protocol. Primary outcomes included quadratic weighted kappa (QWK) for diagnostic agreement with FMPE and the inflation factor (IF) for prevalence estimation bias. The XGB-derived protocol (FDI 47, 27, 17, 26, 37, 16, 42, 46, 36, 41) achieved QWK = 0.85 and IF = 127.29% in the external validation set, with significantly lower IF than CPI (P = 0.003), indicating its potential to replace CPI. Further optimization for age- and gender-specific protocols occasionally yielded localized improvements, such as males aged 55 to 64 y (teeth 17, 16, 27, 47, 26, 33, 45, 37, 43, 25), while the unified XGB-derived protocol remained robust across all strata. These findings support the general use of a unified, data-driven protocol for large-scale epidemiological surveys. SHAP-guided tooth selection offers an interpretable and efficient alternative to traditional PMPE, bridging the gap between accuracy and feasibility in large-scale periodontal surveys. © International Association for Dental, Oral, and Craniofacial Research and American Association for Dental, Oral, and Craniofacial Research 2026

Data-driven versus conventional N₂O EF quantification methods in wastewater; how can we quantify reliable annual EFs?

Item Type Journal Article**Author** V. Vasilaki**Author** S. Danishvar**Author** A. Mousavi**Author** E. Katsou

Abstract A long-term N₂O dataset from a full-scale biological process was analysed for knowledge discovery. Non-parametric, multivariate timeseries changepoint detection techniques were applied to operational variables (i.e. NH₄-N loads) in the system. The majority of changepoints, could be linked with the observed changes of the N₂O emissions profile. The results showed that even three-day sampling campaigns between changepoints have a high probability (>80%) to result to an emission factor (EF) quantification with ~10% error. The analysis revealed that support vector machine (SVM) classification models can be trained to detect operational behaviour of the system and the expected range of N₂O emission loads. The proposed approach can be applied when long-term online sampling is not feasible (due to budget or

equipment limitations) to identify N₂O emissions “hotspot” periods and guide towards the identification of operational periods requiring extensive investigation of N₂O pathways generation. © 2020

Data-Efficient Computational Pathology Platform for Faster and Cheaper Breast Cancer Subtype Identifications: Development of a Deep Learning Model

Item Type Journal Article

Abstract Background: Breast cancer subtyping is a crucial step in determining therapeutic options, but the molecular examination based on immunohistochemical staining is expensive and time-consuming. Deep learning opens up the possibility to predict the subtypes based on the morphological information from hematoxylin and eosin staining, a much cheaper and faster alternative. However, training the predictive model conventionally requires a large number of histology images, which is challenging to collect by a single institute. Objective: We aimed to develop a data-efficient computational pathology platform, 3DHistoNet, which is capable of learning from z-stacked histology images to accurately predict breast cancer subtypes with a small sample size. Methods: We retrospectively examined 401 cases of patients with primary breast carcinoma diagnosed between 2018 and 2020 at the Department of Pathology, National Cancer Center, South Korea. Pathology slides of the patients with breast carcinoma were prepared according to the standard protocols. Age, gender, histologic grade, hormone receptor (estrogen receptor [ER], progesterone receptor [PR], and androgen receptor [AR]) status, erb-B2 receptor tyrosine kinase 2 (HER2) status, and Ki-67 index were evaluated by reviewing medical charts and pathological records. Results: The area under the receiver operating characteristic curve and decision curve were analyzed to evaluate the performance of our 3DHistoNet platform for predicting the ER, PR, AR, HER2, and Ki67 subtype biomarkers with 5-fold cross-validation. We demonstrated that 3DHistoNet can predict all clinically important biomarkers (ER, PR, AR, HER2, and Ki67) with performance exceeding the conventional multiple instance learning models by a considerable margin (area under the receiver operating characteristic curve: 0.75-0.91 vs 0.67-0.8). We further showed that our z-stack histology scanning method can make up for insufficient training data sets without any additional cost incurred. Finally, 3DHistoNet offered an additional capability to generate attention maps that reveal correlations between Ki67 and histomorphological features, which renders the hematoxylin and eosin image in higher fidelity to the pathologist. Conclusions: Our stand-alone, data-efficient pathology platform that can both generate z-stacked images and predict key biomarkers is an appealing tool for breast cancer diagnosis. Its development would encourage morphology-based diagnosis, which is faster, cheaper, and less error-prone compared to the protein quantification method based on immunohistochemical staining. © Kideog Bae, Young Seok Jeon, Yul Hwangbo, Chong Woo Yoo, Nayoung Han, Mengling Feng.

Data-Free Network Debiasing for Long-Tailed Visual Recognition

Item Type Conference Paper

Author J. Cai

Author Z. Wang

Author H. Fu

Author J. Chen

Author Y.-G. Jiang

Abstract Real-world data is often unbalanced and exhibits long-tailed distribution over classes. Vanilla classification models trained on imbalanced datasets inherently exhibit bias towards dominant classes. Existing debiasing methods mostly balance the data or the loss during training. Nevertheless, these data-acquiring methods are not suitable for situations where training data are unavailable. In this paper, we appeal to solutions without access to training data and propose a datafree debiasing (Free-D) method that serves as a plug-and-play module for any standard classification model. Specifically, our method adjusts both the feature representation via feature representation shifting and the classifier weight via class prior compensation in a data-free manner. We evaluate and compare our methods on four long-tailed visual recognition datasets, i.e., long-tailed CIFAR-10/-100, ImageNet-LT, and Places-LT. Extensive experiments demonstrate that the proposed data-free method achieves comparable results of other data-acquired methods. © 2022 IEEE.

Dating skeletal remains with luminol-chemiluminescence. Validity, intra- and interobserver error

Item Type Journal Article

Author F. Ramsthaler

Author K. Kreutz

Author K. Zipp

Author M.A. Verhoff

Abstract Amongst numerous other morphological, chemical, physical, and histological dating methods, the assessment of the chemiluminescence of weathered organic traces on bone finds by means of the luminol reaction is common practice. Opinion differs on the diagnostic value of this procedure for differentiating between historical and recent skeletonized human remains. Design: Chemiluminescence (CL) was tested in randomized, blind experiments on pulverized bone samples with known postmortem intervals from four different periods (1st-3rd century, 1878-1902, 1965-1972,

1995-2003). In addition to determining the sensitivity and specificity of the CL-analysis, likelihood ratios and predictive values were calculated. The degree of interobserver and intraobserver agreement was determined using Kappa statistics. Results: Based on our sample, we found false positive results in approximately 7.5% of all examined historical cases and false negative results in approximately 15% of the recent samples. Altogether, a correct classification of 88.75% (overall classification) was found (sensitivity = 0.85, specificity = 0.925; likelihood ratio = 11.3; odds ratio = 69.8). Taking a-priori probabilities into consideration (prevalence for recent = 26%), a positive predictive value (PPV) of only 79.9% could be calculated, while the negative predictive value (NPV) lay at 94.6%. The results from subsequent Kappa statistics further illustrated that the quality of the results was, on the whole, observer independent ($\kappa = 0.93$; 95% CI = 0.84-1.0). Intraobserver bias calculation yielded a value of $\kappa = 0.975$ (95% CI = 0.92-1.0). Conclusion: The analysis of CL on dry bones in determining the postmortem interval is not valid as an only method. In other respects, the luminol test is reproducible, repeatable and cost-effective and could help in assessing the postmortem interval (PMI). The results of this study document the potential danger of forensically relevant cases being erroneously sorted out if further examinations do not take place. We would like to emphasize that still only a combination of different methods including the analysis of environmental conditions and the interpretation of the anthropological profile can allow an acceptable estimate of the PMI from skeletonized remains, even if the methodological spectrum is being expanded by different absolute dating methods using radionuclide techniques. © 2009 Elsevier Ireland Ltd. De-migration-based supervised learning for interpolation and regularization of 3D offset classes

Item Type Journal Article

Author V. Hlebnikov

Author T.A.L. Greiner

Author V. Vinje

Author J.E. Lie

Author G. Poole

Abstract Regularization and interpolation of 3D offset classes prior to imaging are an important and challenging step in the marine seismic data processing flow. Here we describe how to perform this task using a deep neural network, and we explain how to overcome the challenge of creating a suitable training data set. The training data set is generated by de-migrating stacked pre-stack depth migration images. For each offset class volume, we de-migrate the pre-stack depth migrated stacked image into two configurations: (i) the original survey configuration consisting of the recorded source/receiver positions and (ii) an ‘Ideal’ survey configuration with constant offset and azimuth for each 3D offset class. The training creates a 3D convolutional encoder–decoder model that will regularize and interpolate seismic data. The convolutional encoder–decoder is trained on 3D sliding windows in each 3D offset cube to map from (i) to (ii), i.e. to map the original survey configuration with irregular and sparse sampling into the fully sampled regular offset cubes suitable for offset-based migration, such as Kirchhoff migration. Such migration algorithms rely on regular and sufficiently dense sampling to achieve constructive interference to image the structures and destructive interference to suppress migration noise. We test the new method on one synthetic and one field data example and show that it performs better than a standard regularization/interpolation method based on anti-leakage Fourier transform, especially for the smallest offset classes. On the synthetic data, we also demonstrate that the convolutional encoder–decoder method preserves the amplitude versus offset as well as the standard method. © 2022 CGG Services Norway AS. Decision aggregation in distributed classification by a transductive extension of maximum entropy/improved iterative scaling

Item Type Journal Article

Author D.J. Miller

Author Y. Zhang

Author G. Kesidis

Abstract In many ensemble classification paradigms, the function which combines local/base classifier decisions is learned in a supervised fashion. Such methods require common labeled training examples across the classifier ensemble. However, in some scenarios, where an ensemble solution is necessitated, common labeled data may not exist: (i) legacy/proprietary classifiers, and (ii) spatially distributed and/or multiple modality sensors. In such cases, it is standard to apply fixed (untrained) decision aggregation such as voting, averaging, or naive Bayes rules. In recent work, an alternative transductive learning strategy was proposed. There, decisions on test samples were chosen aiming to satisfy constraints measured by each local classifier. This approach was shown to reliably correct for class prior mismatch and to robustly account for classifier dependencies. Significant gains in accuracy over fixed aggregation rules were demonstrated. There are two main limitations of that work. First, feasibility of the constraints was not guaranteed. Second, heuristic learning was applied. Here, we overcome these problems via a transductive extension of maximum entropy/improved

iterative scaling for aggregation in distributed classification. This method is shown to achieve improved decision accuracy over the earlier transductive approach and fixed rules on a number of UC Irvine datasets.

Decision support system for the diagnosis of Parkinson's disease

Item Type Conference Paper

Author A. Ericsson

Author M.N. Lonsdale

Author K. Astrom

Author L. Edenbrandt

Author L. Friberg

Abstract Recently new nuclear medical diagnostic imaging methods have been introduced by which it is possible to diagnose Parkinson's disease, PD, at an early stage. The binding of a specific receptor ligand [¹²³I]-FP-CIT in specific structures of the human brain is visualized by way of single photon emission computerized tomography, SPECT. The interpretation of the SPECT data can be accessed by visual analysis and manual quantification methods. We have developed a computer aided automatic decision support system in attempt to facilitate the diagnosis of Parkinson's disease from the acquired SPECT images. A rigid model

was used for the segmentation of the basal ganglia of the human brain. The aim of the study was to develop an automated method for quantification and classification of the images. The study comprises SPECT scans 89 patients, who underwent a [123I]-FP-CIT examination because of suspected Parkinson's disease. An experienced nuclear medicine physician interpreted the images and diagnosed 65 of the patients as most likely suffering from Parkinson's disease. The method included the following steps; (i) segmentation of basal ganglia by fitting a rigid 3D model to the image, (ii) extraction of 17 features based on image intensity distribution in the basal ganglia and a reference based on image intensity distribution outside the basal ganglia, (iii) classification using Support Vector Machine (SVM). The classification based on the automated method showed a true acceptance of 96.9% and a true rejection of 91.6%. The classification based on a manual quantification method gave a true acceptance of 98.5% and a true rejection of 100%. The method proposed here is fully automatic and it makes use of the full 3D data set in contrast to a method that is widely used at hospitals today which only uses a few 2D image slices. © Springer-Verlag Berlin Heidelberg 2005.

Decision tree enhancer (DTE): Improving decision trees with optimization

Item Type Journal Article**Author** F.A. Lim-Apo**Author** F. Oliveira**Author** S. Hamacher

Abstract Decision trees are off-the-shelf machine learning models widely used for classification and regression tasks in medical, logistics, financial, and other critical areas where interpretability is a key factor. They can efficiently handle numerical and categorical variables, making them a versatile choice for various applications. However, traditional decision-tree training methods are based on greedy heuristics, which cannot provide guarantees regarding whether further improvements could be achieved. We propose Decision Tree Enhancer (DTE), which employs optimization as a post-training step to improve previously trained decision trees. Moreover, the proposed method precludes the need for a pre-processing step for continuous features such as discretization or bucketization, and can be applied regardless of the model used to first train the decision tree. Lastly, DTE's mathematical programming formulation enables, for example, the consideration of recall thresholds and class prioritization. Tested on 63 classification datasets from the UCI Machine Learning Repository, using tree depths from 1 to 5, four time limits (1, 5, 10, and 30 s), and 5 randomized train-test splits for cross-validation, the proposed post-training step demonstrated superior performance over CART (Classification And Regression Tree), for both in- and out-of-sample data. With a 30 s time limit, DTE was able to improve the weighted recall in 83.2% of the datasets with an average improvement of 9.0% in training and 5.0% in testing. © 2026 The Author(s)

Abstract The mitochondrial DNA (mtDNA) is replicated and canonically functions within intracellular mitochondria, but recent discoveries reveal that the mtDNA has another exciting extracellular life. mtDNA fragments and mitochondria-containing vesicular structures are detected at high concentrations in cell-free forms, in different biofluids. Commonly referred to as cell-free mtDNA (cf-mtDNA), the field is currently without a comprehensive classification system that acknowledges the various biological forms of mtDNA and whole mitochondria existing outside the cell. This absence of classification hampers the creation of precise and consistent quantification methods across different laboratories, which is crucial for unraveling the molecular and biological characteristics of mtDNA. In this article, we integrate recent findings to propose a classification for different types of Extracellular mtDNA [ex-mtDNA]. The major biologically distinct types include: Naked mtDNA [N-mtDNA], mtDNA within non-mitochondrial Membranes [M-mtDNA], Extracellular mitochondria [exM-mtDNA], and mtDNA within Mitochondria enclosed in a Membrane [MM-mtDNA]. We outline the challenges associated with accurately quantifying these ex-mtDNA types, suggest potential physiological roles for each ex-mtDNA type, and explore how this classification could establish a foundation for future research endeavors and further analysis and definitions for ex-mtDNA. By proposing this classification of circulating mtDNA forms, we draw a parallel with the clinically recognized forms of cholesterol, such as HDL and LDL, to illustrate potential future significance in a similar manner. While not directly analogous, these mtDNA forms may one day be as biologically relevant in clinical interpretation as cholesterol fractions are currently. We also discuss how advancing methodologies to reliably quantify distinct ex-mtDNA forms could significantly enhance their utility as health or disease biomarkers, and how their application may offer innovative therapeutic approaches. © 2024 Elsevier B.V. and Mitochondria Research Society

Abstract Purpose: The dual-energy computed tomography (DECT) technique is an emerging imaging tool that can better characterize material features and has the potential to be a noninvasive means of predicting lymph node metastasis. The purpose of this study was to establish a DECT-specified quantitative approach based on a neural network to characterize the sentinel lymph node (SLN). Methods: With IRB approval, we retrospectively collected a total of 229 patients (100/229 metastasis) with biopsy proven breast cancer in this study. The chest and axillary spectral CT examinations were performed prior to the axillary lymph node (ALN) surgery. A decoupling convolution network with 11 ROIs from sequential keV (40 to 140 keV with 10 keV increment) was proposed to explicitly extract the spectral and spatial features in a DECT to predict the lymph node status. Focal loss was introduced as the loss function. The metric of the slope of the spectral Hounsfield unit curve measured at the venous phase was used as the baseline approach in comparison to our approach. In additional, a logistic model with radiomic features was also compared to our approach. The area under ROC curve (AUC) was used as the figure of merit to evaluate the classification performance. Results: By introducing spectral convolution and focal loss, AUC on test set could be improved by 0.15 and 0.01 separately. Compared to the slope of the spectral curve with the average AUC of 0.611 and radiomic model with AUC of 0.825, the proposed approach demonstrates a considerably better performance, with test set AUC value of 0.837, by using decoupling spectral and spatial convolution together with focal loss function. Conclusions: We presented a new decoupling neural network based quantification method for DECT analysis, which might have potential as a noninvasive tool to predict metastasis lymph node status for breast cancer in clinical practice. © 2021 American Association of Physicists in Medicine

Abstract Purpose: Real-time spiral phase contrast MR (PCMR) enables rapid free-breathing assessment of flow. Target spatial and temporal resolutions require high acceleration rates often leading to long reconstruction times. Here we propose a deep artifact suppression framework for fast and accurate flow quantification. Methods: U-Nets were trained for deep artifact suppression using 520 breath-hold gated spiral PCMR aortic datasets collected in congenital heart disease patients. Two spiral trajectories (uniform and perturbed) and two losses (Mean Absolute Error -MAE- and average

structural similarity index measurement -SSIM-) were compared in synthetic data in terms of MAE, peak SNR (PSNR) and SSIM. Perturbed spiral PCMR was prospectively acquired in 20 patients. Stroke Volume (SV), peak mean velocity and edge sharpness measurements were compared to Compressed Sensing (CS) and Cartesian reference. Results: In synthetic data, perturbed spiral consistently outperformed uniform spiral for the different image metrics. U-Net MAE showed better MAE and PSNR while U-Net SSIM showed higher SSIM based metrics. In-vivo, there were no significant differences in SV between any of the real-time reconstructions and the reference standard Cartesian data. However, U-Net SSIM had better image sharpness and lower biases for peak velocity when compared to U-Net MAE. Reconstruction of 96 frames took ~59 s for CS and 3.9 s for U-Nets. Conclusion: Deep artifact suppression of complex valued images using an SSIM based loss was successfully demonstrated in a cohort of congenital heart disease patients for fast and accurate flow quantification. © 2021

Abstract To compensate for incomplete or imprecise tags in training samples, this paper proposes a learning algorithm for the convolutional neural network (CNN) for multi-label image annotation by introducing co-occurrence dependency between tags as a graph Laplacian regularization term. To exploit the co-occurrence dependency, we apply Hayashi's quantification method-type III to the tags in the training samples and use the distances between the acquired representative vectors to define the weights for graph Laplacian regularization. By introducing this regularization term, the possibility of co-occurrence between tags with high co-occurrence frequency can be increased. To confirm the effectiveness of the proposed algorithm, we have done experiments using Corel5k's dataset for multi-label image annotation. © Springer International Publishing AG 2017.

Abstract The aim of this work is to develop and evaluate a deep classifier that can effectively prioritize Emergency Medical Call Incidents (EMCI) according to their life-threatening level under the presence of dataset shifts. We utilized a dataset consisting of 1 982 746 independent EMCI instances obtained from the Health Services Department of the Region of Valencia (Spain), with a time span from 2009 to 2019 (excluding 2013). The dataset includes free text dispatcher observations recorded during the call, as well as a binary variable indicating whether the event was life-threatening. To evaluate the presence of dataset shifts, we examined prior probability shifts, covariate shifts, and concept shifts. Subsequently, we designed and implemented four deep Continual Learning (CL) strategies—cumulative learning, continual fine-tuning, experience replay, and synaptic intelligence—alongside three deep CL baselines—joint training, static approach, and single fine-tuning—based on DistilBERT models. Our results demonstrated evidence of prior probability shifts, covariate shifts, and concept shifts in the data. Applying CL techniques had a statistically significant ($\alpha=0.05$) positive impact on both backward and forward knowledge transfer, as measured by the F1-score, compared to non-continual approaches. We can argue that the utilization of CL techniques in the context of EMCI is effective in adapting deep learning classifiers to changes in data distributions, thereby maintaining the stability of model performance over time. To our knowledge, this study represents the first exploration of a CL approach using real

EMCI data. © 2024 The Author(s)

Abstract Alzheimer's disease (AD) is a prevalent neurodegenerative disorder where early diagnosis is pivotal for effective intervention, yet it is hindered by subtle pathological feature differences among AD subtypes and severe class imbalance in medical imaging datasets. Existing structural magnetic resonance imaging (sMRI) and resting-state functional MRI (rs-fMRI) multimodal fusion methods for AD diagnosis mostly adopt simple concatenation or summation without fine-grained cross-modal alignment and interaction. To address these issues, we propose a Deep Cross-Branch Multi-Modal Fusion Network (DCMFNet) for early AD diagnosis. We first preprocess sMRI and rs-fMRI to extract ROI-based features, then perform dimension unification and normalization to realize cross-modal feature alignment. A novel Deep Cross-branch Multi-modal Feature Fusion (DCMF) module with three parallel branches and a dual-pathway cross-modal branch is designed to fully mine complementary and correlated cross-modal information, and the fused features are input into a Transformer encoder for classification. Moreover, we introduce the Logit Adjustment Cross-Entropy (LACE) loss to mitigate class imbalance by correcting decision boundaries based on class prior probabilities, enhancing the recognition of minor classes. The model is evaluated on a private clinical dataset. Experimental results show that DCMFNet outperforms traditional machine learning methods and state-of-the-art deep learning models in six binary AD subtype classification tasks, with the LACE loss and DCMF module effectively alleviating class imbalance and improving cross-modal feature representation. This work provides a reliable multimodal fusion framework for early AD diagnosis and reduces the diagnostic burden on healthcare professionals. © 2026 Elsevier B.V.

Abstract Empirical studies show that federated learning exhibits convergence issues in Non Independent and Identically Distributed (IID) setups. However, these studies only focus on label distribution shifts, or concept shifts (e.g. ambiguous tasks). In this paper, we explore for the first time the effect of covariate shifts between participants' data in 2D segmentation tasks, showing an impact way less serious than label shifts but still present on convergence. Moreover, current Personalized (PFL) and Clustered (CFL) Federated Learning methods intrinsically assume the homogeneity of the dataset of each participant and its consistency with future test samples by operating at the client level. We introduce a more general and realistic framework where each participant owns a mixture of multiple underlying feature domain distributions. To diagnose such pathological feature distributions affecting a model being trained in a federated fashion, we develop Deep Domain Isolation (DDI) to isolate image domains directly in the gradient space of the model. A federated Gaussian Mixture Model is fit to the sample gradients of each class, while the results are combined with spectral clustering on the server side to isolate decentralized sample-level domains. We leverage this clustering algorithm through a Sample Clustered Federated Learning (SCFL) framework, performing standard federated learning of several independent models, one for each decentralized image domain. Finally, we train a classifier enabling to associate a test sample to its corresponding domain cluster at inference time, offering a final set of models that are agnostic to any assumptions on the test distribution of each participant. We validate our approach on a toy segmentation dataset as well as different partitionings of a combination of Cityscapes and GTA5 datasets using an EfficientViT-B0 model, showing a significant performance gain compared to other approaches. Our code is available at https://github.com/MatthisManthe/DDI_SCFL. © The Author(s), under exclusive license to Springer Nature Switzerland AG 2024.

Deep imbalanced domain adaptation for transfer learning fault diagnosis of bearings under multiple working conditions

Item Type Journal Article

Author C.-G. Lee

Abstract The tremendous success of deep learning and transfer learning broadened the scope of fault diagnosis, especially the latter further improved the diagnosis accuracy under multiple working conditions. However, most existing attempts assume that label distribution is domain-invariant despite taking into account the different feature distributions. This does not accommodate the diversity of fault mode distributions under different operating conditions and weakens the generalization to imbalanced domain adaptation (IDA) scenarios. Therefore, this work proposed a novel deep imbalanced domain adaptation (DIDA) framework for fault diagnosis of bearings, aiming at the challenging scenario where feature shift and label shift exist simultaneously under different working conditions. Specifically, DIDA overcomes the class-imbalanced label shift and achieves a fine-grained latent space matching by cost-sensitive learning and categorical alignment. Besides, margin loss regularization is introduced to further optimize classification boundaries and improve cross-domain generalization for IDA fault diagnosis tasks. Finally, we simulated the IDA protocols on experimental datasets and conducted case studies under multiple working conditions, thus validating the effectiveness and superiority of the proposed framework. © 2022 Elsevier Ltd

Deep Imbalanced Separation Network: A Holistic Fault Detection Framework Considering Class-Imbalance and Partial Label-Unknown

Item Type Journal Article

Author M. Qian

Author Y.-F. Li

Author H. Wu

Abstract The challenges of class-imbalance and partially unknown training labels often arise in fault detection tasks. When these two problems occur simultaneously, existing imbalanced classification methods cannot be directly used due to the absence of the label, and the class-imbalance would lead to severe bias prediction. In this study, we proposed a novel deep imbalance separation network (deepImSN) framework that is capable of dealing with fault detection problems with both class imbalance and partially unknown labels. This framework integrates the one-class learning concept into the positive-unlabeled (PU) learning theory for the first time. It alleviates the bias of the class-imbalance while making full use of the limited label information in the PU set to optimize the feature space and guide model training. The proposed deepImSN is designed to be used in different scenarios. It can accurately complete the fault detection task whether only part of fault samples or normal samples are

labeled, and the class-prior is known or unknown. Experimental results on real-world problems, such as high-speed rail wheels fault inspection and wafer map fault detection, demonstrate that deepImSN outperforms existing methods in various experimental conditions. © 2005-2012 IEEE.

Deep learning based ensemble approach to predict student academic performance: Case study

Item Type Conference Paper

Author Y.K. Salal

Author S.M. Abdullaev

Abstract Traditional practices of education, medicine, and economics often use collective expert methods to find acceptable solutions to complex issues. The computer model of such methods is an ensemble classification which combines prediction of a number base classifier trained by various machine learning techniques. The

predictive sample in the educational process is always not balanced-it leads to a shift in estimates. The basic idea of this work is that the binary forecasting on unbalanced datasets is carried out by a Meta-classifier-an ensemble of different classification algorithm (Decision tree J48, Naive base NB, Multilayer perception MLP, k-Neighbour Nearest k-NN and Support Vector Machine SVM) which trained by stacking, bagging and boosting procedures on SMOTE, RUS, ROS balanced samples. The experiments conducted on moderately unbalanced dataset of 350 tuples of student data with using simple voting Meta-ensemble models, show that the best overall accuracy A and F1 measure of minority class were achieved by the Meta-ensembles containing 5-15 members classifiers trained on samples prepared by SMOTE. It is also proposed that these of Meta-ensembles can be used to resolve quantification learning problem-novel task to predict collective performance. As in our recent works the deterministic outputs of Meta-ensemble members can be transformed to probabilistic outputs and then to prediction of class frequency. After analyzing the results of quantification, it becomes obvious that the most optimal design of the meta-ensembles is to collect pre-boosted classifiers trained on the SMOTE sample. © 2020 IEEE.

Deep Learning for Automated Extraction of Primary Sites from Cancer Pathology Reports

Item Type Journal Article

Author J.X. Qiu

Author H.-J. Yoon

Author P.A. Fearn

Author G.D. Tourassi

Abstract Pathology reports are a primary source of information for cancer registries which process high volumes of free-text reports annually. Information extraction and coding is a manual, labor-intensive process. In this study, we investigated deep learning and a convolutional neural network (CNN), for extracting ICD-O-3 topographic codes from a corpus of breast and lung cancer pathology reports. We performed two experiments, using a CNN and a more conventional term frequency vector approach, to assess the effects of class prevalence and inter-class transfer learning. The experiments were based on a set of 942 pathology reports with human expert annotations as the gold standard. CNN performance was compared against a more conventional term frequency vector space approach. We observed that the deep learning models consistently outperformed the conventional approaches in the class prevalence experiment, resulting in micro- and macro-F score increases of up to 0.132 and 0.226, respectively, when class labels were well populated. Specifically, the best performing CNN achieved a micro-F score of 0.722 over 12 ICD-O-3 topography codes. Transfer learning provided a consistent but modest performance boost for the deep learning methods but trends were contingent on the CNN method and cancer site. These encouraging results demonstrate the potential of deep learning for automated abstraction of pathology reports. © 2013 IEEE.

Abstract Under starvation, *Myxococcus xanthus* bacteria initiate a multicellular developmental program in which cells move to form fruiting bodies and differentiate into distinct cell types. Many genes affecting this process have been identified, and it is assumed that perturbing genes within the same pathway induces similar changes in the phenotype, although these changes may be subtle or obscured by pleiotropy. However, these pathways cannot be systematically mapped because there are no reliable methods for quantifying phenotype similarity. Here, we applied deep learning to quantify phenotype patterns and self-organization dynamics of 292 genetically

distinct strains. We integrated ResNet and StyleGAN2 into a Variational Autoencoder and trained it together with a Siamese network that learns phenotypic similarity. This end-to-end system encoded high-resolution microscopy images into 13-dimensional feature vectors, effectively capturing variation in aggregation patterns across time and strains. Human evaluation confirmed that our model's reconstructions were visually indistinguishable from real images and closely aligned with input phenotypes. Importantly, the feature space is interpretable: Individual dimensions correlate with biological features such as aggregate number and size, and extrapolation along these dimensions produces predictable morphological changes. Remarkably, our model revealed that developmental phenotypes and ultimate aggregation fate are predictable from the earliest images before visible aggregation begins. This predictability held across both genetic and environmental sources of variation, suggesting that subtle, early-stage phenotypic signatures carry critical information about developmental trajectories. These results demonstrate how machine learning can reveal hidden aspects of complex multicellular dynamics and provide methods for phenotypic analysis without manual annotation. Author S. Dalal

Author P. Golland

Author S.J. Berkowitz

Abstract Purpose: To develop a machine learning model to classify the severity grades of pulmonary edema on chest radiographs. Materials and Methods: In this retrospective study, 369 071 chest radiographs and associated radiology reports from 64 581 patients (mean age, 51.71 years; 54.51% women) from the MIMIC-CXR chest radiograph dataset were included. This dataset was split into patients with and without congestive heart failure (CHF). Pulmonary edema severity labels from the associated radiology reports were extracted from patients with CHF as four different ordinal levels: 0, no edema; 1, vascular congestion; 2, interstitial edema; and 3, alveolar edema. Deep learning models were developed using two approaches: a semisupervised model using a variational autoencoder and a pretrained supervised learning model using a dense neural network. Receiver operating characteristic curve analysis was performed on both models. Results: The area under the receiver operating characteristic curve (AUC) for differentiating alveolar edema from no edema was 0.99 for the semisupervised model and 0.87 for the pretrained models. Performance of the algorithm was inversely related to the difficulty in categorizing milder states of pulmonary edema (shown as AUCs for semisupervised model and pretrained model, respectively): 2 versus 0, 0.88 and 0.81; 1 versus 0, 0.79 and 0.66; 3 versus 1, 0.93 and 0.82; 2 versus 1, 0.69 and 0.73; and 3 versus 2, 0.88 and 0.63. Conclusion: Deep learning models were trained on a large chest radiograph dataset and could grade the severity of pulmonary edema on chest radiographs with high performance. © RSNA, 2021.

Abstract Hematological analysis is based on assessing changes in the numbers of different blood cells and their morphological, molecular, and cytogenetic properties via a complete blood count. It is integral to diagnose and monitor a range of blood conditions and diseases, ranging from allergies and infections to different types of cancers. The conventional approach to hematology analysis requires time-consuming protocols, multiple expensive chemical reagents, complex equipment, and highly trained personnel for operation, and presents a significant burden to patients and healthcare systems. There is a need for simple, fast, low-cost alternatives such as label-free techniques that eliminate the need for staining or exogenous labels. We recently demonstrated label-free hematology analysis using deep-ultraviolet (UV) microscopy, a high-resolution imaging technique that yields quantitative molecular and structural information from biological samples. In this work, we present a fast, automated analysis pipeline to classify and count the different blood cell types in single-channel UV microscopy images using a low-cost, compact deep-UV microscope. Our previous work focused primarily on white blood cells; here, we further add platelets and red blood cells. We train a YOLOv7-style network to identify and count different blood cells in smear images acquired from a deep-UV microscopy system. Our deep-UV microscope in an LED-based, compact, and portable configuration and single-step analysis

pipeline could be further combined with UV-transparent PDMS-based microfluidic devices to develop a fully automated, low-cost, label-free hematology analyzer. © COPYRIGHT SPIE. Downloading of the abstract is permitted for personal use only.

Deep Learning-Based Assessment of Lip Symmetry for Patients With Repaired Cleft Lip

Item Type Journal Article
Author K. Rosero
Author A.N. Salman
Author L.M. Harrison
Author A.A. Kane
Author C. Busso
Author R.R. Hallac

Abstract Objective: Post-surgical lip symmetry assessment is a key indicator of cleft repair success. Traditional methods rely on distances between anatomical landmarks, which are impractical for video analysis and overlook texture and appearance. We propose an artificial intelligence (AI) approach to automate this process, analyzing lateral lip morphology for a quantitative symmetry evaluation. Design: We utilize contrastive learning to quantify lip symmetry by measuring the similarity between the representations of the sides, which is subsequently used to classify the severity of asymmetry. Our model does not require patient images for training. Instead, we introduce dissimilarities in face images from open datasets using two methods: temporal misalignment for video frames and face transformations to simulate lip asymmetry observed in the target population. The model differentiates the left and right image representations to assess asymmetry. We evaluated our model on 146 images of patients with repaired cleft lip. Results: The deep learning model trained with face transformations categorized patient images into five asymmetry levels, achieving a weighted accuracy of 75% and a Pearson correlation of 0.31 with medical expert human evaluations. The model utilizing temporal misalignment achieved a weighted accuracy of 69% and a Pearson correlation of 0.27 for the same classification task. Conclusions: We propose an automated approach for assessing lip asymmetry in patients with repaired cleft lip by transforming facial images of control subjects to train a deep learning model, eliminating manual anatomical landmarks. Our promising results provide a more efficient and objective tool for evaluating surgical outcomes. © 2025, American Cleft Palate Craniofacial Association.

Abstract Passive acoustic monitoring (PAM) is emerging as a valuable tool for assessing fish populations in natural habitats. This study compares two deep learning-based frameworks: (1) a multi-label segmentation-based classification system (SegClas) combining convolutional neural networks and long short term memory networks and, (2) an object detection approach (ObjDet) using a You Only Look Once based model to detect, classify, and count sounds produced by soniferous fish in the Tagus Estuary, Portugal. The target species—Lusitanian toadfish (*Halobatrachus didactylus*), meagre (*Argyrosomus regius*), and weakfish (*Cynoscion regalis*)—exhibit overlapping vocalization patterns, posing classification challenges. Results show both methods achieve high accuracy (over 96%) and F1 scores above 87% for species-level sound identification, demonstrating their effectiveness under varied noise conditions. ObjDet generally offers slightly higher classification performance (F1 up to 92%) and can annotate each vocalization for more precise counting. However, it requires bounding-box annotations and higher computational costs (inference time of ca. 1.95 s/h of recording). In contrast, SegClas relies on segment-level labels and provides faster inference (ca. 1.46 s/h). This study also compares both counting strategies, each offering distinct advantages for different ecological and operational needs. Our results highlight the potential of deep learning-based PAM for fish population assessment. © 2025 Acoustical Society of America.

Deep Metric Learning-Based Classification for Pavement Distress Images

Item Type Journal Article**Author** Y. Li**Author** J. Wang**Author** B. Lü**Author** H. Yang**Author** X. Wu**Abstract** This study proposes a deep metric learning-based pavement distress classification method to address critical limitations in conventional approaches, including their dependency on large training datasets and inability to incrementally learn new

categories. To resolve high intra-class variance and low inter-class distinction in distress images, we design a CNN head with multi-cluster centroids trained via SoftTriple loss, simultaneously maximizing inter-class separation while establishing multiple intra-class centers. An adaptive weighting strategy combining sample similarity and class priors mitigates data imbalance, while soft-label techniques reduce labeling noise by evaluating similarity against support-set exemplars. Evaluations on the UAV-PDD2023 dataset demonstrate superior performance—3.2% higher macro-recall than supervised learning, and 6.7%/8.5% improvements in macro-F1/weighted-F1 over iCaRL incremental learning—validating the method’s effectiveness for real-world road inspection scenarios with evolving distress types and limited annotation. © 2025 by the authors.

Deep neural network uncertainty quantification for LArTPC reconstruction

Item Type Journal Article

Author D. Koh

Author A. Mishra

Author K. Terao

Abstract We evaluate uncertainty quantification (UQ) methods for deep learning applied to liquid argon time projection chamber (LArTPC) physics analysis tasks. As deep learning applications enter widespread usage among physics data analysis, neural networks with reliable estimates of prediction uncertainty and robust performance against overconfidence and out-of-distribution (OOD) samples are critical for their full deployment in analyzing experimental data. While numerous UQ methods have been tested on simple datasets, performance evaluations for more complex tasks and datasets are scarce. We assess the application of selected deep learning UQ methods on the task of particle classification using the PiLArNet [1] monte carlo 3D LArTPC point cloud dataset. We observe that UQ methods not only allow for better rejection of prediction mistakes and OOD detection, but also generally achieve higher overall accuracy across different task settings. We assess the precision of uncertainty quantification using different evaluation metrics, such as distributional separation of prediction entropy across correctly and incorrectly identified samples, receiver operating characteristic curves (ROCs), and expected calibration error from observed empirical accuracy. We conclude that ensembling methods can obtain well calibrated classification probabilities and generally perform better than other existing methods in deep learning UQ literature. © 2023 IOP Publishing Ltd and Sissa Medialab.

Abstract This study presents a comprehensive framework for Human Activity Recognition (HAR) using smartphone sensor data, with a specific focus on identifying activities associated with diabetic risk factors. We investigate the efficacy of two deep learning architectures (Long Short-Term Memory (LSTM) networks and Graph Convolutional Networks (GCNs)) for activity recognition under conditions of limited training data. To address data scarcity, we employ Generative Adversarial Networks (GANs) to augment the training dataset with synthetically generated sensor data, enhancing model robustness beyond what is achievable with real sensor data alone. Continuous accelerometer and gyroscope data spanning daily activities were collected from experimental subjects over a 60-day period. This dataset was used to train and evaluate both LSTM and GCN models, with results demonstrating that the GCN architecture achieves superior performance in recognizing diabetes-related activities such as sedentary behavior, physical inactivity, and irregular meal patterns. Furthermore, we propose a novel risk quantification method that estimates diabetes risk by analyzing the duration and frequency of engagement in diabetes-related activities. We employ cosine similarity to measure the correspondence between activity patterns of diagnosed diabetic patients and experimental subjects, yielding a quantitative risk score. To validate the proposed framework, we conducted clinical HbA1c (A1C) assays on experimental subjects. One subject exhibited an A1C level of 6.1%, corresponding to a prediabetes diagnosis, which corroborated the high-risk classification predicted by our framework. These results demonstrate that the proposed HAR-based approach can accurately assess diabetes risk and classify individuals according to clinically validated diagnostic criteria, offering potential applications in continuous health monitoring and early intervention strategies. © 2025 Mohammed Shamsul Alam, Erfanul Hoque Bahadur, Md Fokrul Islam Khan, Farhad Uddin Mahmud, Md Ismail Hossain Siddiqui, Abdul Kadar Muhammad Masum. Deep transfer learning strategy based on TimesBlock-CDAN for predicting thermal environment and air conditioner energy consumption in residential buildings

Item Type Journal Article

Author L. Sun

Author Z. Hu

Author M. Mac

Author T. Imaizumi

Abstract The deployment of data-driven deep learning black-box models for thermal environment and air conditioner energy consumption modeling has gained popularity due to their high accuracy in the residential building sector. However, extensive data collection in real-world residential settings is both time-consuming and costly, complicating the development of these models. Although traditional domain adaptation methods enable transfer learning with minimal data from target buildings, significant discrepancies in insulation performance, thermal capacity, and air conditioner types between different buildings result in substantial label shifts between source and target domains. In this study, a domain adaptation strategy based on the TimesBlock-CDAN approach is proposed. This method integrates conditional features, including air conditioner heat input and the resulting variations in temperature, humidity, and energy consumption, into the adversarial domain

adaptation process, effectively minimizing the domain shift between the source and target domains and thereby enhancing the overall efficiency and accuracy of transfer learning. Specifically, two real-world tasks were designed: transfer learning between different setpoint temperatures within the same building, and transfer learning across different buildings. A comparative analysis of performance in single-step and iterative multi-step predictions within these two tasks demonstrates that the proposed approach improves predictive accuracy by 20% compared to models trained solely on target building data and shows superior performance compared to other transfer learning approaches. © 2024 The Author(s)

Abstract Purpose: The detection of pleural effusion in chest radiography is crucial for doctors to make timely treatment decisions for patients with chronic obstructive pulmonary disease. We used the MIMIC-CXR database to develop a deep learning model to quantify pleural effusion severity in chest radiographs. Methods: The Medical Information Mart for Intensive Care Chest X-ray (MIMIC-CXR) dataset was divided into patients 'with' or 'without' chronic obstructive pulmonary disease (COPD). The label of pleural effusion severity was obtained from the extracted COPD radiology reports and classified into four categories: no effusion, small effusion, moderate effusion, and large effusion. A total of 200 datasets were randomly sampled to manually check each item and determine whether the tags are correct. A professional doctor re-tagged these items as a verification cohort without knowing their previous tags. The learning models include eight common network structures including Resnet, DenseNet, and GoogleNET. Three data processing methods (no sampling, downsampling, and upsampling) and two loss algorithms (focal loss and cross-entropy loss) were used for unbalanced data. The Neural Network Intelligence tool was applied to train the model. Receiver operating characteristic curves, Area under the curve, and confusion matrix were employed to evaluate the model results. Grad-CAM was used for model interpretation. Results: Among the 8533 patients, 15,620 chest X-rays with clearly marked pleural effusion severity were obtained (no effusion, 5685; small effusion, 4877; moderate effusion, 3657; and large effusion, 1401). The error rate of the manual check label was 6.5%, and the error rate of the doctor's relabeling was 11.0%. The highest accuracy rate of the optimized model was 73.07. The micro-average AUCs of the testing and validation cohorts was 0.89 and 0.90, respectively, and their macro-average AUCs were 0.86 and 0.89, respectively. The AUC of the distinguishing results of each class and the other three classes were 0.95 and 0.94, 0.76 and 0.83, 0.85 and 0.83, and 0.87 and 0.93. Conclusion: The deep transfer learning model can grade the severity of pleural effusion. © 2022, The Author(s).

Deep-learning-based probabilistic estimation of solar PV soiling loss

Item Type Journal Article

Author W. Zhang

Author S. Liu

Author O. Gandhi

Author C.D. Rodriguez-Gallegos

Author H. Quan

Author D. Srinivasan

Abstract Although the integration of solar photovoltaic (PV) systems is gaining widespread acceptance, the intermittency and instability of PV power generation lead to several operational challenges. PV power generation can be impacted by multiple environmental factors, such as the soiling of solar PV panels. There are some conventional methods proposed to deterministically estimate the solar power loss caused by soiling. However, the error of deterministic estimation cannot be eliminated due to the inherent volatility of solar power. Therefore, this paper proposes a probabilistic quantification method, namely SolarQRNN, to estimate the power loss by leveraging images captured by surveillance cameras. Specifically, the proposed model employs a novel quantile loss function and deep learning structures (backbone networks based on residual convolution units), which combines quantile regression and computer vision models for the first time. The proposed method has been extensively tested on a solar panel soiling image dataset. Test results indicate that SolarQRNN outperforms benchmark classification models with at least 51% improvements in evaluating metrics. © 2010-2012 IEEE.

DeepWILD: Wildlife Identification, Localisation and estimation on camera trap videos using Deep learning

Item Type Journal Article

Author F. Simões

Author C. Bouveyron

Author F. Precioso

Abstract Videos and images from camera traps are more and more used by ecologists to estimate the population of species on a territory. It is a laborious work since experts have to analyse massive data sets manually. This takes also a lot of time to filter these videos when many of them do not contain animals or are with human presence. Fortunately, deep learning algorithms for object detection can help ecologists to identify multiple relevant species on their data and to estimate their population. In this study, we propose to go even further by using object detection model to detect, classify and count species on camera traps videos. To this end, we developed a 3-step process: (i) At the first stage, after splitting videos into images, we annotate images by associating bounding boxes to each label thanks to MegaDetector algorithm; (ii) then, we extend MegaDetector based on Faster R-CNN architecture with backbone Inception-ResNet-v2 in order to not only detect the 13 relevant classes but also to classify them; (iii) finally, we design a method to count individuals based on the

maximum number of bounding boxes detected. This final stage of counting is evaluated in two different contexts: first including only detection results (i.e. comparing our predictions against the right number of individuals, no matter their true class), then an evolved version including both detection and classification results (i.e. comparing our predictions against the right number in the right class). The results obtained during the evaluation of our model on the test data set are: (i) 73,92% mAP for classification, (ii) 96,88% mAP for detection with a ratio Intersection-Over-Union (IoU) of 0.5 (overlapping ratio between groundtruth bounding box and the detected one), and (iii) 89,24% mAP for detection at IoU = 0.75. Highly represented classes, like humans, have highest values of mAP around 81% whereas less represented classes in the train data set, such as dogs, have lowest values of mAP around 66%. Regarding the proposed counting method, we predicted a count either exact or ± 1 unit for 87% with detection results and for 48% with detection and classification results of our test data set. Our model is also able to detect empty videos. To the best of our knowledge, this is the first study in France about the use of object detection model on a French national park to locate, identify and estimate the population of species from camera trap videos. © 2023 Elsevier B.V.

Defect classification and quantification method based on AC magnetic flux leakage time domain signal characteristics

Item Type Journal Article**Author** R. Wang**Author** Y. Chen**Author** H. Yu**Author** Z. Xu**Author** J. Tang**Author** B. Feng**Author** Y. Kang**Author** K. Song

Abstract Pipelines play a crucial role in industries such as petroleum and nuclear power, where non-destructive testing is essential. Magnetic flux leakage testing methods are widely used for pipeline inspection due to their ability to detect both internal and external defects. However, accurately classifying and evaluating the size of such defects poses challenges due to the complex coupling relationship between ferromagnetic materials and defect magnetic fields. This paper proposes a method for defect classification and quantification based on the time domain characteristics of AC magnetic flux leakage signals. Firstly, the paper explores the shielding effects caused by transient high magnetic permeability within the material on signals from internal defects. It analyzes the differences in signals between internal and external defects. Then, based on the nonlinear attributes of defect signals, the paper proposes a defect classification method based on derivatives analysis of the windowed time-domain signal. Moreover, the study finds that rising time and zero-crossing time can be used to assess the depth of internal and external defects separately, which can decouple the width and depth. Finally, experimental validation confirms the effectiveness of defects classification and quantification. This paper provides a feasible method for evaluating the defect of ferromagnetic materials. © 2024 Elsevier Ltd

Defining the dance: Quantification and classification of endoplasmic reticulum dynamics

Item Type Journal Article

Author C. Pain

Author V. Kriechbaumer

Abstract The availability of quantification methods for subcellular organelle dynamic analysis has increased rapidly over the last 20 years. The application of these techniques to contiguous subcellular structures that exhibit dynamic remodelling over a range of scales and orientations is challenging, as quantification of ‘movement’ rarely corresponds to traditional, qualitative classifications of types of organelle movement. The plant endoplasmic reticulum represents a particular challenge for dynamic quantification as it itself is an entirely contiguous organelle that is in a constant state of flux and gross remodelling, controlled by the actinomyosin cytoskeleton. © The Author(s) 2019. Defining varus thrust assessment and measurement: A scoping review

Item Type Journal Article**Author** H. Shen**Author** N. D'Souza**Author** C.E. Hiller**Author** M.J. McKay**Author** K. Hu**Author** Z. Wang**Author** M. Simic

Abstract Objective: The primary aim of this scoping review was to identify and evaluate the methodologies used for classifying and quantifying varus thrust of the knee during walking. The secondary aim was to report outcomes of reliability, validity, prevalence, and quantitative cutoffs of varus thrust in existing studies. Methods: A systematic literature search was conducted across five electronic databases from inception to April 2024. Studies that reported varus thrust during gait in adults were included. Two independent reviewers extracted data, and data were synthesized based on thrust classification methods, prevalence, reliability, and validity results. Results: A total of 59 studies were included. Varus thrust was classified by observational methods ($k = 22$) with three different definitions used, three-dimensional motion capture systems ($k = 20$), and wearable three-dimensional motion sensors ($k = 17$). Reliability of both classification and quantification of varus thrust were reported by 27% of studies, with kappa values ranging from moderate to high (0.46–0.92). Only three studies reported diagnostic validity of their quantification methodology and their corresponding prevalence. 30 studies reported prevalence of varus thrust, however five different definitions were used across these studies, yielding prevalence values that ranged from 16% to 81.8%, with higher rates reported by three-dimensional motion sensor-based studies. Conclusion: In conclusion, this scoping review identified various methodologies for classifying and quantifying varus thrust, including observational methods and quantitative techniques. Reliability and validity assessments were reported inconsistently, as most studies did not report reliability and validity results. Prevalence of varus thrust ranged widely depending on the methodology used. © 2026 The Authors

Demographic trends of school-based musculoskeletal injuries between 2019 and 2023: An epidemiological and risk analysis

Item Type Journal Article**Author** E. Thompson**Author** S. Sofo**Author** D. Tomchuk**Author** K.R. Schneider**Author** A. Ramos**Author** S. Chung

Abstract Introduction Background Musculoskeletal injuries occur in various school-based settings. However, no information describes musculoskeletal injury risk in school-aged populations relative to age, race, season, body part, and injury classification. We sought to perform an epidemiological analysis and create estimated multinomial logistic regression (MLR) models to profile school-based musculoskeletal injuries seen and treated at United States emergency departments from 2019 through 2023. Methods We retrospectively searched the National Electronic Injury Surveillance System (NEISS) database from the United States Consumer Product Safety Commission (CPSC) between 2019 and 2023 for all school-based injuries in patients between 5 and 18 years of age. Through relative risk ratio calculations and MLR modeling, we created a comprehensive epidemiological analysis and predictive risk assessment profile of school-based musculoskeletal injuries between 2019 and 2023.

Results School-based musculoskeletal injuries declined during the 3-year COVID-19 timeframe and returned to above pre-COVID levels during 2023. Middle school-aged students experienced the most injuries, with high school students experiencing the least. A total of 54.6 % of injuries were to the upper extremity, with 38.5 % of injuries occurring in the lower extremity and 6.9 % in the trunk. Our estimated MLR models indicated that the most at-risk males for school-based musculoskeletal injuries were elementary students for upper and lower arm, wrist, and finger fractures during the summer, while middle and high school females demonstrated the highest risk of sustaining strains/sprains to the wrist and ankle during the summer and winter months. Conclusions From the NEISS database, we described the prevalence estimations of school-based musculoskeletal injuries reported to and treated by the United States emergency departments from 2019 through 2023. With our estimated MLR models, teachers, staff, school districts, administrators, healthcare providers, and other school leaders could create education and supervision initiatives to help prevent musculoskeletal injuries sustained in school settings. © 2025 Elsevier Ltd.

Denoised generative fusion networks for noise-robust few-shot image classification

Item Type Journal Article

Author J. Wu

Author J. Chen

Author J. Luo

Author W. Yu

Author J. Hu

Author H. Li

Abstract Few-shot image classification (FSC) must often contend with inaccurate annotations and biased representations that arise when only a handful of training samples are available. These imperfections severely erode the reliability of existing FSC models. We propose Denoised Generative Fusion Networks (DGFN), a unified framework that tackles the twin challenges of label noise and representation bias in few-shot image classification. DGFN begins by pruning the support set with a principled uniqueness-aware composite distance that jointly considers intra-class coherence and inter-class separability, thus eliminating mislabeled or outlying samples without external supervision. A conditional variational auto-encoder is then trained on the cleaned support instances to hallucinate high-fidelity features, enriching class priors and effectively expanding the sample budget. Finally, an episodic fusion head adaptively weights real and synthetic features so that augmentation gains translate into reliable generalization. Extensive experiments on miniImageNet, tieredImageNet, CIFAR-FS, and CUB-FS show that DGFN boosts 5-way 1-shot accuracy by up to 4.6% over the state of the art and maintains its advantage under 20%~40% synthetic noise and cross-domain shifts, demonstrating its promise for safety-critical applications where clean, abundant annotations are unattainable. © The Author(s) 2025.

Density-Fixing: Simple yet Effective Regularization Method based on the Class Priors

Item Type Conference Paper**Author** M. Kimura**Author** R. Izawa

Abstract Machine learning models suffer from overfitting, which is caused by a lack of labeled data. We proposed a framework of regularization methods, called density-fixing, that can be used commonly for supervised and semi-supervised learning to tackle this problem. Our proposed regularization method improves the generalization performance by forcing the model to approximate the class prior distribution or occurrence frequency. This regularization term is naturally derived from the formula of maximum likelihood estimation and is theoretically justified. We further investigated the asymptotic behavior of the proposed method and how the regularization term behaves when assuming a prior distribution of several classes in practice. We provide several theoretical analyses of the proposed method including asymptotic behavior. Our experimental results on multiple benchmark datasets are sufficient to support our argument, and we suggest that this simple and effective regularization method is useful in real-world machine learning problems. © 2021 IEEE.

Abstract Recent research has identified salivary oral polymorphonuclear neutrophils (oPMNs) as reliable cellular biomarkers for monitoring the progression of periodontal disease (PD). While conventional diagnostic tools such as periodontal probing and radiographic imaging are effective at detecting advanced disease stages, they lack the sensitivity required for early diagnosis. oPMNs, derived from circulating white blood cells (WBCs), transmigrate through the oral epithelium and appear in saliva with diverse morphological characteristics. Although deep learning-based WBC quantification has been extensively explored using peripheral blood datasets, the unique morphology of oPMNs necessitates the development of new image datasets and retraining of models tailored to their detection. To address these challenges, we introduce DePerio—an AI-powered diagnostic pipeline that integrates a novel oPMN

isolation protocol with deep neural network (DNN) architectures. We evaluate the performance of multiple DNN models to achieve accurate detection and quantification of oPMNs. Validated against standard quantification methods for oPMNs and oral inflammatory load (OIL), DePerio achieved a detection error rate of less than 5%. In a clinical study involving 111 human saliva samples, spanning individuals from healthy to severe periodontitis cases, and successfully classified five distinct OIL levels. This robust and low-complexity platform provides a scalable and practical solution for early PD detection and longitudinal monitoring in clinical dental practice. © 2013 IEEE.
